Looking at the ART and ART_w columns and comparing the corresponding rows among agent no. 1, 2, 3 and 4, we see that agent 1 is the loser in all cases. This is expected because of its rigid way of controlling the *detect*, *deliberate* and *execute* components. In the best performing configuration C1, agents 2, 3 and 4 have comparable performance in all event sequences a, b and c. In configurations C2 and C3, generally agents 2 and 3 are better with 3 being the best more often but agent 4 is not the loser every time. So we conclude that it is better to allow the computational components to start processing an item if there is one, then suspend it when its time quota is up and resume in the next round. This works together with the policy that if a component has nothing to do, it will give way to the next computational component.

5. CONCLUSION

In this paper, five ways of organizing and controlling a BDI agent are studied, including the sequential agents and the parallel one. They are evaluated by simulating their operations in processing events of different priorities and examining their performance. We analyze their performance in handling the same sequences of

events. The results show that the parallel BDI agent outperforms the sequential ones in offering significantly shorter response time to events with various inter-arrival times. The parallel BDI agent with its interrupt mechanism is able to guarantee to immediately react to high priority events where none of the sequential ones are capable of. The advantage comes from the following facts:

- The agent process detection, deliberation and execution concurrently. So these actions are carried on at the same time.
- The events can be detected immediately. This ensures that the emergencies will not be overlooked.
- The *deliberation/intention* with higher priority can be performed first by preempting others.

This architecture is useful in implementing agents working in complex and dynamic environments. In the following part, two possible utilities and one problem of the parallel BDI agent architecture are explained.

This architecture should be helpful in the research of continual planning. Continual planning means that the agent will be continuously planning, interleaving planning with execution, because its plans can undergo continual evaluation and revision [3]. For a parallel agent, it will be able to continue with planning while executing an intention plan. Several techniques have been produced for continual planning. For example, the CPEF (continuous planning and execution framework) [11] integrates HTN planning technique [4, 5] to implement open-ended reasoning. Open-ended planning process allows the agent not to generate full level plans before execution. Obviously, the techniques for continual planning increase the needs for time resource. In order to replan, it is better for the agent to detect new situations frequently. So the parallel architecture is ideal to support continual planning.

Another possible utility of the architecture is that it can provide the agent some adaptive behaviour. Adaptive ability is an important attribute for agents to show the autonomy and proactiveness properties [7]. An experimental step was taken in [8]. The learning is implemented by applying the Top-down induction of decision trees on the agent's action models. The models are labeled with success or fail tag. In the situations with fixed action steps, the agent can interact with environment with past experiences. But for agents working in continuous environment, the limitation is obvious: the models may be too voluminous to save. It is possible to extend the original BDI model by adding an experience function library. Some computationally expensive algorithms can be coded in this library and called. The parallel BDI agent will be able to spend time deliberating to learn from past experiences while perceiving the environment and executing intentions at the same time.

As for the sequential agents, we found that it is better to allow more time resources for the deliberating and executing components of the BDI agent. Furthermore, the deliberating and executing components should fully utilize their time quota by suspending unfinished work at the end of the time slice and resuming it next round. When there is nothing to do, it will give way to the next computational component.

Dynamic Control of Intention Priorities of Human-like Agents

Huilang Zhang and Shell Ying Huang¹

Abstract. Intention scheduling mechanism plays a critical role in the correct behaviour of BDI agents. For human-like agents, the independent intentions should be scheduled based on their priorities, which show the respective importance and urgency of the intentions. We propose to enrich the BDI agent architecture with 2 processing components, a PCF (Priority Changing Function) Selector and a Priority Controller. These enable a BDI agent to assign an initial priority value to an intention and change it with time according to the chosen PCF. The initial priority value reflects its urgency at the time of intention creation. The PCF selected defines how the priority should change with time. As an example, we design a function by simulating human behaviors when dealing with several things at the same time. The priority first increases with time according to the Gaussian function to simulate that people are more inclined to do something which has been on their mind for sometime. After a certain time, if the intention still does not get executed because of other higher priority intentions, its priority will decrease according to the Ebbinghaus forgetting curve. Experiment results show that with this mechanism, the agent can show some human-like characteristics when scheduling intention to execute. This can be used when simulating human-like agents.

1. INTRODUCTION

BDI (belief-desire-intention) model is the most famous one of the deliberative agent architectures [2, 10]. Several successful agent architectures and systems based on BDI have been developed. PRS (Procedural Reasoning System) is an implementation of the BDI model. In each cycle, the belief is updated first. Then intentions are selected from the applicable plans. Finally, actions in the chosen intention plan are executed [6, 7]. AgentSpeak(L) [11] and LORA (logic of rational agents) [13] are two sets of operational semantics defined for BDI agents. The decision is made through logic reasoning.

However, the scheduling of intention execution is usually omitted in these BDI systems. The researchers mostly concentrate on solving the problem of intention generation. For example, in AgentSpeak(L) [11], the selection function S_I selects an intention to execute from the intention set I . The detailed selection criteria are not specified. We believe the scheduling of intention is crucial in an agent's ability to cope with the changing world. Some scheduling mechanisms appear in subsequent researches. In AgentSpeak(XL) [1], an extension to the AgentSpeak(L), a task

scheduler is incorporated into the interpreter to decide how to select intentions. The set of intentions in the AgentSpeak(L) is converted into a corresponding TÆMS task structure. Then the selection is done based on the analyses of the relationship among the plans in the TÆMS task structure. The 'enables' and 'hinders' relationships indicate which plan may be executed first. Another method is shown in the JAM agent architecture [5]. The intention selection is done based on the utility value of the plan. The intention with higher utility will be executed first. Recently, another work of intention scheduling is reported in [9]. The researchers take several properties into consideration when scheduling the intentions, such as the importance of the plan, the estimated running time, the deadline utility function, the degree of completeness and FairFacter. In a motivation-based planning and execution framework[3], it was proposed to assign goals and actions priority values indicating their importance based on the agent's motivations. In their work, the strength of the agent's motivations changes with the changes in the environment.

We consider the problem of intention scheduling in an agent who will behave like an "average human". If people identify and accept an agent as human and not machine-like, they tend to trust the agent better. For example, a companion to shut-ins or a playmate for a child should display a human way of handling intentions. We use a single priority value to decide the scheduling order of independent intentions like intentions to eat, to sleep, to play with a friend, to play a certain game or to do school homework. The priority represents the importance and urgency of the intentions to an agent. The priority value is expected to change with time. Currently, the control of the priority changing with time has not been adequately researched even though some work has been done in the artificial life community. In [8], a priority control mechanism for behavioural animation is proposed. The priority is set at minimal value immediately after the agent display a certain behaviour like drinking. Then this priority is increased with time. The increased priority will induce the agent to drink again. However, expecting the priorities of all intentions to change in the same manner is not realistic. Different intentions should be allowed to change their priorities in various suitable ways. Some intentions may also change priorities with the arrival of new beliefs.

In this paper, we proposed an extended architecture to the original BDI architecture in order to support the capabilities of giving different intentions different priorities and changing them dynamically. *Priority Changing Functions* are pre-defined and are associated with the corresponding intentions. A Priority Controller

¹ School of Computer Engineering, Nanyang Technological University, Singapore 639798, email: {pg04043187, ASSYHUANG}@ntu.edu.sg

will change the priority value of the intentions along the time clock. As an example, we design a function which simulates the human behaviours when dealing with several things at the same time. It first increases the priority value according to the Gaussian function and then decreases according to the Ebbinghaus forgetting curve. We call this *reminding-forgetting* function. With the setting of suitable parameter values, this function is also able to simulate the changing of intention priority when a person is not very motivated to put an intention into actions. The function can also represent the changing of intention priority when an intention will get stronger and stronger and stay at its maximum value until it is carried out. To simplify the work, only independent intentions are considered.

The remainder of this paper is structured as follows. In section 2, we present the BDI agent architecture incorporated with an extension of priority control. In section 3, a human-like *priority changing function* (*reminding-forgetting* function) is discussed. And the experiment results are given out in section 4. At the end of the paper, we summarize the contribution of the mechanism and prospects of the future applications.

2. AGENT ARCHITECTURE

A typical BDI system is shown in Figure 1. The agent perceives the environment through the detection system. This information input will be organized into the *beliefs* structure. Then the *deliberate* action begins. Based on the current beliefs, the *desires* are updated and *intentions* generated. Finally, an intention from the *intentions* structure is chosen to be executed. In AgentSpeak(L) language, this is denoted as: $S_i(I) = i$. For independent intentions, they will be weighted by their importance or urgency. This is represented by the priority value. Higher importance, higher priority value will be assigned.

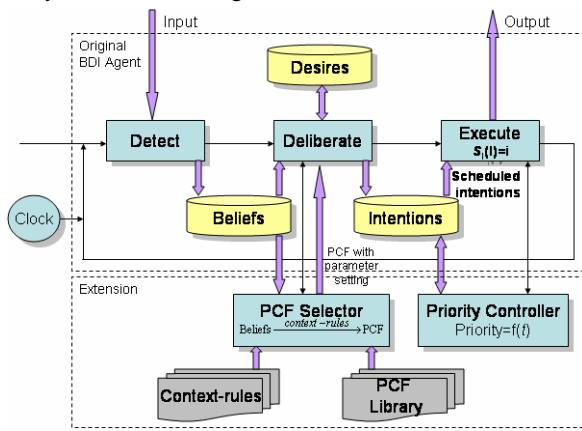

Figure 1. The agent architecture.

As shown in Figure 1, we introduce 2 processing components to the original BDI agent, a PCF (Priority Changing Function) Selector and a Priority Controller. When an intention is generated, the PCF Selector will, based on some context-rules, (i) select a suitable PCF for the new intention from the PCF Library and (ii) decide on the values of the parameters if any for the PCF. The Priority Controller will be responsible for updating the priorities of the intentions according to its PCF as time passes. Each time the BDI agent is to select an intention to execute, the Priority Controller will update the priorities of intentions by:

$$\text{Priority} = f(t) \quad (1)$$

Where, $f(t)$ is the PCF and t is the time.

As an example, for an intention to be completed before a deadline, a simple PCF is:

$$f(t) = \begin{cases} \alpha + \beta * (t - \text{start}) & \text{start} \leq t \leq \text{deadline} \\ 0 & \text{otherwise} \end{cases} \quad (2)$$

Where, start is the time when the intention is generated, α is the initial priority value, β is the rate of increase of the priority value.

The PCF Selector is to choose the function and decide on the values of α and β based on how close start is to the deadline. The Priority Controller will compute the value of $f(t)$ as time passes.

Various PCFs suited to different intentions can be pre-defined. This enriches the BDI agent with the ability of realizing the scheduling of the intentions in a more realistic way. In the following section, we will show a PCF which is designed by simulating human behaviours.

3. A HUMAN-LIKE PCF

The basic PCF is shown as:

$$f(t) = \begin{cases} \text{Maximum priority} * I(t - \text{start}) & \text{start} \leq t \leq \text{deadline} \\ 0 & \text{otherwise} \end{cases} \quad (3)$$

where, *Maximum priority* is the highest value which an intention can achieve; $I(t)$ is the function of influence factor with a range [0, 1].

Normally, humans tend to pay more interests to a new task. After a while, the interests will be reduced and sometimes the task is forgotten. There are also situations where someone has the intention to do something but he is either too lazy to do it or the interest is just not enough, so from the beginning the intention gradually fades away. For some other intentions, the priority will increase till it reaches its maximum and never fade away till it is executed. To simulate these behaviours, $I(t)$ is divided into two modes, reminding and forgetting.

1. Reminding

As time passes, a person will be more inclined to execute a pending intention. The priority of the intention should be increased gradually until it reaches a maximum value. We call this phase ‘reminding’. When the priority value is increased, the intention will have a higher chance to be executed than before. For this phase, we believe that: (1) the value of $I(t)$ should be increased gradually; (2) the gradient of $I(t)$ should be decreasing. This means the priority of the intention will be increased gradually and the rate of increase is decreased gradually. At the initial period, the priority will increase quickly. After that, the priority is increased in a smaller pace and the agent prepares for next phase, forgetting the intention. This so-called *reminding* process will continue until the priority reaches its maximum value ($I(t)$ reaches 1). We use the Gaussian function to simulate the influence factor in this process.

$$G(x) = \eta * \frac{1}{\sqrt{2\pi}\sigma} \exp\left(-\frac{(x - x_0)^2}{2\sigma^2}\right) \quad (4)$$

where, η is a constant value;

σ is the width of Gaussian function;

x_0 is the middle point of the function.

In order to make $I(t)$ reach maximum value 1 at the middle point, we set η to $\sqrt{2\pi}\sigma$. So the function to simulate the reminding process is shown as:

$$I(t) = \exp\left(-\frac{(t-t_m)^2}{2\sigma^2}\right) \quad (5)$$

where, t_m is the time where an intention starts to fade in memory; t is the elapsed time since the intention is created.

Simple differentiation will show that (1) the *reminding* function is increasing; (2) the rate of increase of the *reminding* function value first increases and then decreases before it reaches the middle point t_m .

2. Forgetting

If an intention is deferred for a long time because intentions with higher priority keep on coming, the best way to deal with it is to discard it. This is similar to that humans forget to do something when they are doing something else more important. In biological science, this is a protective mechanism to ensure that human can learn new things. We tend to forget things that the external environment does not remind us of. So as time passes, the priority of the intention in an agent is decreased. If the priority decreases to a value below a threshold, the intention will be removed (forgotten). The first significant study on memory was performed by Hermann Ebbinghaus and published in 1885 as *On Memory*. Ebbinghaus was the first to describe the shape of the forgetting curve [4]. This curve is the biological base on which we simulate the process of intention retention. In [4], the forgetting curve is described as:

$$R = e^{-t/S} \quad (6)$$

where, R is the retention, which means the ability to retain things in memory; t is the elapsed time; S is the strength of memory, which means the durability of things in memory.

Thus, we can make $I(t)$ by combining the functions of the two processes together. The function is shown as:

$$I(t) = \begin{cases} \exp\left(-\frac{(t-t_m)^2}{2\sigma^2}\right) & \text{if } t \leq t_m \\ \exp\left(-\frac{t-t_m}{S}\right) & \text{otherwise} \end{cases} \quad (7)$$

It is noticed that if t_m equals to 0, the reminding process will be skipped. This happens when someone has the intention to do something but he is either too lazy to do it or the interest is just not enough, he(the agent) starts to forget about it according to the forgetting curve from the beginning. If S is set to infinity, the priority will increase according to the reminding function till it reaches its maximum and stay at its maximum so there is no forgetting.

At following, we will prove that the influence function $I(t)$ is continuous.

Proof:

When $t \neq t_m$, it is obvious that $I(t)$ is continuous.

Then we need to prove the continuousness of the function at the point t_m : $\lim_{\Delta t \rightarrow 0} [I(t_m + \Delta t) - I(t_m)] = 0$.

We can see that at the point t_m , $I(t)=1$.

If $\Delta t < 0$, because the normal Gaussian function is continuous, we have $\lim_{\Delta t \rightarrow 0} [I(t_m + \Delta t) - I(t_m)] = 0$.

$$\text{If } \Delta t > 0, \text{ we have } \lim_{\Delta t \rightarrow 0} \left[\exp\left(-\frac{t_m + \Delta t - t_m}{S}\right) - I(t_m) \right] = 0.$$

So $I(t)$ is continuous at t_m .

Thus, the influence function $I(t)$ is continuous at every point. The influence factor does not change significantly at any time.

4. EXPERIMENT

In this part, we will first show how the PCF designed in section 3 is implemented in an agent. Then the function is applied by a BDI agent. The performance of the agent is analyzed.

4.1 Implementation

When the reminding-forgetting function is associated with the intention, the following initial parameters should be decided:

Table 1. Intention parameters related to priority control

Name	Type	Explanation
BP (Basic Priority)	Float	It is decided by initial urgency of the intention.
MP (Max Priority)	Float	The maximum priority for this intention.
t_m	Integer	The time when the forgetting process begins.
S	Integer	Strength of memory. It is assumed that an intention with higher basic priority will have longer retention.
Threshold	Float	In forgetting progress, if the priority is below the threshold, the intention will be removed.

Using the given values, we can calculate the width of Gaussian function σ by:

$$\sigma = \frac{\sqrt{2}}{2} * t_m * \sqrt{\frac{-1}{\ln I(0)}} \quad (8)$$

where, $I(0) = \frac{BP}{MP}$. So at the time of creation, an intention starts at its basic priority.

In Figure 2, the change of priority for 4 sample intentions with basic priority 1, 2, 3 and 4, are shown assuming they are generated at the same time. The maximum priority is set to 1.5 times of the basic priority. Strength is set to 10 times of the basic priority. And t_m is set to 20 time units. The lines 1-4 correspond to the intentions

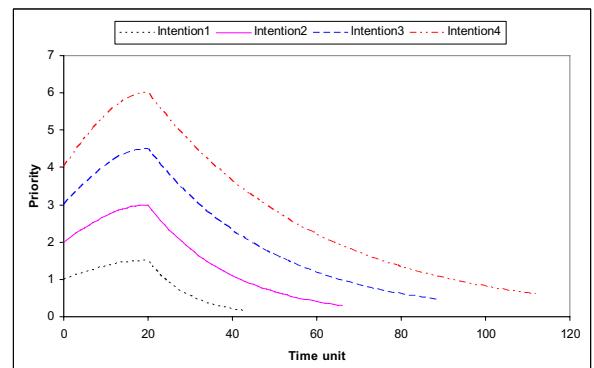

Figure 2. Priority Control of Four Intentions.

with basic priority 1-4. When their priority level is lower than threshold, set as 10% of the maximum priority, the intention will be removed (forgotten). The basic priority will affect the width of the Gaussian function and the strength of memory. With a higher basic priority, the intention will have a longer retention in memory. Another phenomenon is that for intentions created at the same time, the intention with higher basic priority will always has a higher priority level. This ensures that the intentions with higher urgency will be executed earlier.

4.2 Agent performance

In the following experiment, the agent will process a sequence of events. The events are created with random initial priorities from 1 to 4. We will first show how an event sequence is created. Then we will analyze how the agent processes the intentions with or without the *reminding-forgetting* PCF applied.

To evaluate the agent ability to handle events of different importance or urgencies, events will have one of the four different priority levels 1 to 4, with 4 being the highest. We assume that the intention execution time of events at all priority levels is uniformly distributed in the range from 1 to 7 time units. So the average intention execution time is 4 time units.

We use the exponential density function to represent the inter-arrival time between any two events. As shown in [12], the exponential density function is memoryless and often used to model lifetimes or waiting times. The cumulative distribution function is shown as:

$$cdf(t) = 1 - e^{-\lambda t} \quad (9)$$

where, $1/\lambda$ is the mean;

t is the time units.

$cdf(t)$ shows the probability that the inter-arrival time between 2 events is less than t . So given a total number of events, sum , to be used in our experiments, we can decide the number of the intervals with length of n time units by:

$$G(n) = (cdf(n) - cdf(n-1)) * sum \quad (10)$$

The intervals are kept in a vector. Then the intervals are selected randomly. The current time plus the interval length is the arrival time of the next event. The event priority is selected randomly from 1 to 4.

We consider three sequences of events with different average inter-arrival times. The average inter-arrival times of the 3 sequences of events are respectively smaller than, equal to and larger than, the average processing time required by an event. The events statistics used in the experiments are shown in Table 2.

Table 2. Events statistics.

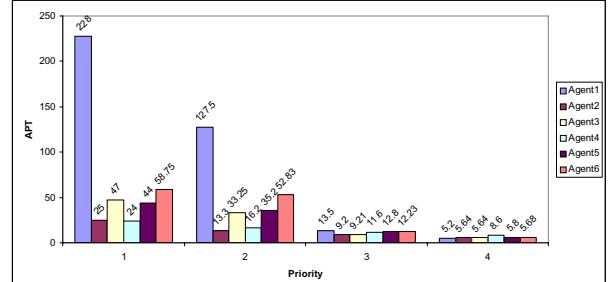

Set	Expected average interval $1/\lambda$	Events count				Actual average interval	
		Priority					
		1	2	3	4		
a	2	25	22	26	25	98	2.42
b	4	25	26	24	21	96	4.04
c	6	26	22	24	23	95	5.64

We experiment with 6 agents: agent 1 has a constant PCF so the initial priority is the priority all the time; agent 2 to 6 each has a different parameter settings for the PCF as shown in Table 3. The initial priority value of an intention is used as the basic priority.

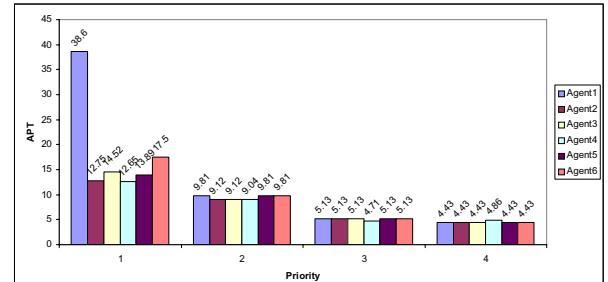

Table 3. Agents types.

Agent no	PCF	PCF parameter settings			
		S	T _m	MP	Threshold
1	-	-	-	-	-
2	✓	10*BP	20	1.5*BP	10%*MP
3	✓	10*BP	20	1.5*BP	1%*MP
4	✓	10*BP	20	2.5*BP	10%*MP
5	✓	10*BP	40	1.5*BP	10%*MP
6	✓	30*BP	20	1.5*BP	10%*MP

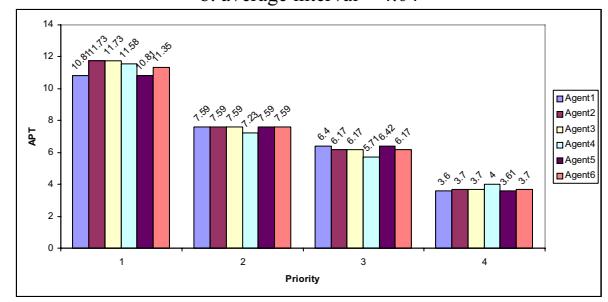

The intention processing time is defined as the duration from the time when the intention is created to the time when the execution of the intention is finished. The average processing time (APT) of the three sets of events by the agents is shown in Figure 3. In set *a*, compared to the expected average processing time 4, agent 1 does not have sufficient time to finish processing an event before the next event arrives. So the intentions with lower priorities have to wait for a long time. The time to process the events with priority 1 is 228 time units. So the intention is starved for a very long time. With the increased average inter-arrival time, the agent 1 has more time to process an event before next event begins and the corresponding APT is decreased to 58.6 for set *b* and 10.8 for set *c*. In agents 2 to 6, the APTs are the APTs of the events that get processed and they are smaller than those for agent 1. Here some intentions with priority 1, 2 or 3 in set *a* and *b* are forgotten due to a long waiting time, which can be seen from the statistics in Table 4. For events with priority 4, the APT is not

a. average interval = 2.42

b. average interval = 4.04

c. average interval = 5.64

Figure 3. APT of events.

affected too much, because the urgent events will be scheduled first. What we see is that many of those low priority events that experience terribly long waiting time in agent 1 are forgotten in agent 2 to 6 for event set *a*.

Looking at Table 4, we see the effect of the parameters of the PCF. For set *a*, 39 events are forgotten by agent 2 (row 2a). This is because the agent has no enough time to process all the crowded events. Rows 2b and 2c have most events processed because of the longer event inter-arrival time. Comparing row 2a and 3a, 5 more intentions are processed because of a lower threshold of retention. Comparing row 2a and 4a, 3 more intentions are processed because of a higher maximum priority. Comparing row 2a and 5a, 6 more intentions are processed because of a longer reminding period before forgetting starts. Comparing row 2a and 6a, 8 more intentions are processed because of a bigger strength of memory. The APT of them are a little bigger for intentions with lower priority in set *a* and *b*.

Table 4. Events processed statistics.

Agent no	Set	completed				sum	
		forgotten					
		Priority					
2	a	1 24	9 13	24 2	25 0	59 39	
	b	20 5	25 1	24 0	21 0	90 6	
	c	26 0	22 0	24 0	23 0	95 0	
3	a	3 22	12 10	24 2	25 0	64 34	
4	a	2 23	11 11	24 2	25 0	62 36	
5	a	3 22	11 11	26 0	25 0	65 33	
6	a	4 21	12 10	26 0	25 0	67 31	

5. CONCLUSION

In this paper, we propose to enrich the BDI agent architecture with 2 processing components, a PCF (Priority Changing Function) Selector and a Priority Controller. The priorities of the intentions can have different initial values and can be changed along the time according to the chosen PCF. The intentions can be scheduled according to their own nature. This provides us a chance to control the scheduling of the intentions in a more human-like manner.

As an example, a *reminding-forgetting* PCF is designed that simulates the way that human deals with several intentions together. The PCF goes through a rising/reminding phase and then a descending/forgetting phase. We proposed to use the Gaussian function to simulate the reminding processes of the intentions. And a forgetting function based on Ebbinghaus forgetting curve is used to simulate the function in forgetting process. With the setting of different parameter values, this PCF may also simulate a priority function that has the forgetting phase alone or the reminding phase alone. From the experiment results, we can see the difference in intention scheduling behaviour brought about by the PCF and the effect of setting the different parameter values.

The so called *reminding-forgetting* PCF is suitable for designing human-like agents. In the comparison experiment, the initial priority of all the intentions are assigned with the arbitrary settings of 1 to 4. To get a precise model of the intention scheduling process of humans, work needs to be done to adjust the parameter settings according to real human behaviours, such as the strength of memory, threshold, and so on.

4. Knowledge Representation and Reasoning

This page intentionally left blank

Knowing Minimum/Maximum n Formulae

Thomas Ågotnes¹ and Natasha Alechina²

Abstract. We introduce a logical language with nullary operators $\min(n)$, for each non-negative integer n , which mean ‘the reasoner has at least n different beliefs’. The resulting language allows us to express interesting properties of non-monotonic and resource-bounded reasoners. Other operators, such as ‘the reasoner has at most n different beliefs’ and the operator introduced in [1, 4]: ‘the reasoner knows at most the formulae ϕ_1, \dots, ϕ_n ’, are definable using $\min(n)$. We introduce several syntactic epistemic logics with $\min(n)$ operators, and prove completeness and decidability results for those logics.

1 Introduction

In this paper we propose a logical language which allows us to say that a reasoner has at least n different beliefs (or knows at least n different formulae). We take a syntactic approach to epistemic and doxastic logics, which allows an agent’s beliefs to be, e.g., not closed under logical consequence, finite, and/or inconsistent. We extend the traditional language of belief logics, propositional logic with an additional unary operator B where $B\phi$ stands for ‘the agent believes ϕ ’, with nullary operators $\min(n)$, for every non-negative integer n . Such operators allow us to formulate interesting properties of reasoners, and the resulting logics have nice formal properties. We introduce several doxastic logics with $\min(n)$ operators, and show that they have (weakly) complete axiomatisations, and are decidable.

In the language with $\min(n)$, we can express dual operators $\max(n)$ (meaning: the reasoner has at most n different beliefs), and those operators, in turn, enable us to completely axiomatically describe reasoners with a bound n on the maximal size of their belief set. The bound on the number of distinct beliefs an agent can have, naturally corresponds to a bound on the size of the agent’s memory (assuming that each formula is a word of fixed size). Logics for agents with bounded memory were studied, for example, in [9], and more recently in [5]. However, in the language of standard epistemic logic it is impossible to express properties such as ‘the agent can apply the rule of modus ponens to its beliefs unless its memory is full’. We show later in the paper some examples of properties of bounded memory reasoners which become expressible in the language with $\min(n)$ operators.

Somewhat surprisingly, we can also define the ∇ operator introduced in [1, 4], where $\nabla\{\phi_1, \dots, \phi_n\}$ stands for ‘the agent believes at most the formulae ϕ_1, \dots, ϕ_n ’. The latter operator makes other useful properties easy to express. For example, formalising non-monotonic arguments becomes easier, because we can say in the language ‘the agent knows a set of formulae X and nothing else’.

The rest of the paper is organised as follows. In section 2, we introduce the language and models of syntactic epistemic logics with

only the B operator, based on syntactic structures introduced in [12]. We show that formulae in this language are preserved under Σ -isomorphism (truth assignments agreeing on atomic and epistemic formulae in the set Σ) for certain sets Σ . In section 3 we introduce the language and interpretation of the logic with operators $\min(n)$ and show that $\min(n)$ is not definable in the basic language, since $\min(n)$ formulae are not preserved under Σ -isomorphism. We also show how to define $\max(n)$, ∇ and other operators in the extended language. In section 4, we give a sound and (weakly) complete axiomatisation of the logic with $\min(n)$, and prove that its satisfiability problem is NP-complete. We also show that adding $\max(n)$ as an axiom captures exactly the set of models where the agent’s belief set has cardinality of at most n . In section 5 we define a modal logic with $\min(n)$ and ‘next state’ modality \diamond , in which we can express properties relating to dynamics of agent’s beliefs, such as bounded monotonicity: until the agent’s state is ‘full’, it carries all its current beliefs to the next state. We prove soundness and weak completeness for this logic and show that its satisfiability problem is in PSPACE.

2 Syntactic Structures

In this section we introduce the language and models of basic syntactic epistemic logic. Syntactic epistemic logic considers beliefs as syntactic objects rather than propositions (sets of possible worlds). This is done to, e.g., avoid closure under logical consequence and identifying logically equivalent beliefs. We base our account of the interpretations of the language of epistemic logic on *syntactic structures* introduced in [12].

The language \mathcal{L} of basic syntactic epistemic logic is parameterised by a set \mathcal{P} of primitive propositions. \mathcal{L} is defined as follows.

$$\phi ::= p \in \mathcal{P} \mid \neg\phi \mid \phi_1 \wedge \phi_2 \mid B\phi$$

We use the usual derived propositional connectives. The intended meaning of $B\phi$ is that ϕ is believed by the agent. We denote the set of *epistemic atoms* $\{B\phi : \phi \in \mathcal{L}\}$ by \mathcal{B} . The elements of the set $\mathcal{P} \cup \mathcal{B}$ of primitive propositions and epistemic atoms, are called *atoms*.

A *syntactic structure* [12], henceforth sometimes called just ‘a model’, is a pair $M = (S, \sigma)$, where S is a set of *states* and

$$\sigma : S \rightarrow 2^{\mathcal{P} \cup \mathcal{B}}$$

Thus a syntactic structure identifies a set of formulae believed by the agent in a state $s \in S$. We call this set the agent’s *epistemic state* in s , and denote it $\overline{\sigma}(s)$: $\overline{\sigma}(s) = \{\phi : B\phi \in \sigma(s)\}$. A pair M, s , where s is a state of M , is called a *pointed model*. The definition of satisfaction of a formula ϕ in a pointed model M, s , written $M, s \models$

¹ University of Bergen, Norway, agotnes@ii.uib.no

² University of Nottingham, UK, nza@cs.nott.ac.uk

ϕ , is straightforward:

$$\begin{aligned} M, s \models p &\Leftrightarrow p \in \sigma(s) \\ M, s \models B\phi &\Leftrightarrow \phi \in \overline{\sigma}(s) \\ M, s \models \neg\phi &\Leftrightarrow M, s \not\models \phi \\ M, s \models \phi_1 \wedge \phi_2 &\Leftrightarrow M, s \models \phi_1 \text{ and } M, s \models \phi_2 \end{aligned}$$

We remark that in this definition of syntactic knowledge by [12] in a possible worlds framework, the states themselves do not play any important part: the interpretation of a formula in a state s does not depend on any state different from s . Thus, the interpretation in s of any formula can be defined solely in terms of the set $\sigma(s)$. We will, however, make use of the full set of states S when we introduce syntactic relational structures in Section 5.

We use \mathcal{M} to denote the class of all syntactic structures. \mathcal{M} can be seen as models of agents with unbounded memory. In the following, we will also be interested in other classes of syntactic structures. For a given natural number n , \mathcal{M}^n is the class of syntactic structures where at most n formulae are believed at the same time, i.e., where $|\overline{\sigma}(s)| \leq n$ for every $s \in S$. \mathcal{M}^n can be seen as models of agents with a fixed memory size. \mathcal{M}_{fin} denotes the class of syntactic structures with finite epistemic states, i.e., $\mathcal{M}_{fin} = \bigcup_{n \in \mathbb{N}} \mathcal{M}^n$. \mathcal{M}_{fin} can be seen as models of agents with finite memory.

2.1 Preservation

As we will soon extend the logical language, we need to be able to compare the expressiveness of different languages. To do that precisely, we introduce the notion of Σ -isomorphism between two pointed models, where Σ is a set of atoms. Two pointed models are Σ -isomorphic, if they agree on all formulae in Σ . Formally:

Definition 1 Let $M = (S, \sigma)$ and $M' = (S', \sigma')$ be models, $s \in S$ and $s' \in S'$, and $\Sigma \subseteq \mathcal{P} \cup \mathcal{B}$. $(M, s) \sim_\Sigma (M', s')$, (M, s) and (M', s') are Σ -isomorphic, is defined as follows:

$$(M, s) \sim_\Sigma (M', s') \iff \sigma(s) \cap \Sigma = \sigma'(s') \cap \Sigma$$

Given a $\phi \in \mathcal{L}$, the set $Subf(\phi)$ is the set of all subformulae of ϕ (with subformulae of the form $B\psi$ treated as atomic formulae), and $At(\phi)$ is the set of atomic subformulae of ϕ , including epistemic atoms: $At(\phi) = Subf(\phi) \cap (\mathcal{P} \cup \mathcal{B})$.

The following lemma states that the truth value of a formula depends only on the truth value of its atomic subformulae, or, in other words, satisfaction of \mathcal{L} formulae ϕ is invariant under $At(\phi)$ -isomorphism.

Lemma 1 For any two pointed models M, s and M', s' , $\Sigma \subseteq \mathcal{P} \cup \mathcal{B}$ and $\phi \in \mathcal{L}$ such that $At(\phi) \subseteq \Sigma$:

$$(M, s) \sim_\Sigma (M', s') \Rightarrow (M, s \models \phi \Leftrightarrow M', s' \models \phi)$$

The proof is straightforward.

3 Upper/Lower Bounds on Belief Sets

We now extend the language \mathcal{L} with operators for expressing properties of syntactic structures such as ‘‘at most n different formulae are believed’’. Furthermore, we show that an extension of the language indeed was necessary to express such properties.

The language \mathcal{L}_{min} is defined by adding a nullary operator $min(n)$, for each natural number n , to the language \mathcal{L} . Formally \mathcal{L}_{min} is defined as follows:

$$\phi ::= p \in \mathcal{P} \mid \neg\phi \mid \phi_1 \wedge \phi_2 \mid B\alpha : \alpha \in \mathcal{L} \mid min(n) : n \in \mathbb{N}$$

Let $M = (S, \sigma)$ be a model, and $s \in S$. The satisfaction of a \mathcal{L}_{min} formula ϕ in (M, s) is defined by adding the following clause to the definition of satisfaction of \mathcal{L} formulae:

$$M, s \models min(n) \Leftrightarrow |\overline{\sigma}(s)| \geq n$$

A formula $min(n)$ captures the notion that *at least* n formulae are believed. As mentioned above, we are also interested in a dual expressing that *at most* n formulae are believed. The reason that a dual operator to $min(n)$ is not included in \mathcal{L}_{min} , is that it is in fact derivable. We define it as the following derived operator:

$$max(n) \equiv \neg min(n+1)$$

It is easy to see that

$$M, s \models max(n) \Leftrightarrow |\overline{\sigma}(s)| \leq n$$

3.1 Expressive Power

We compare the expressive power of the languages \mathcal{L} and \mathcal{L}_{min} : are, for example, $min(n)$ and/or $max(n)$ expressible in \mathcal{L} ?

It was shown in the previous section that \mathcal{L} formulae are invariant under Σ -isomorphism. On the other hand, as the following lemma shows, in the case of \mathcal{L}_{min} formulae, satisfaction is *not* invariant under Σ -isomorphism³.

Lemma 2 There are pointed models M, s, M', s' and $\Sigma \subseteq \mathcal{P} \cup \mathcal{B}$ such that $(M, s) \sim_\Sigma (M', s')$, but for some $\phi \in \mathcal{L}_{min}$ with $At(\phi) \subseteq \Sigma$

$$M, s \models \phi \text{ and } M', s' \not\models \phi$$

Proof. Take $\phi = min(1)$, $M = (S, \sigma)$, $M' = (S', \sigma')$, $\overline{\sigma}(s) = \{\alpha\}$ for some $\alpha \in \mathcal{L}$, $\overline{\sigma}(s') = \emptyset$ and $\Sigma = \emptyset$. Trivially, $At(\phi) \subseteq \Sigma$. $|\overline{\sigma}(s)| \geq 1$, so $M, s \models \phi$. $|\overline{\sigma}(s')| \not\geq 1$, so $M', s' \not\models \phi$. \square

The following theorem follows immediately from the fact that \mathcal{L}_{min} can discern between Σ -isomorphic models, while \mathcal{L} cannot (Lemmata 1 and 2).

Theorem 1 \mathcal{L}_{min} is strictly more expressive than \mathcal{L} .

3.1.1 Knowing At Least and At Most

In [1, 4] two dual operators were introduced to express properties of syntactic knowledge. Both operators are unary, and take a *finite* set of object formulae as argument (it is thus assumed that the language has symbols for finite sets of formulae). Let $X \subseteq \mathcal{L}$ be finite. First, ΔX is intended to mean that the agent knows *at least* the formulae in the set X : the agent knows every formula in X , but might in addition also know other formulae not in X . Second, ∇X is intended to mean that the agent knows *at most* the formulae in the set X : every formula the agent knows is in X , but it might not know every formula in X . The ∇ operator can thus be seen as a syntactic version, without the assumption that belief is closed under logical consequence, of an ‘‘only knowing’’ operator [15]. ∇X is not definable by B [2]. The

³ Most logics satisfy the principle of locality: the truth value of a formula does not depend on the assignment to variables other than the formula’s free variables. This is such an obvious property that it usually goes unremarked; however some logics do violate it. This phenomenon was investigated for predicate logics in e.g. [16]; for propositional logics, the only example we know of in addition to the logics of ∇ and $min(n)$ is the logic of *only knowing* [15].

conjunction of knowing at least X and knowing at most X , knowing *exactly* X , is written $\boxtimes X$. The \triangleright and \boxtimes operators can be used to express compactly that the agent knows the given formulas *and nothing else*. For example, from the fact that $\boxtimes\{\text{Bird}(\text{Tweety})\}$ we can derive $\neg B \neg \text{Flies}(\text{Tweety})$.

Formally, satisfaction is defined as follows:

$$\begin{aligned} M, s \models \Delta X &\Leftrightarrow X \subseteq \overline{\sigma}(s) \\ M, s \models \triangleright X &\Leftrightarrow \overline{\sigma}(s) \subseteq X \\ M, s \models \boxtimes X &\Leftrightarrow \overline{\sigma}(s) = X \end{aligned}$$

It turns out that both notions of knowing at most and knowing at least a finite set of formulae are definable in \mathcal{L}_{\min} . We leave it to the reader to check that

$$\begin{aligned} \Delta X &\equiv \bigwedge_{\alpha \in X} B\alpha \\ \boxtimes X &\equiv \Delta X \wedge \max(|X|) \\ \triangleright X &\equiv \bigvee_{Y \subseteq X} \boxtimes Y \end{aligned}$$

4 Completeness and Complexity

In this section, we give a complete and sound axiomatisation of the logic of $\min(n)$. Let \mathcal{S} be the logic defined by the following axiom schemata and rules over the language \mathcal{L}_{\min} :

Prop	all substitution instances of propositional logic
MIN0	$\min(0)$
MIN1	$\min(n) \rightarrow \min(m)$ $m < n$
MIN2	$(B\phi_1 \wedge \dots \wedge B\phi_n) \rightarrow \min(n)$ $\forall i \neq j \in [1, n] \phi_i \neq \phi_j$
MP	If $\phi, \phi \rightarrow \psi$ then ψ

It is easy to see that all axioms are valid on all syntactic structures, and that the following holds.

Lemma 3 \mathcal{S} is sound with respect to \mathcal{M} .

Observe that the logic of \mathcal{M} (or of \mathcal{M}_{fin}) is not compact. For example, consider a set of formulae which says that the agent has at least one belief, but it does not believe any formula: $\{\min(1)\} \cup \{\neg B\phi : \phi \in \mathcal{L}\}$. Every finite subset of this set is satisfiable, but the set itself is not. This means that we can at most prove weak completeness.

The remainder of this section consists of constructions and intermediate results leading up to the main completeness results in Theorems 2, 3 and 4. First, some definitions. Given sets of formulae Δ, Ξ , we say that Ξ is Δ -maximal if either $\phi \in \Xi$ or $\neg\phi \in \Xi$ for each $\phi \in \Delta$. Let $Cl(\phi)$ be the closure of $Subf(\phi)$ with respect to single negations and $\min(..)$, namely:

- if $\psi \in Subf(\phi)$, then $\psi \in Cl(\phi)$
- $\min(0) \in Cl(\phi)$
- $\min(|\{B\alpha : B\alpha \in Subf(\phi)\}|) \in Cl(\phi)$
- if $\min(n) \in Cl(\phi)$, then $\min(m) \in Cl(\phi)$, for all m with $0 < m < n$
- if $\psi \in Cl(\phi)$, then $\neg\psi \in Cl(\phi)$ unless $\psi = \neg\chi$ for some χ

Clearly, $Cl(\phi)$ is finite.

To prove completeness, given an \mathcal{S} -consistent formula ϕ we now construct a finite model M_ϕ and show that it satisfies ϕ . When ϕ is an \mathcal{S} -consistent formula, let Γ_ϕ be some $Cl(\phi)$ -maximal \mathcal{S} -consistent subset of $Cl(\phi)$ which contains ϕ (it is easy to prove that such a set exists if ϕ is \mathcal{S} -consistent, just pick one of them). Let $Bel(\Gamma_\phi) = \{\psi : B\psi \in \Gamma_\phi\}$. Let $m_\phi = \max(m : \min(m) \in \Gamma_\phi)$. Since Γ_ϕ is finite and contains $\min(0)$ (by **MIN0** and the fact that $\min(0) \in$

$Cl(\phi)$), such an m_ϕ exists. By **MIN2** and the fact that $\min(|\{B\alpha : B\alpha \in Subf(\phi)\}|) \in Cl(\phi)$, the cardinality of $Bel(\Gamma_\phi)$ is less or equal to m_ϕ .

To build the model M_ϕ , in the case that $|Bel(\Gamma_\phi)| = m_\phi$ we can just let the epistemic state be identical to $Bel(\Gamma_\phi)$; as we show below, it is easy to prove a truth lemma in that case. However, when $|Bel(\Gamma_\phi)| < m_\phi$ (for example, if $\phi = \min(10)$, then $|Bel(\Gamma_\phi)| = 0$ and $m_\phi = 10$), we must pad the epistemic state with $m_\phi - |Bel(\Gamma_\phi)|$ extra formulae. These formulae should not come from $\{\psi : B\psi \in Subf(\phi)\}$, but we have an infinite supply of formulae in \mathcal{L} . So let $k_\phi = m_\phi - |Bel(\Gamma_\phi)|$ and for all $i \in \{1, \dots, k_\phi\}$, choose some (unique) $B\alpha_\phi^i \notin Subf(\phi)$. We are now ready to define M_ϕ . Let $M_\phi = (\{s_\phi\}, \sigma_\phi)$ where σ_ϕ is such that

$$p \in \sigma_\phi(s_\phi) \Leftrightarrow p \in \Gamma_\phi \text{ when } p \in \mathcal{P}$$

$$\sigma_\phi(s_\phi) = \begin{cases} Bel(\Gamma_\phi) & |Bel(\Gamma_\phi)| = m_\phi \\ Bel(\Gamma_\phi) \cup \{\alpha_\phi^1, \dots, \alpha_\phi^{k_\phi}\} & \text{otherwise} \end{cases} \quad (A)$$

Note that in both case (A) and (B), the size of the epistemic state is exactly m_ϕ : $|\sigma_\phi(s_\phi)| = m_\phi$.

Lemma 4 (Truth Lemma) For each $\psi \in Subf(\phi)$,

$$M_\phi, s_\phi \models \psi \Leftrightarrow \psi \in \Gamma_\phi$$

Proof. The proof is by induction over the structure of ψ . The case when p is a propositional variable is immediate. When $\psi = B\alpha$, $\alpha \neq \alpha_\phi^i$ for all $i \in [1, k_\phi]$ since $B\alpha \in Subf(\phi)$, so that case is also immediate. Let $\psi = \min(n)$. $M_\phi, s_\phi \models \psi$ iff $m_\phi \geq n$. For the direction to the right, $\min(m_\phi) \in \Gamma_\phi$, so $\min(n) \in \Gamma_\phi$ for any n such that $m_\phi \geq n$ by **MIN1** (and the fact that $\min(n) \in Cl(\phi)$). For the direction to the left, if $\min(n) \in \Gamma_\phi$, then $n \leq m_\phi$ immediately by definition of m_ϕ . The inductive step (negation and conjunction) is straightforward. \square

Define \max_ϕ as the maximum of $|\{B\alpha : B\alpha \in Subf(\phi)\}|$ and $\max(m : \min(m) \in Subf(\phi))$. The following Lemma, showing that every satisfiable ϕ is satisfied in a model of bounded size – particularly in one where the size of the epistemic state is no greater than \max_ϕ , follows immediately (it is easy to see that $m_\phi \leq \max_\phi$):

Lemma 5 Any \mathcal{S} -consistent formula ϕ is satisfied in a state in a model $M = (\{s\}, \sigma)$ where $|\sigma(s)| \leq \max_\phi$ and $|\sigma(s) \cap \mathcal{P}| \leq |\text{At}(\phi) \cap \mathcal{P}|$.

The following theorem follows immediately from Lemmata 3 and 5.

Theorem 2 \mathcal{S} is sound and weakly complete with respect to \mathcal{M} .

Furthermore, since Lemma 5 shows satisfiability in a model with a *finite* epistemic state, the following also holds.

Theorem 3 \mathcal{S} is sound and weakly complete with respect to \mathcal{M}_{fin} .

We now discuss axiomatisation of the class \mathcal{M}^n . Let $n \in \mathbb{N}$ be fixed. Define \mathcal{S}^n to be \mathcal{S} extended with the axiom $\max(n)$.

Theorem 4 \mathcal{S}^n is sound and weakly complete with respect to \mathcal{M}^n .

Proof. Soundness follows immediately from Lemma 3 and the definition of \mathcal{S}^n . For completeness, let ϕ be a \mathcal{S}^n -consistent formula, and let $\phi' = \phi \wedge \max(n)$. Since ϕ is \mathcal{S}^n -consistent, ϕ' is \mathcal{S} -consistent, so it is satisfied in a state with epistemic state of size no greater than $\max_{\phi'}$. It must be the case that $\neg\min(n+1) \in \Gamma_{\phi'}$

(otherwise $\min(n+1) \in \Gamma_{\phi'}$, since $\min(n+1) \in Cl(\phi')$, and thus $\Gamma_{\phi'}$ would be inconsistent). If $\max_{\phi'} \geq n+1$, $\min(n+1) \in \Gamma_{\phi'}$ by **MIN1** and the fact that $\min(\max_{\phi'}) \in \Gamma_{\phi'}$ which is a contradiction, so $\max_{\phi'} < n+1$. Thus, ϕ' , and therefore also ϕ , are satisfied in a state where the epistemic state is no greater than n . \square

4.1 Complexity

The *satisfiability problem* for \mathcal{S} is the problem of determining, given a formula ϕ , whether there exists a structure M with a state s such that $M, s \models \phi$ (we here abuse the terminology somewhat and use \mathcal{S} to denote not only the axiomatic system but also the logic of M).

To determine the complexity of the satisfiability problem precisely, we need to decide on the encoding of formulas and models. Consider some standard encoding of propositional formulas as strings, for example where propositional variables are encoded by a single symbol p followed by an index of the variable in binary (see, e.g., [7]). We can encode $\min(n)$ in a similar way, as a single symbol m followed by the representation of n in binary. Pointed models, which are essentially just assignments to atoms, can be encoded either as a concatenation of encodings of the atoms which are true under the assignment, or, if it is an assignment to a finite ordered set of m atoms, as a binary string of length m . Note that in either case the length of the encoding of a satisfying model for a formula ϕ guaranteed by Lemma 5 may be exponential in $|\phi|$. For example, if $\phi = \min(n)$, then $|\phi| = 1 + \log_2(n)$ and the length of the encoding of the satisfying assignment is n (under the bit string approach) or $n \log(n)$ (under the list of atoms approach). This is bad news, because from the existence of an exponential satisfying model we can only infer a NEXPTIME upper bound for the complexity of satisfiability. However, we can encode the satisfying model more efficiently, so that the encoding is not exponential in size, but still can be recognised as a model and used to evaluate a formula. Namely, when we are guessing a model M_ϕ for ϕ , with a single state s_ϕ , we will only explicitly represent the assignment to $At(\phi)$ in s_ϕ , which is polynomial in $|\phi|$. Instead of explicitly representing the assignment to ‘padding formulae’, we will guess the total number of epistemic atoms in $\overline{\sigma}(s)$ and write it down in binary. So the representation of s_ϕ will look as follows: $(\alpha_1, \dots, \alpha_m, n)$, where $\alpha_1, \dots, \alpha_m \subseteq At(\phi)$ are the atoms true in s_ϕ , and $n \geq m$ is a binary representation of the size of $\overline{\sigma}(s)$. Clearly, this is polynomial in $|\phi|$, and this information is sufficient to evaluate ϕ , which can be done in polynomial time.

Theorem 5 *The satisfaction problem for \mathcal{S} is NP-complete.*

Proof. We know that ϕ is satisfiable iff it is satisfiable in a model of size at most \max_{ϕ} , by Lemma 5. We guess this model M_ϕ , and represent it as a string linear in the size of $|\phi|$, by explicitly representing truth values for atoms in $At(\phi)$, and guessing the total number of true epistemic atoms, written in binary. We can check whether ϕ is satisfied by the model in polynomial time. NP-hardness follows from the fact that the logic extends propositional logic. \square

5 Adding State Transitions

In this section we consider the dynamics of the agent’s beliefs. We extend syntactic structures to include state transitions, and the languages \mathcal{L} and \mathcal{L}_{\min} to include a ‘next state’ modality \diamond , to obtain the languages \mathcal{L}^\diamond and $\mathcal{L}_{\min}^\diamond$, respectively; a formal definition is given

below. Extending the logic this way allows us to describe how the agent’s beliefs change. For example, if the agent knows an inference rule, then it can apply it to beliefs in its current state to derive new beliefs which are added to the next epistemic state. To use an example from [12], suppose the agent knows $a = b$ and $b = c$, and is capable of reasoning about equality. Unlike in [12], we do not assume that in this case the agent can derive $a = c$ instantaneously. Rather, we interpret ‘being able to reason about equality’ as being able to derive new statements about equality which follow from the current beliefs, in some future state. In particular, the agent should be able to reach a state where it believes $a = c$. This property is expressible by the following \mathcal{L}^\diamond formula, in which \diamond stands for ‘there exists a successor state where...’:

$$B(a = b) \wedge B(b = c) \rightarrow \diamond B(a = c)$$

We may also want to express that the agent’s knowledge grows monotonically, which can be done by adding an axiom schema

$$B\phi \rightarrow \square B\phi$$

(where \square is the dual of \diamond , meaning ‘in every successor state...’).

The expressive power we get in \mathcal{L}^\diamond is similar to, for example, step logics [10]: we can describe how the beliefs of an agent capable of applying certain inference rules increase over time. Imposing some simple conditions would guarantee that the set of beliefs remains finite. One of such possible conditions is requiring that each state transition corresponds to deriving exactly one new formula; this is expressible by a schema:

$$\diamond(B\phi \wedge B\psi) \rightarrow (B\phi \vee B\psi)$$

(if in the next state the agent believes two formulae, then at least one of those formulae is already believed in the current state). Note that the condition that each successor state has at most one extra formula can be more elegantly expressed in $\mathcal{L}_{\min}^\diamond$:

$$\max(n) \rightarrow \square \max(n+1)$$

Another useful property, namely that each state transition adds some new belief, is not expressible in \mathcal{L}^\diamond at all, unless we introduce existential quantification over formulae or infinite disjunctions; however in $\mathcal{L}_{\min}^\diamond$ we can say

$$\min(n) \rightarrow \square \min(n+1)$$

If we do take the size bound on the agent’s epistemic state seriously, however, the combination of monotonicity and ability to derive new formulae becomes problematic. A natural restriction on monotonicity in this case would be to say: if the set of beliefs is less than the maximal size, then monotonicity holds; otherwise, the agent can still derive a new formula, but at the expense of ‘overwriting’ one of the old beliefs. This assumption is made, e.g., in [5], which studies logics for bounded memory reasoners. The property of bounded monotonicity (if the cardinality of the set of beliefs is less than n , then all beliefs persist into the next state) can be expressed in $\mathcal{L}_{\min}^\diamond$ as

$$\max(n-1) \wedge B\phi \rightarrow \square B\phi$$

Hopefully, the examples above have given the reader a flavour of the kind of properties we would like to express in $\mathcal{L}_{\min}^\diamond$. Now we proceed to give formal definitions of the language and the structures.

Let the language $\mathcal{L}_{\min}^\diamond$ is defined by the following grammar:

$$\phi ::= p \in \mathcal{P} \mid \neg\phi \mid \phi_1 \wedge \phi_2 \mid B\phi : \phi \in \mathcal{L} \mid \min(n) : n \in \mathbb{N} \mid \diamond\phi$$

Define $\Box\phi$ as $\neg\Diamond\neg\phi$. A *syntactic relational structure* is a triple $M = (S, \sigma, R)$ where (S, σ) is a syntactic structure and $R \subseteq S \times S$ a relation over the states. The class of all syntactic relational structures is denoted \mathcal{M}^\diamond . The satisfaction relation $M, s \models \phi$ is defined as before; the extra clause for $\Diamond\phi$ is standard in modal logic:

$$M, s \models \Diamond\phi \Leftrightarrow \exists s' (R(s, s') \text{ and } M, s' \models \phi)$$

Let \mathcal{K}_{min} be the logical system obtained by adding to \mathcal{S} the axiom schema \mathbf{K} : $\Box(\phi \rightarrow \psi) \rightarrow (\Box\phi \rightarrow \Box\psi)$ and the necessitation rule \mathbf{N} : $\vdash \phi \Rightarrow \vdash \Box\phi$.

Theorem 6 \mathcal{K}_{min} is sound and weakly complete wrt. \mathcal{M}^\diamond .

Proof. The proof consists of minor modifications of the constructions and proof in Section 4. The construction of a satisfying model $M \in \mathcal{M}^\diamond$ for a \mathcal{K}_{min} -consistent formula ϕ uses a method described in [7].

Define $Cl(\phi)$ as in Section 4. Construct $M = (S, \sigma, R)$ as follows. Let S be the set of ($Cl(\phi)$ -) maximal consistent subsets of $Cl(\phi)$. In Section 4 it was enough to define a satisfying assignment in a single state s_ϕ corresponding to the maximal consistent set Γ_ϕ containing ϕ ; here we must repeat that exercise for *any* such set. For each $s \in S$, the assignment $\sigma(s)$ is defined from s in exactly the same way as $\sigma_\phi(s_\phi)$ was defined from Γ_ϕ in Section 4. Note that we do not include the ‘padding’ formulae $B\alpha_1, \dots, B\alpha_k$ in the state s ; they are just a technical device we use to define the assignment. In particular, the statement of the Truth Lemma is restricted to the subformulas of ϕ .

Finally, let $R(s, t)$ hold if, and only if, $\phi_s \wedge \Diamond\phi_t$ is \mathcal{K}_{min} -consistent, where ϕ_s (ϕ_t) is the conjunction of formulae in $\sigma(s)$ ($\sigma(t)$). The proof of the Truth lemma is standard, see e.g. [7]. \square

Since the model we have constructed is exponential in length of the encoding of a formula ϕ , the theorem above implies that \mathcal{K}_{min} is decidable in NEXPTIME. However, it is possible to give a tighter upper bound, namely PSPACE:

Theorem 7 The problem of whether a formula $\phi \in \mathcal{L}_{min}^\diamond$ is satisfied in a model in \mathcal{M}^\diamond is PSPACE complete.

Proof. It is easy to show that every satisfiable formula ϕ has a tree model of polynomial depth (the proof is the same as for basic modal logic K, see for example [7]). Each state in the model has polynomial size, as we have shown in Lemma 5. Hence, each branch of the satisfying model can be encoded as a string whose length is polynomial in the length of the encoding of ϕ . The *Witness* algorithm given in [7] which essentially builds a tableaux for ϕ one branch at a time, can be easily adapted to check for satisfiability in \mathcal{M}^\diamond . For PSPACE-hardness, observe that the satisfiability problem for modal logic K can be reduced to the satisfiability problem for \mathcal{K}_{min} , and the former is PSPACE-complete [7]. \square

6 Conclusions

We have modeled the beliefs of an agent with the help of syntactic assignments, an approach also used by several others [14, 11, 6, 4] in order to model properties of reasoners which are difficult or impossible to model with traditional modal epistemic logics. The same model of belief we have used in this paper, was recently used [3] to give a semantics to Ho Ngoc Duc’s [8] logic of rational, but not logically omniscient, agents. While many approaches have been suggested to alleviate the logical omniscience problem [13] the syntactic approach can be seen as the most general one. The results in this

paper should be readily applicable to other logics with a syntactic component. Of particular interest for future work would be to apply them to the logic of general awareness [11].

In the language of syntactic epistemic logic with $\min(n)$ operators, we can express many interesting properties of agents, such as bounded memory, and knowing exactly or at most the given set of formulae and nothing else. We introduce several natural logics in this language, and show that they have sound and complete axiomatisations, and that their decidability problem is in the same class as their non-epistemic counterparts.

Modal logics for communicating rule-based agents

Natasha Alechina and Mark Jago and Brian Logan¹

Abstract. In this paper, we show how to establish correctness and time bounds (e.g., quality of service guarantees) for multi-agent systems composed of communicating rule-based agents. The formal models of multi-agent systems we study are transition systems where each transition corresponds to either a rule firing or an act of communication by an agent. We present a complete and sound modal logic which formalises how the beliefs of communicating rule-based agents change over time. Using a simple example, we show how this logic can be used to specify temporal properties of belief change in multi-agent systems in a precise and realistic way, and how existing modal logic techniques such as model-checking can be used to state and verify properties of agents.

1 INTRODUCTION

There has recently been considerable interest in rule-based approaches to various aspects of agent technology. For example, rules and rule engines (rule interpreters) have been advocated as a means of managing the business logic of applications in a wide range of domains such as insurance, financial services, government, telecom customer care and billing, and ecommerce [19]. Another important application of rule-based approaches in agent-based systems is the semantic web, for example, ontological reasoning in DAML/OWL and, more generally, in rule extensions to ontologies such as OWL+Rules [17] and SWRL[18], which significantly increase the expressive power of ontology languages [17].

At the same time there has been a growing use of rule engines as key components of agent based systems. Much of this work is based on mature rule-based systems technology such as the Jess rule engine [14], e.g., the FIPA-OS JessAgent, the use of Jess in reasoning about ontologies (DAML JessKB) and in web service composition (DAML-S Virtual Machine [20]) and supporting tools such as Jena which convert XML/RDF to Jess facts, and, more generally, the Java Rules API.² However, while the adoption of rule-based approaches brings great benefits in terms of flexibility and ease of development, these approaches also raise new challenges for the agent developer, namely how to ensure correctness of rule-based designs (will a rule-based agent produce the correct output for all legal inputs), termination (will a rule-based agent produce an output at all) and response time (how much computation will a rule-based agent have to do before it generates an output).

As a motivating example, consider an agent which acts as a provider agent for a company which sells goods or services on the web. Such an agent may require a combination of ontological rules to match a potential customer's request against the goods and services it offers (e.g., to realise that dog food is a kind of pet food

[21]) and business rules to determine, e.g., the appropriate level of discount to be offered. The designer or developer of such an agent may wish to ensure that the agent's behaviour is correct, e.g., that the agent does not offer a customer an inappropriate discount, or accept an order from a customer with an unpaid bill, and/or may wish to offer certain quality of service guarantees, e.g., to bound the time a potential customer has to wait between the acknowledgement of a request for a price and receiving a quote.

The upper limit on deliberation (or response) time in rule-based systems is a well-established problem. However previous work has studied expert and diagnostic systems as single isolated systems [15], and has focused mainly on termination (or worst case response time), rather than more general issues of correctness and quality of service. In this paper, we show how to establish correctness and time bounds for multi-agent systems composed of rule-based agents. The formal models of multi-agent systems we study are transition systems where each transition corresponds to a rule firing by an agent (or an act of communication, which we also model as an effect of a rule firing). To solve a particular problem or to achieve a particular state, agents typically need to fire multiple rules; the number of transitions until the goal state is reached gives an estimate of the time required for deliberation. We present a modal epistemic logic where the agent's rules and its knowledge in each state determine conditions on the accessibility relation in the model. The novelty of our work is in representing a multi-agent system of communicating rule-based agents as a transition system, and proposing a modal logic to describe these systems. In addition to being able to state time-related properties of the system, this also enables us to use existing modal logic techniques such as model-checking to state and verify properties of agents.

The remainder of the paper is organised as follows: in section 2 we introduce our model of communicating rule-based agents. In sections 3, 4 and 5 we introduce the language and its semantics, present a complete and sound axiomatisation of our logic, and state decidability. In section 7 we briefly illustrate the logic by giving an example and show how properties expressed in the logic can be verified using an existing model checker, before discussing related work in section 8.

2 COMMUNICATING RULE-BASED AGENTS

We assume that each agent has a *program*, consisting of Horn clause rules, and a working memory, which contains facts. The set of rules comprising the agent's program and the facts contained in the agent's working memory together constitute the agent's beliefs.

To define the agent's internal language more precisely, we fix a set of predicate symbols \mathcal{P} , a set of variables \mathcal{X} and a set of constants \mathcal{D} . A literal λ is a predicate symbol of n arguments followed by n variables or constants and possibly preceded by a negation symbol ' \neg '. For example, *LuxuryProduct(x)* and

¹ School of Computer Science, University of Nottingham, Nottingham, NG1 1BB, UK, email: {nza,mtw,bsl}@cs.nott.ac.uk

² Jess is the reference implementation for the Java Rules API.

$\text{LuxuryProduct(Porsche)}$ are both literals. When every argument of the predicate symbol in a literal is an element of \mathcal{D} , e.g., $\text{LuxuryProduct(Porsche)}$, that literal is called a *ground literal*. Each rule-based agent has a finite set \mathcal{R} of rules, which are of the form

$$\lambda_1, \dots, \lambda_n \rightarrow \lambda$$

where λ_i, λ are literals. λ is called the *consequent* of the rule (denoted by $\text{cons}(\lambda_1, \dots, \lambda_n \rightarrow \lambda)$), and each λ_i is an *antecedent* of the rule. An example of a rule is:³

$$\begin{aligned} \text{PremiumCustomer}(x), \text{LuxuryProduct}(y) \rightarrow \\ \text{Discount}(x, y, 7.5\%) \end{aligned}$$

We assume that the rules do not contain functional symbols. Given a rule $\lambda_1, \dots, \lambda_n \rightarrow \lambda$, we denote an *instance* of this rule as $\delta(\lambda_1, \dots, \lambda_n \rightarrow \lambda)$, where δ is some substitution function from the set of variables of the rule into \mathcal{D} . For example, if δ assigns *Miller* to x and *Porsche* to y , then

$$\begin{aligned} \delta(\text{PremiumCustomer}(x), \text{LuxuryProduct}(y) \rightarrow \\ \text{Discount}(x, y, 7.5\%)) \\ = \\ \text{PremiumCustomer(Miller)}, \text{LuxuryProduct(Porsche)} \rightarrow \\ \text{Discount}(Miller, Porsche, 7.5\%) \end{aligned}$$

A rule $\lambda_1, \dots, \lambda_n \rightarrow \lambda$ *matches* if there is a substitution δ such that the agent's working memory contains $\delta(\lambda_1), \dots, \delta(\lambda_n)$. *Firing* the matching rule instance $\delta(\lambda_1, \dots, \lambda_n \rightarrow \lambda)$ adds the ground literal $\delta(\lambda)$ to the agent's working memory. In what follows, we assume that the agents fire at most one rule per cycle (we discuss other rule application strategies in section 6), and that rule matching is refractory, i.e., that each rule instance is fired at most once.

Consider a set $\mathcal{A} = \{1, \dots, n\}$ of n agents. To model communication between agents, we assume that agents have special communication constructs in their language: ‘tell(i, j) λ ’, which we will refer to as a *tell* and ‘ask(i, j) λ ’, which we will refer to as an *ask*. In both cases, i and j are agents and λ is a literal not containing an ask or a tell. tell(i, j) λ stands for ‘ i tells j that λ ’ and ask(i, j) λ stands for ‘ i asks j whether λ is the case’. The position in which these formulas may appear in a rule depends on which agent's program the rule belongs to. Agent i may have an ask or a tell with arguments (i, j) , in the *consequent* of a rule, e.g.:

$$\lambda_1, \dots, \lambda_n \rightarrow \text{ask}(i, j)\lambda$$

Whereas agent j may have the same expressions in the *antecedent* of the rule. For example:

$$\text{tell}(i, j)\lambda \rightarrow \lambda$$

is a well-formed rule for agent j which makes it trust i when i informs it that λ is the case. No other occurrences of tell(i, j) and ask(i, j) are allowed. In particular, i must be distinct from j in all the cases just listed, for our agents neither ask nor tell themselves anything.

When a rule has either an ask or a tell as its consequent, we call it a *communication rule*, or *c-rule* for short. All other rules are known as *deduction rules*, or *d-rules*. These include rules with asks and tells in the antecedent (as well as rules containing neither an ask nor a tell).

³ The business rules in the running example are taken from the RuleML tutorial [8].

Firing a *c-rule* instance with the consequent tell(i, j) λ adds the literal $\delta(\text{tell}(i, j)\lambda)$ both to the working memory of i and of j . Intuitively, i has a record that it told j that $\delta(\lambda)$, and j has a record of being told by i that $\delta(\lambda)$. Similarly, if the consequent of a *c-rule* instance is of the form $\delta(\text{ask}(i, j)\lambda)$, then the corresponding ask is added to the working memories of both i and j .

In this paper, for simplicity we do not consider the interaction between agents and their environment. However we could model the environment as a distinguished agent, e.g., with a different rule application strategy, and interpret tells from the agents to the environment as actions, and tells from the environment to the agents as sensing.

3 LANGUAGE

First we define agent i 's internal language \mathcal{L}_i . For simplicity, we assume that all agents have the same finite set of predicate symbols \mathcal{P} and a finite set of constants \mathcal{D} (although this assumption is not essential). We denote the set of all possible substitutions $\delta : \mathcal{X} \longrightarrow \mathcal{D}$ by Σ . Note that given finite sets \mathcal{X} and \mathcal{D} , the set of all possible substitutions Σ and the set of all possible rule instances are finite as well. Literals are denoted by $\lambda, \lambda_1, \lambda_2, \dots, \text{tell}(i, j)\lambda, \text{ask}(i, j)\lambda, \dots$ ($i, j \in \mathcal{A}$), ground literals are denoted by $\delta(\lambda), \delta(\lambda_1), \dots, \text{tell}(i, j)\delta(\lambda), \text{ask}(i, j)\delta(\lambda), \dots$, where $\delta \in \Sigma$, and rules of the form $\lambda_1, \dots, \lambda_n \rightarrow \lambda$ are denoted by $\rho, \rho_1, \rho_2, \dots$. Note that only rules and ground literals are formulas of \mathcal{L}_i , and that rules are well-formed only if the conditions on the occurrences of asks and tells are satisfied.

In the modal language \mathcal{ML} over \mathcal{L}_i , we have a belief operator B_i for each agent $i \in \mathcal{A}$. The primitive wffs of $\mathcal{ML}(\mathcal{P}, \mathcal{D})$ are:

$$B_i \delta(\lambda) \mid B_k \text{tell}(i, j)\delta(\lambda) \mid B_k \text{ask}(i, j)\delta(\lambda) \mid B_i \rho$$

where $\delta(\lambda)$ is a ground literal, i and j are two different agents (we assume that $|\mathcal{A}| \geq 2$), $k \in \{i, j\}$, and ρ is a well-formed rule of agent i . If ϕ_1 and ϕ_2 are both $\mathcal{ML}(\mathcal{P}, \mathcal{D})$ wffs, the complex wffs of $\mathcal{ML}(\mathcal{P}, \mathcal{D})$ are then given by

$$\neg\phi_1 \mid \phi_1 \wedge \phi_2 \mid \diamond\phi_1$$

where \diamond is the next state modality; \vee and \rightarrow are defined as usual, and $\square\phi =_{df} \neg\diamond\neg\phi$.

4 SEMANTICS

In this section we define the transition systems we use to interpret the language introduced above. The states of the transition system are tuples of local states of the agents and are used to interpret the basic belief formulas of the language; intuitively, $B_i \alpha$ is true if the formula α is either a rule of agent i 's program, or is contained in the agent's local state (working memory) in that state. Transitions between states correspond to the agents firing a single rule instance each, in parallel. In the case in which an agent fires an instance of a *d-rule*, a single new formula is added to the agent's state. In the case in which an agent fires an instance of a *c-rule* involving another agent j , the conclusion of the rule is added both to the agent's state and to the agent j 's state.

The formal definition of models is as follows.

Definition 1 (Models) Given a group of agents $\mathcal{A} = \{1, \dots, n\}$, a multi-agent model M is an $n + 3$ -tuple

$$\langle S, \mathcal{A}, T, V_1, \dots, V_n \rangle$$

where S is a set of states, T is the transition relation and each $V_i : S \rightarrow \wp(\mathcal{L}_i)$ is the labelling function for agent $i \in \mathcal{A}$ assigning a set of \mathcal{L} -formulas to each state.

We say that a rule $\lambda_1, \dots, \lambda_n \rightarrow \lambda$ is s - δ - i -applicable if s is a state, δ a substitution, i an agent, $\delta(\lambda_1), \dots, \delta(\lambda_n) \in V_i(s)$ and $\delta(\lambda) \notin V_i(s)$.

The following conditions on the assignments V_i (for all $i \in \mathcal{A}$) and the accessibility relation T hold in all models:

1. for every $i \in \mathcal{A}$, any two states $s, s' \in S$, and every rule formula $\rho, \rho \in V_i(s)$ if, and only if, $\rho \in V_i(s')$
2. For any two states s and s' , $T(s, s')$ holds if, and only if, for every agent i , $V_i(s') = V_i(s) \cup \{\delta_i(\text{cons}(\rho_i))\} \cup C_i$, where ρ_i is some s - δ_i - i -applicable rule if such a rule exists (otherwise $\{\delta_i(\text{cons}(\rho_i))\} = \emptyset$), and $C_i = \{\delta_j \text{ cons}(\rho_j) : \delta_j \text{ cons}(\rho_j)$ is of the form $\text{tell}(j, i)\alpha$ or $\text{ask}(j, i)\alpha\}$.

Condition 1 says that the agent's program does not change, and condition 2 says that each agent fires a single applicable rule instance if it has one, otherwise its state does not change apart from possibly as a result of communication from other agents.

A state transition system can be visualised as follows. Each state contains n finite sets of formulas, corresponding to the beliefs of each of the n agents. Each applicable rule instance of agent i corresponds to a possible ‘action’ by i , namely the addition of the consequent of the rule to the next state. A transition by the system is an n -tuple of such actions (if agent j has no applicable rule instance, the j th component of the tuple is a null action). If in a state s , each agent i has k_i different applicable rule instances, then there are $k_1 \times \dots \times k_n$ different transitions from s , one for every possible combination of agent ‘actions’. This also means that on different execution paths originating in s , applicable rule instances of agent i may be fired in a different order. Suppose there are two such rule instances in s , $\delta_1(\rho_1)$ and $\delta_2(\rho_2)$. Then there is a path to some state s' reached by agent i firing $\delta_1(\rho_1)$ (and other agents firing their rule instances) and from s' to s'' where i gets to fire $\delta_2(\rho_2)$. There is also a path where the order in which $\delta_1(\rho_1)$ and $\delta_2(\rho_2)$ are fired is reversed, and it is also possible that in the next state agent i will acquire other applicable rule instances which on some execution paths will be fired earlier than the one instance remaining from s . If none of the agents has an applicable rule instance, then only one transition is possible (a null action by all agents), to the same state.

The relation of a formula ϕ being satisfied in a model M ($M \models \phi$) is defined as follows:

$$\begin{aligned} M, s \models B_i \alpha &\text{ iff } \alpha \in V_i(s), \text{ for } i \in \mathcal{A}, \alpha \in \mathcal{L}(\mathcal{P}, \mathcal{D}) \\ M, s \models \neg\phi &\text{ iff } M, s \not\models \phi \\ M, s \models \phi \wedge \psi &\text{ iff } M, s \models \phi \text{ and } M, s \models \psi \\ M, s \models \diamond\phi &\text{ iff there is a } u \in S \text{ such that } T(s, u) \text{ and } M, u \models \phi \end{aligned}$$

Although our agents share a common language, each has its own program. Given a program (set of rules) \mathcal{R}_i for each agent $i \in \mathcal{A}$, we define the *program set* $\mathbb{R} = \{\mathcal{R}_1, \dots, \mathcal{R}_n\}$. We want to pick out those models in which agents believe all the rules in their program and no other rules. Such models comprise the class $\mathbf{M}_{\mathbb{R}}$.

Definition 2 (The class $\mathbf{M}_{\mathbb{R}}$) A model $M \in \mathbf{M}_{\mathbb{R}}$, where $\mathbb{R} = \{\mathcal{R}_1, \dots, \mathcal{R}_n\}$, iff for every state s in M , $M, s \models B_i \rho$ iff $\rho \in \mathcal{R}_i$. Given a set of \mathcal{ML} -formulas Γ and an \mathcal{ML} -sentence ϕ , we write $\Gamma \Vdash_{\mathbb{R}} \phi$ iff every model of Γ which is in the class $\mathbf{M}_{\mathbb{R}}$ is also a model of ϕ .

We now ask, given a set of programs $\mathbb{R} = \{R_1, \dots, R_n\}$ for n agents in the language $\mathcal{L}(\mathcal{P}, \mathcal{D})$, what logic corresponds to the class $\mathbf{M}_{\mathbb{R}}$?

5 AXIOMATISATION

The logic $\Lambda_{\mathbb{R}}$ over \mathcal{ML} is defined as follows. First, fix a set of agents $\mathcal{A} = \{1, \dots, n\}$, then fix a program set $\mathbb{R} = \{\mathcal{R}_1, \dots, \mathcal{R}_n\}$. Then we define

$$\delta \text{ app}_i(\lambda_1, \dots, \lambda_n \rightarrow \lambda) \stackrel{\text{df}}{=} B_i \delta(\lambda_1) \wedge \dots \wedge B_i \delta(\lambda_n) \wedge \neg B_i \delta(\lambda)$$

and $\text{app}(\rho) \stackrel{\text{df}}{=} \bigvee_{\delta \in \Sigma} \delta \text{ app}_i(\rho)$, where $\rho \in R_i$. The logic $\Lambda_{\mathbb{R}}$ has the following axiom schemata and rules:

C1 all classical propositional tautologies

$$\mathbf{K} \quad \square(\phi \rightarrow \psi) \rightarrow (\square\phi \rightarrow \square\psi)$$

A1 $B_i \rho$, where $\rho \in \mathcal{R}_i$ (agent i believes its rules)

A2 $\neg B_i \rho$, where $\rho \notin \mathcal{R}_i$ (agent i only believes its rules)

A3 $B_i \alpha \rightarrow \square B_i \alpha$ (agents are monotonic reasoners)

A4 $B_i(\lambda_1, \dots, \lambda_n \rightarrow \lambda) \wedge B_i \delta(\lambda_1) \wedge \dots \wedge B_i \delta(\lambda_n) \rightarrow \diamond B_i \delta(\lambda)$

for each $\delta \in \Sigma$ (if a rule matches, its consequent belongs to some successor state)

A5 $\diamond(B_i \alpha \wedge B_i \beta) \rightarrow (B_i \alpha \vee B_i \beta)$

where α and β are not of the form $\text{tell}(j, i)\lambda$ or $\text{ask}(j, i)\lambda$ (at most one new belief of agent i is added in each transition as a result of agent i firing a rule)

A6 $\diamond B_i \alpha \rightarrow (B_i \alpha \vee \bigvee_{\lambda_1, \dots, \lambda_n \rightarrow \lambda \in \mathcal{R}_i, \delta(\lambda)=\alpha} B_i \delta(\lambda_1) \wedge \dots \wedge B_i \delta(\lambda_n))$

where α is not of the form $\text{tell}(j, i)\beta$ or $\text{ask}(j, i)\beta$ (new beliefs of agent i only arise as a result of firing a rule of i , unless it is a communication from another agent j)

A7 $\delta_1^1 \text{ app}_1(\rho_1^1) \wedge \dots \wedge \delta_{k_1}^1 \text{ app}_1(\rho_{k_1}^1) \wedge \dots \wedge \delta_1^n \text{ app}_n(\rho_1^n) \wedge \dots \wedge \delta_{k_n}^n \text{ app}_n(\rho_{k_n}^n) \wedge \dots \wedge \delta_{\delta(\rho)}^{\delta(\rho)} \text{ app}_{\delta(\rho)}(\rho) \rightarrow \neg \delta \text{ app}_1(\rho) \wedge \dots \wedge \neg \delta \text{ app}_n(\rho) \wedge \dots \wedge \neg \delta \text{ app}_{\delta(\rho)}(\rho) \rightarrow \square \bigvee_{f(i) \in \{1, \dots, k_i\}} (B_1 \delta_{f(1)}(\text{cons}(\rho_{f(1)})) \wedge \dots \wedge B_n \delta_{f(n)}(\text{cons}(\rho_{f(n)})))$

for each possible set of applicable rule instances $\{\delta_1^i(\rho_1^i), \dots, \delta_{k_i}^i(\rho_{k_i}^i)\}$ for each agent i , provided this set is non-empty for at least one of the agents. This axiom constrains all possible successors of each state to states resulting from firing applicable rule instances in parallel by all agents.

A8 $\bigwedge_{\rho \in \mathcal{R}} \neg \text{app} \rho \rightarrow \diamond \bigwedge_{\rho \in \mathcal{R}} \neg \text{app} \rho$ (the terminating state has a transition to itself)

A9 $B_i \text{ tell}(i, j)\lambda \leftrightarrow B_j \text{ tell}(i, j)\lambda$ (communication involving tells is perfect)

A10 $B_i \text{ ask}(i, j)\lambda \leftrightarrow B_j \text{ ask}(i, j)\lambda$ (communication involving asks is perfect)

MP From ϕ and $\phi \rightarrow \psi$ derive ψ

N From ϕ derive $\square\phi$

The notion of derivation is standard.

Theorem 1 $\Lambda_{\mathbb{R}}$ is sound and complete for $\mathbf{M}_{\mathbb{R}}$: $\Gamma \vdash_{\mathbb{R}} \phi$ iff $\Gamma \Vdash_{\mathbb{R}} \phi$.

Due to the lack of space, we can only sketch a proof here. Soundness is proved as usual by induction of the length of a derivation. For completeness, we build a canonical model for a $\Lambda_{\mathbb{R}}$ -consistent set of formulas and prove that this model is in $\mathbf{M}_{\mathbb{R}}$.

Theorem 2 The satisfiability problem for $\mathbf{M}_{\mathbb{R}}$ is decidable.

The proof is omitted due to lack of space; it uses filtration to prove that every satisfiable formula has a model of size bounded by the size of the formula and the size of \mathbb{R} .

6 ADDITIONAL AXIOMS

In this section, we discuss additional axiom schemata which we can use to express interesting properties of agents.

First, we consider properties relating to agent communication. The property of agent 1 trusting agent 2 with respect to some literal λ can be expressed as a *c-rule* belonging to agent 1. This is reflected in the following axiom:

Trust(1,2, λ) $B_1(\text{tell}(2, 1)\lambda \rightarrow \lambda)$

The following axiom says that agent 1 is cooperative in that it believes that it should answer agent 2's queries concerning λ , if it already believes that λ :

Answer(1,2, λ) $B_1(\text{ask}(2, 1)\lambda, \lambda \rightarrow \text{tell}(1, 2)\lambda)$

We can state more general properties of trust and cooperativeness by replacing the axioms above by axiom schemas: e.g., trust any agent i rather than a particular agent, and do so with respect to all formulas, rather than a particular predicate.

Another kind of property we can express relates to the rule application strategy of the agents. The logic described above is based on the assumption that agents may fire matching rule instances in any order. This is not a very realistic assumption (although it still allows us to establish an upper bound on when a certain belief will be derived, because all possible rule orderings will include the actual one). For example, an agent's rules (and rule instances) may be ordered, or more recent information may be acted upon first, or queries answered in preference to applying internal deduction rules. Logics corresponding to an ordered rule application strategy were studied in detail in [5]; unfortunately, rule ordering in general cannot be captured by a single, simple axiom schema.

However, there are some rule application strategies which are relatively simple to capture in modal logic. For example, the ‘all rules at each cycle’ strategy can be easily modelled.⁴ This strategy requires the agent to apply all of its rules to all of its ground beliefs in order to transit to the next state. Note that rules are not applied immediately to the *consequences* of matching rule instances; the rules are applied only once in each transition. To model the ‘all rules at each cycle’ strategy, we remove axiom **A5** (which says that at most one new formula is derived) and add the axiom schema which says that there is at most one successor to each state: $\Diamond\phi \rightarrow \Box\phi$. Note that **A7** then becomes redundant.

7 EXAMPLE

In this section we show how the logic defined above can be used to specify temporal properties of belief change in multi-agent systems in a precise and realistic way. We then go on to show how these properties can be verified using an existing model checker.

Consider a simple multi-agent system which implements the business rules example introduced in section 2. Suppose there are two agents involved in giving a quote. Agent 1 is in charge of quoting for products, and has data relating to current prices and the following discount rules:

⁴ This is also the strategy that is used in step logic [13].

R0 $\text{Quote}(x, y) \rightarrow \text{ask}(1, 2)\text{PremiumCustomer}(x)$

R1 $\text{tell}(2, 1)\text{PremiumCustomer}(x) \rightarrow \text{PremiumCustomer}(x)$

R2 $\text{Quote}(x, y), \text{PremiumCustomer}(x), \text{LuxuryProduct}(y) \rightarrow \text{Discount}(x, y, 7.5\%)$

Rule **R0** states that if a quote is required for customer x , ask agent 2 whether x is a premium customer. **R1** states that agent 1 should believe agent 2 if agent 2 tells agent 1 that x is a premium customer, and **R2** states that premium customers get at 7.5% discount. Agent 2 is in charge of customer data, and has rules to determine who counts as a premium customer:

R3 $\text{Spending}(x, \text{min}5000, 2005) \rightarrow \text{PremiumCustomer}(x)$

R4 $\text{ask}(1, 2)\text{PremiumCustomer}(x), \text{PremiumCustomer}(x) \rightarrow \text{tell}(2, 1)\text{PremiumCustomer}(x)$

Suppose we are interested in quality of service guarantees of the form: every request for a quote is answered within at most 4 timesteps. To simplify, we have reformulated this as a question of whether agent 1 believes that a particular customer qualifies for a discount in at most 4 steps, provided that the information on customer spending and luxury products is immediately available. This can be re-expressed as a problem of verifying the formula

Q $\Box^4 B_1 \text{Discount}(\text{Miller}, \text{Porsche}, 7.5\%)$

(where \Box^n stands for n nestings of \Box) in a state where agent 1 believes $\text{Quote}(\text{Miller}, \text{Porsche})$ and $\text{LuxuryProduct}(\text{Porsche})$, and agent 2 believes $\text{Spending}(\text{Miller}, \text{min}5000, 2005)$. This reformulation presupposes that no other queries are being processed by agents 1 and 2.

It is straightforward to verify this property using existing model checking techniques. As proof of concept, we converted the example multi-agent system above into a system specification for the Mocha model checker [6] and verified that the formula **Q** is true. The translation into *reactive modules*, the description language used by Mocha, is straightforward: ground literals in the agent’s working memory are represented as boolean *state variables*, rules are represented by *atoms* (which describe the initial condition and transition relation for a group of related variables), and agents by *modules* (collections of atoms specifying which state variables are visible from outside the module). The multi-agent system is then simply a parallel composition of agent modules (this translation assumes an ‘all rules at each cycle’ rule application strategy, but ‘one instance at a time’ is also possible). The translation of \mathcal{ML} formula **Q** expressing the property to be verified into the ATL specification language used by Mocha is similarly straightforward.

This example is extremely simplified, and gives the response time guarantee in terms of ‘inference steps’ rather than of units of time. However, if we know the number of beliefs an agent has and the rule-matching strategy it uses, we can produce a mapping from ‘steps’ to time durations, and verify quality of service guarantees such as ‘every request for a quote will be answered within n milliseconds’.

8 RELATED WORK

Our work relates both to the field of epistemic logics (and their use in verifying properties of agents) and to work on verifying properties of rule-based programs, such as bounded response time.

A considerable amount of work has been done in the area of model-checking multi-agent systems (see, e.g., [9, 7]). However, the

emphasis of this work is on correctness rather than the timing properties of agents, which is our primary interest. An exception is our recent joint work on automatic verification of space and time requirements for resource-bounded agents [3, 2]. However this work focuses on verifying properties of a single agent and does not consider the multi-agent case.

Another strand of related work is verifying temporal properties of agent systems, in particular real-time properties, where actions are assumed to take non-trivial time. In [22], Singh proposed a framework for modelling agent systems where actions have duration and can be executed in parallel. As far as we know, it was not applied to actions as inferences. Recent work in dynamic and temporal epistemic logic [23] has a similar motivation to our work (modelling knowledge change) but assumes that the agent's knowledge is deductively closed before and after the update. There are, however, approaches in epistemic logic which explicitly reflect time required for a certain inference. For example, step logics [13] study development of agents' belief sets over discrete linear time. In [16] Grant, Kraus and Perlin present a semi-decidable formalism for expressing agent knowledge and inference steps with explicit time increments, which is implemented in Prolog. Other related work [12, 1, 4] also describes epistemic logics where each inference step takes the agent into the next (or some future) moment in time.

There has also been considerable work on the execution properties of rule based systems, both in AI and in the active database community. Perhaps the most relevant is that of Chen and Cheng on predicting the response time of OPS5-style production systems. In [10], they show how to compute the response time of a rule based program in terms of the maximum number of rule firings and the maximum number of basic comparisons made by the Rete network. In [11], Cheng and Tsai describe a tool for detecting the worst-case response time of an OPS5 program by generating inputs which are guaranteed to force the system into worst-case behaviour, and timing the program with those inputs.

9 CONCLUSION

We have presented a sound, complete and decidable logic which describes how the beliefs of communicating agents which reason using rules evolve over time. This logic can be used to express and verify temporal properties of multi-agent systems such as 'if agent i asks agent j λ , agent j is guaranteed to reply within n inference cycles'. This is useful, for example, for verifying quality of service guarantees, which may have the form of 'each query is going to be answered within n milliseconds'.

We are aware of a number of limitations of the work presented here. We currently assume that the agent's reasoning is monotonic (they never discard beliefs, only acquire new ones). It is, however, possible to expand our framework to incorporate rules which delete information, either to restore consistency or due to memory limitations and we plan to investigate this in future work. (An example of a similar logic which models a reasoner who deletes formulas to save memory can be found in [3].) Finally, the assumptions on communications are only made for the sake of simplicity; it is very easy to modify the semantics to allow for communication delays and lossy communication channels.

Causation as Production

John Bell ¹

Abstract.

Recently I suggested that a cause is an event which, in its context of occurrence, is both necessary and sufficient for the effect. However this definition is only appropriate if there is a single potential cause of the effect. Consequently I suggest a generalization of the definition and discuss the resulting “Production Theory”. I suggest that this can be seen as a combination of a regularity theory in the Hume tradition and a dependence theory in the Lewis tradition, and argue that the Production Theory inherits the strengths of the component theories while avoiding their weaknesses.

1 INTRODUCTION

In [1] I propose a formal, logico-pragmatic, theory of causation. This defines a cause to be an event which, in its context of occurrence, is both necessary and sufficient for the effect. However I now consider that this definition is only appropriate in cases of non-redundant causation, where there is only one potential cause for the effect. Consequently I suggest an appropriate generalization, by weakening the contextual necessity condition, and justify the resulting “Production Theory” by relating it to the philosophical tradition and to recent philosophical discussions of causation.

The central theme of the discussion is Hall’s [8, p. 225] suggestion that causation should be viewed as production: that event c is a cause of effect e if c helps to *generate* or *bring about* or *produce* e . However, Hall argues that production should be analyzed in terms of regularity and that it conflicts with dependence, whereas I argue that production involves a combination of (appropriate forms of) regularity and dependence.

In §2 I briefly recall the regularity theories of Hume and Mill, provide an informal introduction to the theory of sufficient causation (the contextual-sufficiency part of the Production Theory) in this setting, and discuss the major problem confronting regularity theories; that of distinguishing between regularities which are causal and regularities which are accidental.

In §3 I recall Lewis’s theory of causation as counterfactual dependence and argue that, like the contextual necessity condition that I gave in [1], the simple form of dependence he adopts is too restrictive because it excludes symmetrically redundant causes. Consequently I suggest a weaker form counterfactual dependence called *individual dependence*. Then, in the resulting Production Theory, a cause is defined to be an event which, in its context of occurrence, is both sufficient and individually necessary for the effect. The Production Theory can thus be regarded as a combination of a regularity theory and a dependence theory.

In §4 I discuss Hall’s [7] argument that transitivity and dependence conflict, and argue that they do so only if, as in Lewis’s theory, depen-

dence is taken to be a sufficient condition for causation. I conclude that, contrary to Hall’s [p. 212] suggestion, dependence does “bear a deep connection to causation”, but it does so in conjunction with the theory of sufficient causation.

Finally, in §5 I discuss the varieties of redundancy, and argue that, while these cause problems for simple dependence theories, they do not do so for the Production Theory.

2 REGULARITY

Hume [10, Bk I, Pt III] suggests that we inductively acquire knowledge of regularities of succession of the form: A -type events are followed by B -type events. We then consider that A -type events cause B -type events, because whenever we see an A -type event, we expect it to be followed by a B -type event.

Mill [15, Bk III, Ch 5] complicates this picture by considering assemblages of conditions. A single assemblage might consist of an A -type event together with certain conditions which must be present (positive conditions) and certain conditions which must be absent (negative conditions). For example, an assemblage concerning the lighting of matches might include the striking of the match, the presence of oxygen, and the absence of dampness in the match head. This idea is complicated by the possibility of a plurality of causes; the possibility that an effect can be realized in more than one way. For example, a match can also be lit (in the presence of oxygen and the absence of dampness, etc.) by touching its head with a red hot poker. So assemblages should be thought of as disjunctions of conjunctions of conditions. Mill suggests that it is possible, at least in principle, to specify assemblages which, if true, logically guarantee their associated effects. However, this does not appear to be a realistic possibility because in practice it is impossible to come up with an exhaustive list, especially of negative conditions. There is also the problem of interference from other events.

Rather than begin with the concept of causation, I begin with a theory of events [4], in the AI reasoning-about-actions tradition [14, 16, 17, 18, 19], and use this as the basis for a definition of sufficient causation. A simplified version of the theory is described here. The full theory allows for the representation of context-dependent effects and non-deterministic effects; and hence of non-deterministic causation.

The theory is interpreted in a possible partial worlds setting. Each possible partial world (henceforth simply “world”) represents a possible history. At each world, time is taken to consist of points and to be discrete and linear. At any time point at a world, certain *facts* and certain *event occurrences* may be defined (be established as true or established as false). The idea behind the fact-event distinction is that events are dynamic (active) and introduce changes (impinge on the world, change the course of history), and facts are static (passive) and persist through time until affected by some event (until some event impinges on them). The partiality of worlds reflects notions such as

¹ Department of Computer Science, Queen Mary, University of London, United Kingdom, email: jb@dcs.qmul.ac.uk

partial observability (we typically do not have complete knowledge of a world) and relevance/localness (typically we are concerned only with a small region of it).

These ideas can be conveyed graphically by means of the Lewis-type neuron diagrams in Figure 1; reproduced from [8, Fig. 9.2]. In

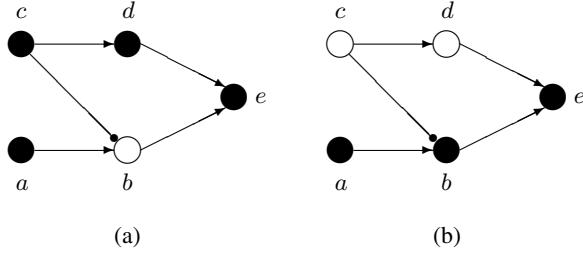

Figure 1. Two neuron diagrams: (a) c fires, (b) if c had not fired

these diagrams, shaded vertices represent firing neurons, arrows represent stimulatory connections, and the remaining edges represent inhibitory connections. Thus, in (b) the effect of a firing is the subsequent firing of b . However, in (a), this effect is inhibited by the firing of c . Figures (a) and (b) can be thought of as representing alternative world histories in which different neurons fire in the same neuron network.

World histories are described by the event language \mathcal{EL} . For example, the occurs atom $Occ(C)(1)$ states that neuron c fires at time 1 (at the world in question, at the actual world). The partial histories of worlds (a) and (b) can be represented by the following sets of atoms:

$$\begin{aligned} w_a &= \{Occ(C)(1), Occ(A)(1), Occ(D)(2), Occ(E)(3)\}, \\ w_b &= \{Occ(A)(1), Occ(B)(2), Occ(E)(3)\}. \end{aligned}$$

As non-firings have no effects they are, in the interests of economy, regarded as undefined occurrence atoms.

The behaviour of the neurons can be defined by regarding neuron firings as event types, and by defining their preconditions, effects, and interactions. This is done by the axioms in Table 1. For example,

Table 1. Sample event definition axioms.

$$\begin{aligned} \forall t(Pre(C)(t) &\equiv Occ(C)(t)) \\ &\wedge \forall t(Eff(C)(t) \equiv (Occ(D)(t) \wedge \neg T Occ(B)(t))) \quad (1) \\ \forall t(Pre(A)(t) &\equiv Occ(A)(t)) \\ &\wedge \forall t(Eff(A)(t) \equiv Occ(B)(t)) \wedge \forall t(Pre(C, A)(t) \\ &\equiv \neg Pre(A)(t)) \quad (2) \\ \forall t(Pre(D)(t) &\equiv Occ(D)(t)) \wedge \forall t(Eff(D)(t) \equiv Occ(E)(t)) \quad (3) \\ \forall t(Pre(B)(t) &\equiv Occ(B)(t)) \wedge \forall t(Eff(B)(t) \equiv Occ(E)(t)) \quad (4) \end{aligned}$$

Axiom (1) states that the precondition for c 's firing is that c occurs (in effect no preconditions are required in this case), and its effects are that d fires and it is not the case that b fires. The operator T , used in this axiom, is a classically-valued (truth-value designation) operator: a sentence $T\phi$ is true if ϕ is true, and is false otherwise (if ϕ is undefined or false). Consequently the combination $\neg T$ represents weak negation: the sentence $\neg T\phi$ is true if ϕ is false (if $\neg\phi$ is true) or ϕ is undefined, and is false otherwise. The truth operator makes it possible to reason classically with partial information; in particular, when using weak negation only two cases need to be considered; either sentence ϕ is true or it is not. The final conjunct of Axiom (2) is explained below.

Thus preconditions and effects embody specific causal knowledge. Their use is common in AI theories and has its origin in the repre-

sentation used by the planner STRIPS [6]. Note the similarities with Hume's regularities and Mill's assemblages.

Unlike most AI theories, the theory of events begins with the recognition that events are defeasible; that their preconditions are not always sufficient on occurrence for their effects. This may be because some unusual condition holds (the qualification problem), or because some other simultaneously occurring event interferes (the interaction problem), or, as Hume suggests, because we are mistaken in thinking that the regularity invariably holds (the problem of induction). In order to represent this, we begin with the notion of success. As Axiom (5) in Table 2 states, an event (token) succeeds (at time t) iff it is true that: the event occurs, its preconditions obtain, and its expected effects do indeed follow. The intention is that events

Table 2. The Production Theory of causation.

$$\forall e, t(Succ(e)(t) \equiv T(Occ(e)(t) \wedge Pre(e)(t) \wedge Eff(e)(t+1))) \quad (5)$$

$$\forall R, \bar{x}, t(Inert(R, \bar{x})(t) \equiv (R(\bar{x})(t) \equiv R(\bar{x})(t+1))) \quad (6)$$

$$\begin{aligned} \forall \epsilon, \phi, e, t(SCause(\epsilon, \phi) &\equiv \\ (\epsilon = Occ(e)(t) \wedge Succ(e)(t)) &\wedge \square((\theta \wedge Eff(e)(t+1)) \rightarrow \phi) \wedge \neg \square(\theta \rightarrow \phi))) \quad (7) \\ \forall \epsilon, \phi(Cause_1(\epsilon, \phi) &\equiv \\ (SCause(\epsilon, \phi) \wedge (\neg T\epsilon \Downarrow (\neg T\phi \vee \exists \epsilon' Cause_1(\epsilon', \phi)))))) \quad (8) \\ \forall \epsilon, \epsilon', \phi, \psi, \chi(Cause(\epsilon, \phi) &\equiv \\ (Cause_1(\epsilon, \phi) \vee (Cause_1(\epsilon, \epsilon') \wedge Cause(\epsilon', \phi))) \\ \vee (\phi = (\psi \wedge \chi) \wedge Cause(\epsilon, \psi) \wedge Cause(\epsilon, \chi)))) \quad (9) \end{aligned}$$

should normally succeed given their preconditions. So the preconditions should normally be sufficient on occurrence for the effect, and Axiom (5) should be used to infer by default that events succeed. So, given that the event occurs and its preconditions are true, $Occ(e)(t) \wedge Pre(e)(t)$, the *success assumption*, $Succ(e)(t)$, should, whenever consistent, be assumed, and the axiom used to infer its effects, $Eff(e)(t+1)$.

We can now return to the final conjunct of Axiom (2) which states that, in case of conflict, the success of event C is normally preferred to that of event A . Thus if, as in Figure 1(a), neurons c and a fire simultaneously, then the firing of c succeeds and the firing of a fails. More generally, event preferences can be used to represent the expected resolution of conflicts between events.

Axiom schema (6) defines inertia, and states that the fact represented by relation R and variables \bar{x} is inert at time t iff $R(\bar{x})(t)$ and $R(\bar{x})(t+1)$ have the same truth value. The axiom schema is intended to be used inductively to infer persistence whenever it is consistent to do so.

The *theory of events* consists of axioms (5) and (6) given in Table 2, and an *event theory* is a theory containing these axioms. The intended interpretation of event theories is enforced by their formal pragmatics (their nonmonotonic "semantics") [3], which interprets event theories chronologically, giving priority to success assumptions over inertia assumptions in case of conflict and respecting the event preferences of the theory.

The theory of causation is expressed in the more inclusive language \mathcal{CL} ; which admits quantification over \mathcal{EL} sentences and which includes the modal operators \square and \Downarrow , which refer across worlds.

Axiom (7) defines the notion of sufficient causation. It assumes a theory of background laws, which are represented as the conjunction θ and which include those defining the preconditions and effects of events. The axiom states that the occurrence of event e at time t is a *sufficient cause* (an *SCause*) of effect ϕ iff e succeeds at t , and ϕ is a logical consequence of the back-

ground laws together with e 's defined effects but not of the background laws alone. For example, $SCause(Occ(C)(1), Occ(D)(2))$ and $SCause(Occ(C)(1), \neg\text{TOcc}(B)(2))$ are true at w_a .

The theory of sufficient causation can be viewed as a regularity theory in the Humeian tradition. It avoids the problems of traditional regularity theories raised by Lewis [11, pp. 159-160]; in particular, the problem of preemption is discussed in §5. However, the theory suffers from the fundamental problem of regularity theories, that of distinguishing between those regularities of succession which represent genuine causal connections and those which are merely accidental. In particular, the theory is faced with the *inertia problem*, as it is unable to distinguish between effects which are produced by events and those which remain true by inertia; for example [1, p. 2], whitewashing a white wall is sufficient, but not necessary, for the wall being white. The theory thus fails to capture an important feature of causes, namely that they are events which are efficacious, which make a difference, which alter the course of history, which impinge, which "biff" (to use a technical term of Lewis's [13, pp. 283-4] non-technically).

3 DEPENDENCE

Lewis [11, Ch. 21] goes further and equates causation with difference: "We think of a cause as something that makes a difference, and the difference it makes must be a difference from what would have happened without it. Had it been absent, its effects—some of them, at least, and usually all—would have been absent as well" [pp. 160-1]. Consequently Lewis suggests that causation should be understood in terms of *counterfactual dependence* between pairs of events. Thus, for distinct events c and e , the occurrence of e is counterfactually dependent on the occurrence of c iff (1) c and e both occur, and (2) if c had not occurred, then e would not have occurred. Dependence of this kind will be called *simple dependence*. The causation relation is then taken to be the ancestral (transitive closure) of the (counterfactual) dependence relation.

Simple dependence can be represented in \mathcal{CL} by a conditional of the form $\neg\text{T}\phi \Downarrow \psi$, which, at a world at which ϕ is true, can, for present purposes, be understood as stating that ψ is true at the closest world at which $\neg\text{T}\phi$ is true; that removing ϕ from the world results in a world at which ψ is true. The formal pragmatics [3] ensures that the closest world to a given world is the expected one. (In general, there may be more than one closest world to a given world.) Thus, in the neuron example, both $\neg\text{TOcc}(C)(1) \Downarrow \neg\text{TOcc}(D)(2)$ and $\neg\text{TOcc}(C)(1) \Downarrow \text{Occ}(B)(2)$ are true at w_a (on the intended interpretation); as removing $\text{Occ}(C)(1)$ from w_a results in w_b . Consequently, on the basis of simple dependence, $\text{Occ}(C)(1)$ counts as the cause of both $\text{Occ}(D)(2)$ and $\neg\text{TOcc}(B)(2)$ at w_a .

Hall argues that simple dependence is inadequate as a definition of causation, because it is neither a necessary [8, §§3.2-3] nor a sufficient condition [7] for it. His argument against its sufficiency is discussed in the next section. His argument against its necessity can, I suggest, be made by appealing to cases of symmetrical redundancy.

Redundancy (a phenomenon discussed more generally in §5) arises when two (or more) separate potential causes for a certain effect are present and either one by itself would have been followed by the effect, and so the question arises as to which, if any, of the events the effect depends on. The problem is particularly acute when the redundancy is symmetrical, when both candidates have equal claim to being called causes of the effect; as nothing, either obvious or hidden, breaks the tie between them. Lewis [12, p. 80] suggests that our intuitions in these cases are unclear. So that we may consider that

neither event is a cause or consider that both events are causes; although we cannot reasonably say that one of the events is a cause and the other is not.

The institution of execution by firing squad exploits this uncertainty. Supposing that the riflemen in the squad all aim true and fire simultaneously, then the victim's death is redundantly caused, and so each rifleman is tempted to think that his shot was not the fatal one. On Lewis's simple dependence theory there is no cause in such cases; because the effect does not depend on any one of the candidate causes.

However, it seems more appropriate to say that each of the shots was a cause of the victim's death. This intuition is supported when causation is viewed as production. Each of the shots produces a non-inertial effect (biffs), so it seems odd to say that the effect is uncaused simply because there is a surplus of (candidate) causes. Overproduction may remove simple dependence, but it is, nevertheless, still production. This accounts for the guilt which the members of the firing squad feel; each knows that his shot was sufficient to kill the victim and that it would have done so even if all of the others had missed.

Consequently I suggest that simple dependence should be replaced by *individual dependence* as defined by Axiom (8) in Table 2. This states that event ϵ is a direct cause (a $Cause_1$) of effect ϕ iff ϵ is a sufficient cause of ϕ at a world and removing ϵ from the world results in a world at which either $\neg\text{T}\phi$ is true or some other event ϵ' directly causes ϕ . The individual dependence condition thus ensures that every $SCause$ in a given context biffs, but does not require that any of them biffs uniquely.

For example, in the case of the neurons, $\text{Occ}(C)(1)$ still counts as a cause of both $\text{Occ}(D)(2)$ and $\neg\text{TOcc}(B)(2)$, by sufficiency and simple dependence, at w_a . Moreover, we can obtain a formal analogue of the firing-squad example by supposing that (b) is changed so that d also fires, giving:

$$w_c = \{\text{Occ}(A)(1), \text{Occ}(D)(2), \text{Occ}(B)(2), \text{Occ}(E)(3)\}.$$

Then $Cause_1(\text{Occ}(D)(2), \text{Occ}(E)(3))$ and $Cause_1(\text{Occ}(B)(2), \text{Occ}(E)(3))$ are both true at w_c ; as removing either cause results in a world at which the other causes e to fire (by sufficiency and simple dependence).

The definition of $Cause_1$ is a generalization the definition of direct causation that I gave in [1]; which was restricted to cases of non-redundant or *singular* causation, and which can now be defined as follows: $\forall \epsilon, \phi (Cause_1(\epsilon, \phi) \equiv (Cause_1(\epsilon, \phi) \wedge \neg\exists \epsilon' (\neg\epsilon' = \epsilon \wedge SCause(\epsilon', \phi))))$.

4 TRANSITIVITY

Transitivity is a property that is naturally associated with production when we think of processes or causal chains; for example, in Figure 1(a) it seems natural to conclude that the firing of c (indirectly) causes the firing of e . Accordingly, as stated by Axiom (9) in Table 2, the (indirect) causation relation $Cause$ is taken to be transitive and to be closed under conjunction of effects. In this section three kinds of counterexample to transitivity are discussed.

Counterexamples of the first kind raise what might be called the *remoteness* objection. It seems odd to say that Queen Victoria's birth caused her death. However, according to the Production Theory, the statement is true; Queen Victoria's birth initiated a causal process leading ultimately to the events which directly caused her death. The oddness of the claim arises because, while Queen Victoria's birth was indeed an indirect cause of her death, her birth is not adequate

as an *explanation* of her death. An adequate explanation would consist of causes which were more proximate to her death, and which contributed more directly to it. But determining which causes constitute an adequate explanation is a pragmatic problem, not a metaphysical one. The metaphysical task is to define the causal chain, the pragmatic task is to decide which parts of the chain are relevant to a particular explanation.

An example of the second kind is Hall's [7, p. 187] engineer who: "is standing by a switch in the railroad tracks. A train approaches in the distance. She flips the switch, so the train travels down the right-hand track instead of the left. Since the tracks reconverge up ahead, the train arrives at its destination all the same; let us further suppose that the time and manner of its arrival are exactly as they would have been had she not flipped the switch. Let c be the engineer's action and e be the train's arrival. Pick an event d that is part of the train's journey down the right-hand track. Clearly c is a cause of d and d of e ; but is c a cause of e ? Is her flipping the switch a cause of the train's arrival?" Intuitively it might seem not, because it seems to be clear that the switching event makes no difference to whether the train arrives, but merely determines the *route* by which it arrives. However, Hall [§§4-5] argues that, despite this consideration, flipping the switch is a cause of the train's arrival. If, as the example persuades us to do, we think in terms of the train's arrival and *dependence*, then we are inclined to think that if the switch had not been flipped, the train would have arrived just the same, and so the switch cannot be considered to be a cause. However, if we think in terms of how the train's arrival was *produced*, then we need to consider the causal chain leading to it, and clearly this includes the switching event. In Hall's terminology, the switching event is a "causal switch", as it changes the course of events; without it a different sequence of events would have produced (caused) the train's arrival. Readers who are unconvinced by this summary are referred to Hall's detailed and persuasive discussion.

Formally, suppose an event theory analogous to the one for the neurons, which determines the following partial histories:

$$\begin{aligned} w_0 &= \{Occ(C)(1), Occ(D)(2), Occ(E)(3)\}, \\ w_1 &= \{Occ(C)(1)\}, \\ w_2 &= \{Occ(B)(2), Occ(E)(3)\}. \end{aligned}$$

Thus w_0 represents the actual world in which the switch is flipped, and the train travels via the right-hand track; w_1 represents the world where the switch is flipped, but the train's progress on the right-hand track is obstructed; and w_2 represents the world in which the switch is not flipped, and the train travels down the left-hand track. Then both $Cause_1(Occ(C)(1), Occ(D)(2))$ and $Cause_1(Occ(D)(2), Occ(E)(3))$ are true at w_0 . Consequently $Cause(Occ(C)(1), Occ(E)(3))$ is true at w_0 by Axiom (9).

Examples of the third kind involve cases of what Hall calls "double prevention", and are designed to show that simple dependence cannot be a sufficient condition for causation if causation is taken to be transitive. In one of his examples [pp. 183-4]: "Billy sees Suzy about to throw a water balloon at her neighbor's dog. He runs to try to stop her, but trips over a root and so fails. Suzy, totally oblivious to him, throws the water balloon at the dog. . . . Billy's running toward Suzy causes him to trip, which in turn causes the dog to yelp (by *Dependence*: if he hadn't tripped, he would have stopped her from throwing and so the dog wouldn't have yelped). But, intuitively, his running toward her does not cause the dog's yelp". In this example, Billy's trip is a double preventer because it prevents him from preventing her from throwing the balloon. Hall rightly suggests that

double preventers are not causes and concludes [p. 182] that: "the price of transitivity—a price well worth paying—is to give up the claim that there is any *deep* connection between counterfactual dependence and (the central kind of) causation". As there is no distinction between simple and individual dependence in examples like the one given, it seems that they challenge the necessity of individual dependence. However Hall's double-prevention examples all assume that dependence is a sufficient condition for causation (note, for instance, the appeal to dependence in the *Billy-Suzy* example), and so do not challenge the Production Theory because dependence is not taken to be a sufficient condition for causation; any $Cause_1$ is also required to be an $SCause$.

5 REDUNDANCY

Symmetrical redundancy is discussed in §3, and it arises when two or more potential causes have equal claim to being regarded as the cause of an effect. Other redundancies are asymmetrical: intuition suggests that one of the events is a cause and the other is not; that one of the events is a *preempting* cause and that the other is a *preempted* cause. Lewis [12, p. 80] comments that: "When our opinions are clear, it's incumbent on an analysis of causation to get them right. This turns out to be a severe test".

Figure 1(a) provides an example of what Lewis calls *early pre-emption*. Both a and c fire simultaneously, with the firing of c causing (and thereby preempting the firing of a from causing) the firing of e . On Lewis's theory c counts as the cause because of the stepwise dependence of the firing of e on the firing of d , and the firing of d on the firing of c . In the case of the Production Theory, suppose the following partial histories:

$$\begin{aligned} w_0 &= \{Occ(C)(1), Occ(A)(1), Occ(D)(2), Occ(E)(3)\}, \\ w_1 &= \{Occ(C)(1), Occ(A)(1)\}, \\ w_2 &= \{Occ(A)(1), Occ(B)(2), Occ(C)(3)\}. \end{aligned}$$

Here w_0 represents the actual world, w_1 represents the alternative history in which the occurrence of D is removed, and w_2 represents the alternative history in which the occurrence of C is removed. Then $\neg TOcc(C)(1) \Downarrow \neg TOcc(D)(2)$ and $\neg TOcc(D)(2) \Downarrow \neg TOcc(E)(3)$ are both true at w_0 . So, $Cause_1(Occ(C)(1), Occ(D)(2))$ and $Cause_1(Occ(D)(2), Occ(E)(3))$ are true at w_0 . Consequently $Cause(Occ(C)(1), Occ(E)(3))$ is true at w_0 (by Axiom (9)).

The most common examples of asymmetrical redundancy are cases of what Lewis calls *late pre-emption*. In such cases the preempting cause produces the effect before the preempted alternative can do so. Wright [20] gives the example of two forest fires, A and B approaching a house from opposite directions. Suppose that A arrives first and destroys the house. Then it seems reasonable to conclude that A caused the destruction; despite the fact that if A not done so, then B would have. Halpern and Pearl [9, p. 1] motivate their theory of causation as contingent dependency with this example. They suggest that the house burning down depends on (is caused by) fire A under the contingency that the fire fighters arrive and extinguish fire B before it reaches the house, but not otherwise. This seems wrong. For example, if A was started by arsonist a , B was started by rival arsonist b , and B was not extinguished by the fire fighters, then a would be considered to be guilty of arson, and b of attempted arson. The usual, and it seems correct, solution to cases of this kind is to appeal to the time at which events occur. This is done in the formal treatment of the example in [1, pp. 9-10], A destroys the house at

time t thereby preempting B from doing so at the later time t' as the house is no longer flammable at t' . A preempts B by removing one of B 's preconditions, and so the conflict is resolved at the "event level" (by the event theory).

However in cases of *trumping preemption* this resource is not available, as the two candidate causes are followed by the very same effect. Lewis [12] gives the following example, which was suggested by van Fraassen. Suppose that a sergeant and a major simultaneously order their soldiers to advance and that the soldiers do so. Their advance is redundantly caused, since either order would, on its own, have been sufficient. However, the redundancy is asymmetric, since the soldiers obey the senior officer. The soldiers advance because the major orders them to, not because the sergeant does. The major's order trumps the sergeant's. Once again, the formal treatment [pp. 10–11] shows that an event-level resolution is possible by making it a precondition of issuing an order that no more senior soldier issues an order at the same time; with the consequence that the major's order succeeds and the sergeant's fails. An alternative, more flexible, solution is to use an event preference to represent the fact that the senior officer's orders normally override conflicting orders from the junior officer.

Redundancy causes difficulty for dependence considered as a sufficient condition. Indeed, the problem of trumping prompted Lewis to abandon simple dependence in favour of the more complex and vague notion of counterfactual covariance [12]. However, it does not appear to pose problems for the Production Theory because conflicts can be resolved at the event level (by the underlying event theory). This seems to be the appropriate place because the resolution of conflicts depends on specific causal knowledge of the kind encoded in the definitions of events and event preferences. This also has the advantage of making it possible to give a simple, general, definition of causation.

6 CONCLUDING REMARKS

I agree with Hall that causation as production should be seen as the central metaphysical notion of causation, and suggest that this notion can be formalized by combining appropriate forms of regularity and dependence. The resulting Production Theory captures two significant features of production: regular succession (expected/normally dependable outcome) and making a difference in context (efficacy), and inherits the strengths of regularity and dependence theories while avoiding their weaknesses. The Production Theory also offers a clear division between a general, and relatively simple, definition of causation, and particular causal knowledge embodied in the definition of events and event preferences.

As the common sense concept of causation is complex and vague, any comprehensible formal theory of it must inevitably be prescriptive rather than descriptive. In a related paper [2] I consider the more exotic causal notions of prevention and causation by absence, and show that prevention can be reduced to counterfactual production and that causation by absence can be reduced to counterfactual production together with a pragmatic parameter. For example, the ordinary language claim "Lack of food causes hunger" can be analyzed as the counterfactual 'If food were present, then eating would cause (produce) an absence of hunger' provided that it is assumed that eating normally occurs when food and hunger are present.

These considerations suggest that the Production Theory is of some philosophical interest. Moreover as the theory is entirely formal, it can be implemented (in simple cases at least) and used by artificial agents to reason about actual and counterfactual causation.

ACKNOWLEDGEMENTS

I am grateful to the reviewers and to everyone else who has commented on this work.

Merging possibilistic networks

Salem Benferhat¹

Abstract. This paper deals with merging multiple-source uncertain pieces of information, which are encoded by means of possibilistic networks. We first show that the merging of possibilistic networks having the same graphical structure can be easily achieved in polynomial time. When possibilistic networks have different graphical structures we show that their fusion can also be efficiently done by extending initial possibilistic networks into a same common structure. We then address two important problems: how to deal with cycles, and how to solve the subnormalization problem which reflects conflicts between sources?

1 Introduction

Possibilistic networks [11, 12] are important tools proposed for an efficient representation of uncertain information. Their success is due to their simplicity of representing and handling independence relationships. Possibilistic networks are directed acyclic graphs (DAG), where each node encodes a variable and every edge represents a relationship between two variables. Uncertainties are expressed by means of conditional possibility distributions for each node in the context of its parents.

This paper addresses the problem of merging uncertain pieces of information represented by possibilistic networks. The fusion of uncertain pieces of information issued from different sources is an important issue that can be encountered in various fields of applications.

The problem of fusing propositional or weighted logical knowledge bases, issued from different sources, was studied in several works [1, 6, 8, 3]. However, few works have been done for fusing possibilistic networks (e.g., [2]). These recent works are not satisfactory, since either they are computationally hard, or their use is very limited to special cases.

This paper proposes alternative approaches which overcome limitations of existing approaches. Its main contributions are:

- We first propose efficient ways for fusing possibilistic networks having the same graphical structure
- We show how to expand possibilistic networks (by adding new variables and/or links) without modifying joint distributions
- We then consider the case where possibilistic networks to fuse have different graphical structures. The idea is : i) to compute a common structure (which is basically the union of the initial graphs), ii) to expand each network to this common structure, and iii) to apply the fusion procedure

defined for merging possibilistic networks having the same graphical structure.

- We address the problem of cycles. Indeed, even if initial possibilistic networks are free of cycles, it may happen that their union contains cycles. We show that existing propagation algorithms, in particular the well-known junction tree algorithm, can be extended to the case with cycles.
- Lastly, we deal with the normalization problem which expresses the presence of conflicts between sources.

The rest of this paper is organised as follows. Next section gives a brief background on possibility theory. Section 3 presents the fusion of possibilistic networks. Section 4 deals with cycles and normalization problems. Section 5 concludes the paper.

2 Basics of possibility theory

Let $V = \{A_1, A_2, \dots, A_N\}$ be a set of variables. We denote by $D_A = \{a_1, \dots, a_n\}$ the domain associated with the variable A , and a denotes any instance of A . $\Omega = \times_{A_i \in V} D_{A_i}$ denotes the universe of discourse, which is the Cartesian product of all variable domains in V . In the following, we only give a brief overview on possibility theory, for more details see [10].

2.1 Possibility distributions

A possibility distribution π is a mapping from Ω to the interval $[0, 1]$. It represents a state of knowledge about a set of possible situations distinguishing what is plausible from what is less plausible. Given a possibility distribution π , we can define a mapping grading the *possibility measure* of an event $\phi \subseteq \Omega$ by $\Pi(\phi) = \max_{\omega \in \phi} \pi(\omega)$. A possibility distribution π is said to be *normalized*, if $\max_{\omega} \pi(\omega) = 1$.

In this paper, we only use the so-called min-based conditioning proposed in an ordinal setting [10] [13], and defined by:

$$\Pi(\psi | \phi) = \begin{cases} \Pi(\psi \wedge \phi) & \text{if } \Pi(\psi \wedge \phi) < \Pi(\phi) \\ 1 & \text{otherwise} \end{cases} \quad (1)$$

2.2 Possibilistic networks revisited

In existing works, graphs associated with possibilistic networks are DAGs (Directed Acyclic Graph). However, as we will see later propagation algorithms can be adapted to the case of graphs with cycles. Therefore, we provide a revised definition of possibilistic networks, where we simply relax the condition that the associated graph should be a DAG.

¹ CRIL-CNRS, Université d'Artois, Rue Jean Souvraz 62307 Lens Cedex, France. Email: benferhat@cril.univ-artois.fr

Namely, a *min-based possibilistic network* or simply *possibilistic network* over a set of variables V , denoted by $\mathbb{N} = (\pi_{\mathbb{N}}, G_{\mathbb{N}})$, consists of:

- a *graph*, denoted by $G_{\mathbb{N}}$, where nodes represent variables and edges encode the link between the variables. The parent set of a node A is denoted by U_A .
- a *numerical component*, denoted by $\pi_{\mathbb{N}}$, which quantifies different links. For every root node A uncertainty is represented by the conditional possibility distributions $\pi_{\mathbb{N}}(A | u_A)$ over A in the context of each $u_A \in D_{U_A}$.

When $G_{\mathbb{N}}$ is a DAG, we call \mathbb{N} a standard possibilistic network. The set of a priori and conditional possibility degrees induces a unique joint possibility distribution defined by:

Definition 1 Given the a priori and conditional possibility distributions, the joint distribution denoted by $\pi_{\mathbb{N}}$, is expressed by the following min-based chain rule (which the counterpart of probabilistic chain rule) :

$$\pi_{\mathbb{N}}(A_1, \dots, A_N) = \min_{i=1 \dots N} \pi_{\mathbb{N}}(A_i | U_{A_i}) \quad (2)$$

3 Merging min-based possibilistic networks

3.1 Conjunctive merging

One of the important aims in merging uncertain information is to exploit complementarities between the sources in order to get a more complete and precise global point of view.

In possibility theory, given a set of possibility distributions π'_i 's, the basic combination mode is the conjunction (i.e., the minimum) of possibility distributions. Namely:

$$\forall \omega, \pi_{\oplus}(\omega) = \min_{i=1, \dots, n} \pi_i(\omega).$$

The conjunctive aggregation mode makes sense if all the sources are regarded as equally reliable (for more details see [5]).

3.2 The problem

Our aim is to directly construct from n standard possibilistic networks $\mathbb{N}_1, \dots, \mathbb{N}_n$, issued from different sources, a new possibilistic network, denoted by \mathbb{N}_{\oplus} .

The new possibilistic network should be such that:

$$\forall \omega, \pi_{\mathbb{N}_{\oplus}}(\omega) = \min_{i=1, \dots, n} \pi_{\mathbb{N}_i}(\omega),$$

where $\pi_{\mathbb{N}_{\oplus}}, \pi_{\mathbb{N}_i}$'s are respectively the possibility distributions associated with \mathbb{N}_{\oplus} and \mathbb{N}_i 's using Definition 1.

Recently, in [2] a preliminary work has been proposed to fuse possibilistic networks. Unfortunately, this work is not satisfactory. Indeed, it only considers a very restricted case where the union of graphs, associated with possibilistic networks to fuse, is free of cycles. This is a real limitation. For instance, assume that two sources have a same joint distribution π defined on a set of two variables $\{A, B\}$. Assume moreover, that these two sources use different possibilistic networks to represent this distribution. The first source defines a network where we have a link from A to B . While the other source uses the converse link from B to A . Since the union of the graphs contains a cycle, the approach proposed in [2] cannot

be applied, even if the possibility distribution, associated with possibilistic networks is the same.

Moreover, the approach proposed in [2] does not deal with the sub-normalization problem. Hence, this approach is not appropriate when the sources are conflicting.

Another way to deal with the fusion of possibilistic networks is to exploit the equivalent transformations between possibilistic graphs and possibilistic knowledge bases. Namely, to fuse possibilistic networks : i) first transform initial possibilistic networks into their associated possibilistic knowledge bases using results given in [4], ii) fuse the obtained knowledge bases using results of [3], and iii) transform the fused possibilistic knowledge base into a fused possibilistic network using results of [4].

This procedure has at least three main limitations. First, the transformation step from a possibilistic base into a possibilistic graph is generally a hard problem. Secondly, it does not preserve initial structure between variables. For instance, if the two graphs to fuse have exactly the same singly connected DAG (for which the propagation algorithm is efficient), then the result can be a multiply connected DAG (for which the propagation algorithm is hard). Lastly, existing transformations only deal with binary variables.

This paper proposes alternative approaches for fusing possibilistic networks that overcome the above limits. Let us start with the construction of \mathbb{N}_{\oplus} when the standard possibilistic networks \mathbb{N}_i 's have exactly the same DAG.

3.3 Fusion of the same-structure networks

This section presents the procedure of merging possibilistic networks of a same DAG structures. The possibilistic networks to merge, denoted by \mathbb{N}_i 's, only differ on conditional possibility distributions assigned to variables. The following definition and proposition show that the result of merging of networks is immediate.

Definition 2 Let $\mathbb{N}_i = (\pi_{\mathbb{N}_i}, G_{\mathbb{N}_i})$'s ($i = 1, \dots, n$) be n possibilistic networks such that :

$\forall i = 1, \dots, n, \forall j = 1, \dots, n$ we have $G_{\mathbb{N}_i} = G_{\mathbb{N}_j}$.

The result of merging \mathbb{N}_i 's is a possibilistic network denoted by $\mathbb{N}_{\oplus} = (\pi_{\mathbb{N}_{\oplus}}, G_{\mathbb{N}_{\oplus}})$, where :

- $G_{\mathbb{N}_{\oplus}} = G_{\mathbb{N}_i}$ (for any $i = 1, \dots, n$) and
- $\pi_{\mathbb{N}_{\oplus}}$ is defined by:

$$\forall A, \pi_{\mathbb{N}_{\oplus}}(A | U_A) = \min_{i=1, \dots, n} \pi_{\mathbb{N}_i}(A | U_A).$$

Proposition 1 Let $\mathbb{N}_i = (\pi_{\mathbb{N}_i}, G_{\mathbb{N}_i})$'s ($i = 1, \dots, n$) be n standard possibilistic networks having exactly the same associated DAG. Let $\mathbb{N}_{\oplus} = (\pi_{\mathbb{N}_{\oplus}}, G_{\mathbb{N}_{\oplus}})$ be the result of merging \mathbb{N}_i 's using the above definition. Then, we have :

$$\forall \omega, \pi_{\mathbb{N}_{\oplus}}(\omega) = \min_{i=1, \dots, n} \pi_{\mathbb{N}_i}(\omega),$$

where $\pi_{\mathbb{N}_{\oplus}}, \pi_{\mathbb{N}_i}$'s are respectively the possibility distributions associated with \mathbb{N}_{\oplus} and \mathbb{N}_i 's using Definition 1.

3.4 Fusion of different-structure networks

The above subsection has shown that the fusion of possibilistic networks can be easily achieved if they have the same DAG. This section considers the case when the networks have not

necessarily the same structure. The idea is to expand initial possibilistic networks into a common structure, which is simply the union of initial graphs.

A union of a set of DAGs (G_1, \dots, G_n) is a graph where : i) the set of its variables is the union of variables in G_1, \dots, G_n and ii) for each variable A, its parents are those in G_1, \dots, G_n .

The two following propositions are very useful since they show that any possibilistic network can be extended with additional variables and/or links. The following concerns the addition of variables.

Proposition 2 Let $\mathbb{N} = (\pi_{\mathbb{N}}, G_{\mathbb{N}})$ be a possibilistic network defined on a set variables V . Let A be a new variable. Let $\mathbb{N}^E = (\pi_{\mathbb{N}}^E, G_{\mathbb{N}}^E)$ be a new possibilistic networks such that :

- $G_{\mathbb{N}}^E$ is such that : i) the set of variables of $G_{\mathbb{N}}^E$ is the one of $G_{\mathbb{N}}$ plus the new variable A , and ii) the set of arcs between variables in $G_{\mathbb{N}}^E$ is exactly the same as the one in $G_{\mathbb{N}}$ (the new variable A has neither parents nor children).
- $\pi_{\mathbb{N}}^E$ is identical to $\pi_{\mathbb{N}}$ for variables in V , and is equal to a uniform possibility distribution on the node A (namely, $\forall a \in D_A, \pi_{\mathbb{N}}^E(a) = 1$).

Then, we have :

$\forall \omega \in \times_{A_i \in V} D_{A_i}, \pi_{\mathbb{N}}(\omega) = \max_{a \in D_A} \pi_{\mathbb{N}}^E(a\omega)$, where $\pi_{\mathbb{N}}$ and $\pi_{\mathbb{N}}^E$ are respectively the possibility distributions associated with \mathbb{N} and \mathbb{N}^E using Definition 1.

If \mathbb{N}^E is the obtained augmented network, then the possibility distribution $\pi_{\mathbb{N}}$ can be recovered by marginalizing $\pi_{\mathbb{N}}^E$ on the new added variables. We now provide a proposition which shows how to add links to a possibilistic network without changing its possibility distribution.

Proposition 3 Let $\mathbb{N} = (\pi_{\mathbb{N}}, G_{\mathbb{N}})$ be a possibilistic network. Let A be a variable. Let $B \notin Par(A)$. Let $\mathbb{N}^E = (\pi_{\mathbb{N}}^E, G_{\mathbb{N}}^E)$ be a new possibilistic network obtained from $\mathbb{N} = (\pi_{\mathbb{N}}, G_{\mathbb{N}})$ by adding a link from B to A . The new conditional possibility distribution associated with A is:

$$\forall a \in D_A, b \in D_B, u \in D_{Par(A)}, \pi_{\mathbb{N}}^E(a | ub) = \pi_{\mathbb{N}}(a | u).$$

Then, we have :

$$\forall \omega, \pi_{\mathbb{N}}(\omega) = \pi_{\mathbb{N}}^E(\omega).$$

Given these two above propositions the fusion of n possibilistic networks $\mathbb{N}_1, \dots, \mathbb{N}_n$ is immediate, using the following two steps:

Step 1 Let $G_{\mathbb{N}\oplus}$ be the union of $G_{\mathbb{N}1}, \dots, G_{\mathbb{N}n}$. Using Propositions 2 and 3, expand $\mathbb{N}_1, \dots, \mathbb{N}_n$ to $\mathbb{N}_1^E, \dots, \mathbb{N}_n^E$ such that $\forall i = 1, \dots, n, G_{\mathbb{N}_i}^E = G_{\mathbb{N}\oplus}$.

Step 2 As in Definition 2, define conditional possibility distribution $\pi_{\mathbb{N}\oplus}(A|U_A)$ associated with each variable given their parents, namely:

$$\forall A, \pi_{\mathbb{N}\oplus}(A|U_A) = \min_{i=1, \dots, n} \pi_{\mathbb{N}_i}^E(A|U_A).$$

Proposition 4 Let $\mathbb{N}\oplus$ be the result of merging \mathbb{N}_i 's using the above steps 1 and 2. Then, we have :

$$\forall \omega, \pi_{\mathbb{N}\oplus}(\omega) = \min_{i=1, \dots, n} \pi_{\mathbb{N}_i}(\omega).$$

Example 1 Let us consider two standard possibilistic networks, where their DAG are given by Figure 1. These two DAGs have a different structure. Figure 2 provides the DAG of $G_{\mathbb{N}\oplus}$. Note that $G_{\mathbb{N}\oplus}$ contains a cycle.

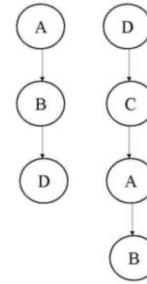

Figure 1. $G_{\mathbb{N}1}$ and $G_{\mathbb{N}2}$: Initial DAGs

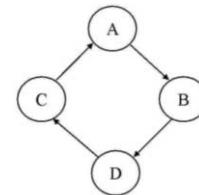

Figure 2. $G_{\mathbb{N}\oplus}$: Fused graph of $G_{\mathbb{N}1}$ and $G_{\mathbb{N}2}$

Tables 1-4 give conditional possibility distributions associated with $\mathbb{N}_1^E, \mathbb{N}_2^E$ and $\mathbb{N}\oplus$. Initial possibility distributions associated with \mathbb{N}_1 and \mathbb{N}_2 appear in bold columns. In our example, possibility distributions associated with expanded networks are either equal to initial possibility distributions or to uniform distributions.

From these different tables of conditional distributions, we can easily show that the joint possibility of $\pi_{\mathbb{N}\oplus}$ computed by chain rule, is equal to the minimum of $\pi_{\mathbb{N}1}$ and $\pi_{\mathbb{N}2}$. For instance, let $\omega = a_1 b_2 c_1 d_1 \in \Omega$. Using chain rule, we have:
 $\pi_{\mathbb{N}1}(a_1 b_2 c_1 d_1) = .4, \pi_{\mathbb{N}2}(a_1 b_2 c_1 d_1) = .8$
and $\pi_{\mathbb{N}\oplus}(a_1 b_2 c_1 d_1) = .4$.

Table 1. Possibility distributions associated with B given A

A	B	$\pi_{\mathbb{N}1}^E = \pi_{\mathbb{N}1}$	$\pi_{\mathbb{N}2}^E = \pi_{\mathbb{N}2}$	$\pi_{\mathbb{N}\oplus}$
a_1	b_1	.1	.8	.8
a_1	b_2	.4	1	.4
a_2	b_1	.6	1	.6
a_2	b_2	1	.7	.7

4 Dealing with cycles and subnormalized joint distributions

4.1 Dealing with cycles

Results of above sections guarantee that the joint distribution associated with the fused possibilistic networks is indeed equal to a conjunctive combination of joint distributions associated with initial standard possibilistic networks. However, even if initial graphs are free of cycles it may happen that their union produces cycles. This was illustrated by our running example.

Table 2. Possibility distributions associated with D given B , where – means that the link $B \rightarrow A$ does not exists in $G_{\text{N}2}$

B	D	$\pi_{\text{N}1} = \pi^E_{\text{N}1}$	$\pi_{\text{N}2}$	$\pi^E_{\text{N}2} = \pi_{\text{N}2}$	$\pi_{\text{N}\oplus}$
b_1	d_1	1	-	1	1
b_1	d_2	.9	-	1	.9
b_2	d_1	1	-	1	1
b_2	d_2	.8	-	1	.8

Table 3. Possibility distributions associated with C given D , where – means that the link $C \rightarrow D$ does not exists in $G_{\text{N}1}$

D	C	$\pi_{\text{N}1}$	$\pi^E_{\text{N}1}$	$\pi^E_{\text{N}2} = \pi_{\text{N}2}$	$\pi_{\text{N}\oplus}$
d_1	c_1	-	1	.9	.9
d_1	c_2	-	1	1	1
d_2	c_1	-	1	1	1
d_2	c_2	-	1	.4	.4

This section shows that, due to the idempotency of the conjunctive operator, the presence of cycles can be easily managed in a possibility framework. More precisely, we show that the propagation algorithm for multiply connected graphs can be easily adapted for dealing with cycles.

The idea is, as for multiply-connected probabilistic networks, to proceed to a transformation of the fused network $G_{\text{N}\oplus}$ into a junction tree structure. Given a cyclic fused possibilistic network $G_{\text{N}\oplus}$, the construction of its corresponding junction tree is performed exactly in the same manner as in the probabilistic case [7]. In a first step, the graph is moralized by adding undirected edges between the parents and by dropping the direction of existing edges. Then, the moral graph is triangulated. Finally, the triangulated graph is transformed into a junction tree where each node represents a *cluster* of variables and each edge is labelled with a *separator* corresponding to the intersection of its adjacent clusters.

Figure 3 gives the junction tree associated with the fused graph $G_{\text{N}\oplus}$ of figure 2 (there are two clusters $C_1 = \{ABC\}$ and $C_2 = \{BCD\}$ and one separator $\{BC\}$ which is the intersection of the two clusters).

Once the junction tree is constructed, the main steps of the junction tree propagation algorithm are :

- **Step 1 (Initialization) :**

- For each cluster $C_i : \pi_{C_i}^I \leftarrow \mathbf{1}$, where $\mathbf{1}$ is a possibility distribution where all elements have a highest possibility degree 1.
 - For each separator $S_{ij} : \pi_{S_{ij}}^I \leftarrow \mathbf{1}$,
 - For each variable A , select a cluster C_i containing $A \cup U_A$ (such cluster exists, thanks to the moralisation step) and update its possibility distributions as follows :
- $$\pi_{C_i}^I : \pi_{C_i}^I \leftarrow \min(\pi_{C_i}^I, \Pi(A | U_A)).$$

Proposition 5 Let $\text{N}\oplus$ be the result of merging N_i 's given in Proposition 4. Let $\pi_{C_i}^I$ be the possibility distribution

Table 4. Possibility distributions associated with A given C , where – means that the link $C \rightarrow A$ does not exists in $G_{\text{N}1}$

C	A	$\pi^E_{\text{N}1}$	$\pi_{\text{N}1}$	$\pi^E_{\text{N}2} = \pi_{\text{N}2}$	$\pi_{\text{N}\oplus}$
c_1	a_1	-	1	.8	.8
c_1	a_2	-	1	1	1
c_2	a_1	-	1	.4	.4
c_2	a_2	-	1	1	1

Figure 3. Junction tree associated with graph $G_{\text{N}\oplus}$ of figure 2

associated with clusters after the initialisation step. Then :

$$\pi_{\oplus} = \min_{C_i} \pi_{C_i}^I.$$

Example 2 Let us consider again our example. In tables 5 and 6, we provide possibility distributions associated with the two clusters after the initialization step (bold column). They are obtained as follows :

$$\pi_{C_1}^I(ABC) = \min(\pi_{\text{N}\oplus}(B | A), \pi_{\text{N}\oplus}(A | C)),$$

and

$$\pi_{C_2}^I(BCD) = \min(\pi_{\text{N}\oplus}(D | B), \pi_{\text{N}\oplus}(C | D)).$$

We already computed $\pi_{\text{N}\oplus}(a_1 b_2 c_1 d_1) = .4$. We have:

$$\pi_{C_1}^I(a_1 b_2 c_1) = .4 \text{ and } \pi_{C_2}^I(b_2 c_1 d_1) = .9. \text{ Hence:}$$

$$\pi_{\text{N}\oplus}(a_1 b_2 c_1 d_1) = \min(\pi_{C_1}^I(a_1 b_2 c_1), \pi_{C_2}^I(b_2 c_1 d_1)).$$

Table 5. Possibility distributions associated with the cluster $C_1 = \{A, B, C\}$

A	B	C	$\pi_{C_1}^I(ABC)$	$\pi_{C_1}^S(ABC)$
a_1	b_1	c_1	.8	.8
a_1	b_1	c_2	.4	.4
a_1	b_2	c_1	.4	.4
a_1	b_2	c_2	.4	.4
a_2	b_1	c_1	.6	.6
a_2	b_1	c_2	.6	.6
a_2	b_2	c_1	.7	.7
a_2	b_2	c_2	.7	.7

Table 6. Possibility distributions associated with the cluster $C_2 = \{D, B, C\}$

B	C	D	$\pi_{C_2}^I(BCD)$	$\pi_{C_2}^S(BCD)$
b_1	c_1	d_1	.9	.8
b_1	c_1	d_2	.9	.7
b_1	c_2	d_1	1	.6
b_1	c_2	d_2	.4	.4
b_2	c_1	d_1	.9	.7
b_2	c_1	d_2	.8	.7
b_2	c_2	d_1	1	.7
b_2	c_2	d_2	.4	.4

• **Step 2 (Updating of separators):** Each cluster computes its possibility distribution and sends it to the adjacent separator. The separator's distribution, denoted $\pi_{S_{ij}}^{t+1}$, is then updated as follows:

$$\pi_{S_{ij}}^{t+1} \leftarrow \max_{C_i \setminus S_{ij}} \pi_{C_i}^t. \quad (3)$$

• **Step 3 Updating of clusters:** Each cluster updates its possibility distribution, denoted $\pi_{C_j}^{t+1}$, when receiving a message from its adjacent separator as follows :

$$\pi_{C_j}^{t+1} \leftarrow \min(\pi_{C_j}^t, \pi_{S_{ij}}^t). \quad (4)$$

Steps 3 and 4 are repeated until the junction tree is globally stable (or consistent), namely adjacent clusters should have same marginal distributions with respect to common variables, namely:

$$\max_{C_i \setminus S_{ij}} \pi_{C_i}^t = \pi_{S_{ij}}^{t+1} = \max_{C_j \setminus S_{ij}} \pi_{C_j}^t$$

Proposition 6 Let $\mathbb{N}\oplus$ be the result of merging \mathbb{N}_i 's given in Proposition 4. Let $\pi_{C_i}^S$ be the possibility distribution associated with clusters after applying steps 2 and 3 until the stabilisation of the junction tree. Then :

$$\pi_{\oplus} = \min_{C_i} \pi_{C_i}^S$$

Example 3 Let us consider again our example. Tables 5 and 6 give the possibility distributions associated with clusters C_1 and C_2 after applying steps 2 and 3 until reaching stabilization. We can check that the marginal distribution on $\{B, C\}$ is the same in π_{C_1} and π_{C_2} .

We can also check that $\pi_{\mathbb{N}\oplus}(a_1 b_2 c_1 d_1) = \min(\pi_{C_1}^S(a_1 b_2 c_1), \pi_{C_2}^S(b_2 c_1 d_1)) = .4$ since we have: $\pi_{C_1}^S(a_1 b_2 c_1) = .4$ and $\pi_{C_2}^S(b_2 c_1 d_1) = .7$.

The following shows that marginals can be locally recovered:

Proposition 7 When the junction tree is consistent, computing $\Pi(A = a)$ consists in selecting any cluster containing A and marginalizing Π_{C_i} on A :

$$\Pi(A = a) = \Pi_{C_i}(A = a).$$

4.2 Dealing with subnormalized distribution

When merging multiple source information, we often meet the problem of conflicts. This is reflected by the fact that the fused possibility distribution $\pi_{\mathbb{N}\oplus}$ is subnormalized. We denote by $Cons(\pi)$ the consistency degree of a possibility distribution, defined by :

$$Cons(\pi) = \max_{\omega \in \Omega} \pi(\omega).$$

In possibility theory, the normalization procedure is given as follows:

$$\pi^{normalized}(\omega) = \begin{cases} \pi(\omega) & \text{if } \pi(\omega) < Cons(\pi) \\ 1 & \text{otherwise} \end{cases}$$

Let JT be the stable junction tree associated with fused (cyclic or not) possibilistic network. Let us denote by $\pi_{C_i}^{normalized}$ be the result of normalizing possibility distributions associated with clusters. Then we have:

Proposition 8 Let $\mathbb{N}\oplus$ be the result of merging \mathbb{N}_i 's given in Proposition 4. Then :

$$\pi_{\oplus}^{normalized} = \min_{C_i} \pi_{C_i}^{normalized}$$

The idea of the proof is to first note that for a stable junction tree, the consistency degree associated with clusters is the same, and is equal to the one associated with π_{\oplus} . Let us denote $Best(\pi)$ be the set of elements in π having their value equal to $cons(\pi)$. Then we can easily check that for

each $\omega \in \Omega$, $\omega \in Best(\pi_{\oplus})$ if and only if $\omega \in \times_{C_i} Best(\pi_{C_i})$, where $\times_{C_i} Best(\pi_{C_i})$ is the cartesian product of elements in $Best(\pi_{C_i})$. Namely, elements of $Best(\pi_{\oplus})$ are exactly those obtained by only considering elements of $Best(\pi_{C_i})$. Hence increasing the degree of elements of $Best(\pi_{C_i})$ (for all C_i 's) to 1 guarantees that only elements of $Best(\pi_{\oplus})$ will be increased to one, and the others remain unchanged. In our example, to locally renormalize π_{\oplus} , it is enough to let $\pi_{C_1}^S(a_1 b_1 c_1) = \pi_{C_2}^S(b_1 c_1 d_1) = 1$.

5 conclusion

This paper has proposed a fusion of possibilistic networks. We first showed that fusing possibilistic networks with the same structure can be easily achieved. Starting from the observation that any possibilistic networks can be equivalently extended (by adding variables or links), we suggested a method to fuse any possibilistic networks. These results also show that if the fused graph is singly connected graph, then the propagation algorithm is polynomial (wrt number of variables) even if the possibility distribution is subnormalized. They also show that the graphs associated with possibilistic networks can have cycles and hence are not restricted to be DAGS.

Compiling possibilistic knowledge bases

Salem BENFERHAT¹ and Henri PRADE²

Abstract. Possibilistic knowledge bases gather propositional formulas associated with degrees belonging to a linearly ordered scale. These degrees reflect certainty or priority, depending if the formulas encode pieces of beliefs or goals to be pursued. Possibilistic logic provides a simple format that turns to be useful for handling qualitative uncertainty, exceptions or preferences. The main result of the paper provides a way for compiling a possibilistic knowledge base in order to be able to process inference from it in polynomial time. The procedure is based on a symbolic treatment of the degrees under the form of sorted literals and on the idea of forgetting variables. The number of sorted literals that are added corresponds exactly to the number of priority levels existing in the base, and the number of binary clauses added in the compilation is also equal to this number of levels. The resulting extra compilation cost is very low.

1 Introduction

Possibilistic knowledge bases [Dubois *et al.* 1994] offer a representation framework for the qualitative handling of uncertainty or for the encoding of prioritized formulas expressing preferences. A key feature of possibilistic logic is its capability to deal with inconsistent knowledge bases. Indeed a possibilistic knowledge base is associated with a level of inconsistency, and the set of formulas whose associated level is strictly greater than this inconsistency level are safe from inconsistency, while the formulas with a level smaller or equal are ignored in the inference process. Adding new pieces of knowledge to the base may increase this inconsistency level, which provides a mechanism for encoding nonmonotonic reasoning [Benferhat *et al.* 1999]. Clearly, the computation of the inconsistency level in possibilistic logic inference, as well as for related consequence relations that are able to also take advantage of some of the ignored formulas (drawn in inconsistencies) [Benferhat *et al.* 1999], is a key issue.

Two related entailment relations can be defined from a possibilistic knowledge base. The first one yields the classical consequences of the subpart of the base made of the formulas whose certainty levels are strictly above the inconsistency level of the base, the second one yields the same consequences together with an associated certainty level (which is the greatest possible one compatible with the information in the base).

The computational complexity of possibilistic logic is the one of classical logic multiplied by the logarithm of the number of distinct levels used in the base [Lang2000]. As in classical logic,

the compilation of possibilistic knowledge bases is a key issue in order to be able to process inference in a polynomial time. The method proposed in this paper takes advantage of ideas recently introduced in [Benferhat and Prade2005] for handling an extension of possibilistic logic allowing for the symbolic handling of partial preorders between the levels. However, the case of possibilistic logic, where there is a complete preorder between the levels, requires a particular adaptation of these ideas. A key issue not considered in [Benferhat and Prade2005] is then to compute to what level a formula can be inferred. Possibilistic logic levels are encoded by means of propositional symbols. Then the possibilistic logic base we start with is turned into a new base where on the one hand the original clauses are augmented with this encoding of their levels, and where on the other hand as many binary clauses as there are certainty levels are added to the base, thus for a very small extra computational cost. This rewriting makes possible the design of an efficient original algorithm for computing the result of a possibilistic inference with its associated degree in polynomial time.

The paper is organized as follows. Section 2 provides a short background on possibilistic logic, while Section 3 introduces the symbolic encoding of levels. Section 4 presents the main results for computing of plausible inference, using DNF forms and the forgetting variable technique. Section 5 describes the general procedure for computing compiled possibilistic bases. Sections 6 and 7 show that the computation of possibilistic entailment with the level associated to the consequent can be achieved in polynomial time, and provide the algorithms for doing it.

2 Brief background on possibilistic logic

We start with a brief refresher on possibilistic logic (for more details see [Dubois *et al.* 1994]). Let V be a set of propositional variables. Let L_V be a propositional language built from V using the propositional connectors \wedge, \vee, \neg . A possibilistic logic formula is a pair made of a classical logic formula and a degree a expressing certainty or priority. The degree $a \in (0, 1]$ of a formula p is interpreted as the lower bound of a necessity measure N , i.e., the possibilistic logic expression (p, a) is understood as $N(p) \geq a$. Since $N(p \wedge q) = \min(N(p), N(q))$ it is always possible to put a possibilistic formula (p, a) under the form of a conjunction of clauses (p_i, a) where $p \equiv \wedge_i p_i$. In the following, ordinary propositions are denoted by lower case letters p, q, r, \dots , numerical degrees (belonging to the interval $[0, 1]$) are denoted by lower case letters from the beginning of the alphabet a, b, c, \dots . Anyway since the degrees play an ordinal role only, they could be replaced by the values in any linearly ordered scale.

The basic inference rule in possibilistic logic put in clausal form

¹ CRIL-CNRS, Université d'Artois, rue Jean Souvraz 62307 Lens Cedex, France. email: benferhat@cril.univ-artois.fr

² IRIT (CNRS-UPS), 118, Route de Narbonne 31062 Toulouse Cedex 04, France. email: prade@irit.fr

is the resolution rule: $(\neg p \vee q, a); (p \vee r, b) \vdash (q \vee r, \min(a, b))$. Classical resolution is retrieved when all the degrees are equal to 1.

Definition 1 Let $\Sigma = \{(p_i, a_i) : i = 1, n\}$ be a possibilistic knowledge base. The level of inconsistency of Σ is defined as:

$$\text{Inc}(\Sigma) = \max\{a : \Sigma_a \vdash \perp\}$$

(by convention $\max(\emptyset) = 0$), where :

$$\Sigma_a = \{p_i : (p_i, a_i) \in \Sigma, \text{ and } a_i \geq a\}.$$

It can be shown that $\text{Inc}(\Sigma) = 0$ iff $\Sigma^* = \{p_i : (p_i, a_i) \in \Sigma\}$ is consistent in the usual sense.

Refutation can be easily extended to possibilistic logic. Proving (p, a) from Σ amounts to adding $(\neg p, 1)$, put in clausal form, to Σ , and using the above rule repeatedly until getting $\Sigma \cup \{(\neg p, 1)\} \vdash (\perp, a)$. Clearly, we are interested here in getting the empty clause \perp with the greatest possible degree or level, i.e., $\text{Inc}(\Sigma \cup \{(\neg p, 1)\}) \geq a$. Indeed, the conclusion (p, a) is valid only if $a > \text{Inc}(\Sigma)$. More formally, the following defines the possibilistic inference:

Definition 2 Let Σ be a possibilistic knowledge base, and p be a propositional formula. Then :

- p is a possibilistic consequence of Σ , denoted by $\Sigma \models_{\pi} p$, iff $\text{Inc}(\Sigma \cup \{(\neg p, 1)\}) > \text{Inc}(\Sigma)$.
- p is a possibilistic consequence of Σ to degree a , also denoted by $\Sigma \models_{\pi} (p, a)$, iff $\text{Inc}(\Sigma \cup \{\neg p\}) > \text{Inc}(\Sigma)$ and $a = \text{Inc}(\Sigma \cup \{\neg p\})$.

Thus inferring from Σ inconsistent is equivalent to infer from the consistent subbase $\{p_i : (p_i, a_i) \in \Sigma, \text{ and } a_i > a\}$. The following illustrative example is used in the whole paper.

Example 1 Let $\Sigma = \{(\neg q \vee r, .8), (q, .6), (e, .6), (\neg r, .5), (q, .3)\}$. We have: $\text{Inc}(\Sigma) = .5$. Now, let us check if r is a possibilistic consequence of Σ and to what degree. It is enough to compute:

$$\text{Inc}(\Sigma \cup \{\neg r\}) = .6 > \text{Inc}(\Sigma).$$

Hence, r is a possibilistic consequence of Σ and its degree of inference is equal to .6.

Semantic aspects of possibilistic logic, including soundness and completeness results with respect to the above syntactic inference, are presented in [Dubois et al. 1994]. Semantically, a possibilistic knowledge base $\Sigma = \{(p_i, a_i) : i = 1, n\}$ is understood as a complete pre-ordering on the set of interpretations:

$\omega >_{\Sigma} \omega'$ iff $\max\{a_i : (p_i, a_i) \in \Sigma \text{ and } \omega' \not\models p_i\} > \max\{a_j : (p_j, a_j) \in \Sigma \text{ and } \omega' \not\models p_j\}$. Thus ω is all the less plausible as it falsifies formulas of higher degrees.

3 Symbolic encoding of possibilistic knowledge

Let $\Sigma = \{(p_i, a_i) : i = 1, \dots, n\}$ be a standard possibilistic knowledge base. Let $H = \{a_1, \dots, a_n\}$ be the set of numerical degrees or levels in Σ . Each symbol in H takes its value in the interval $[0, 1]$. We assume without loss of generality that $a_1 \geq a_2 \geq \dots \geq a_n$.

The first step in the symbolic encoding of a possibilistic knowledge base is to associate to each numerical degree a_i in the knowledge base a propositional symbol denoted by the corresponding capital letter A_i . We denote by S the set of propositional symbols associated with H (with $S \cap V = \emptyset$). Let L_S be the propositional language built from S using the propositional connectors \wedge, \vee, \neg .

We also need to encode the ordering relation between degrees. A constraint $a \geq b$ is translated into $\neg A \vee B$ in agreement with the fact that a and b are lower bounds (of a necessity measure) and thus a refers to the set of numbers $[a, 1[$ and $[a, 1] \subseteq [b, 1[$ holds iff $a \geq b$. The translation of $a \geq b$ into $\neg A \vee B$ can be read as as "if the situation is at least very abnormal (A), it is at least abnormal (B)" (indeed, the greater a , the more certain p in (p, a) , and the more exceptional a situation where p is false).

If two formulas have the same degree a , they will be associated with the same symbol A . It agrees with the equivalence $\{(p, a), (q, a)\}$ and $\{(p \wedge q, a)\}$ in possibilistic logic.

Definition 3 A total order $a_1 \geq a_2, a_2 \geq a_3, \dots, a_{n-1} \geq a_n$ between numerical degrees present in Σ is encoded by the following set of $(n-1)$ binary clauses: $\{\neg A_i \vee A_{i+1} : i = 1, \dots, n - 1\}$.

Completely certain formulas, such as tautologies, are supposed to have a level equal to $a_0 = 1$. In fact, the corresponding literal A_0 will be equivalent to \perp . Then $\forall i \geq 1, \neg A_0 \vee A_i$ holds. As suggested in the introduction, the idea is to manipulate numerical degrees as formulas [Benferhat and Prade2005]. Thus, a possibilistic formula (p, a) is associated with the classical clause $p \vee A$ where A means something as "the situation is A -abnormal". Thus $p \vee A$ means p is true or the situation is abnormal. Note that $p \vee A_0 \equiv p$.

The following definition gives the propositional logic encoding of possibilistic knowledge base:

Definition 4 Let $\Sigma = \{(p_i, a_i) : i = 1, n\}$ be a possibilistic knowledge base. Let A_i be a propositional symbol associated with a_i . Then the propositional base associated with Σ , denoted by K_{Σ} , is defined by :

$$K_{\Sigma} = \{p_i \vee A_i : (p_i, a_i) \in \Sigma \text{ and } A_i \text{ is associated with } a_i\} \\ \cup \{\neg A_i \vee A_{i+1} : i = 1, \dots, n - 1\}.$$

As can be seen from definition 4, the size of K_{Σ} is exactly the one of Σ increased by $n - 1$ binary clauses, if there are n uncertainty levels used. So the cost of this rewriting is very low.

On our running example, this rewriting gives:

Example 2 Let $\Sigma = \{(\neg q \vee r, .8), (q, .6), (e, .6), (\neg r, .5), (q, .3)\}$.

Let A, B, C, D be four propositional (representing symbolic degrees) associated respectively with the four degrees present in the possibilistic knowledge base, namely : .8, .6, .5, .3.

Using the above definition, the propositional knowledge base associated with the knowledge base Σ is :

$$K_{\Sigma} = \{A \vee \neg q \vee r, B \vee q, B \vee e, C \vee \neg r, D \vee q, \neg A \vee B, \neg B \vee C, \neg C \vee D\}.$$

The three last binary clauses are used to encode the facts that the degree associated with A is greater than B , the one of B is greater than the one of C , and the one of C is greater than the one of D .

It is easy to check that the resolution rule now reads $\neg p \vee q \vee A, p \vee r \vee B \vdash q \vee r \vee A \vee B$, and $\min(a, b)$ translates into $A \vee B$ with $A \vee B \equiv A$ if $b \geq a = \min(a, b)$ (and indeed $\neg B \vee A, A \vee B \vdash A$).

4 A refresher on forgetting variables

This section recalls the notion of forgetting variables, which are very useful for characterizing possibilistic inferences (see for instance [Lang et al. 2003, Darwiche and Marquis2004] for more details on forgetting variables). Forgetting a variable p from a set of propositional formulas K comes down to remove any reference of p in K .

Definition 5 Let p be a propositional symbol of V . Then :

$$\text{ForgetVariable}(K, p) = K_{p=\perp} \vee K_{p=\top}$$

$K_{p=\perp}$ (resp. $K_{p=\top}$) is the knowledge base obtained from K by replacing p by false (resp. true). To forget a set of variables, we forget variable by variable, namely if X denotes a set of variables, then: $\text{ForgetVariable}(K, X) = \text{ForgetVariable}(\text{ForgetVariable}(K, p), X - \{p\})$.

It is also possible to only forget literals (atoms or negated atoms):

Definition 6 Let l be a literal. Then :

$$\text{ForgetLiteral}(K, l) = K_{l=\top} \vee (\neg l \wedge K)$$

Some properties of ForgetVariable ([Darwiche and Marquis2004], [Lang et al.2003]), viewing a base as a conjunct of its formulas are:

- (1) $\text{ForgetVariable}(p \vee q, X) = \text{ForgetVariable}(p, X) \vee \text{ForgetVariable}(q, X)$.
- (2) if q does not contain any variable of X , then $\text{ForgetVariable}(p \wedge q, X) = q \wedge \text{ForgetVariable}(p, X)$

ForgetLiteral satisfies (1) and (2), which is enough for the purpose of the paper. The computation of forgetting variables can be efficiently achieved if a propositional knowledge base is in a form such as DNF (disjunctive normal form) or d-DNNF forms. Indeed, forgetting a variable in a DNF amounts to forget it in each term, and forgetting it in a term amounts just to suppress the term. This clearly shows that this is polynomial in time. A similar procedure applies as well to d-DNNF format. This format known as Deterministic, Decomposable Negation Normal Form, which has been proposed recently [Darwiche2004], is a compact format, and has allowed the computation of generally intractable logical queries in time polynomial in the form size. An algorithm has been presented in [Darwiche2004] for compiling Conjunctive Normal Forms into d-DNNF directly. Our approach can clearly take advantage of this format as well.

In the following, we denote $\text{DNF}(K)$ the result of putting K under DNF form. It is represented as a unique formula.

5 Characterising plausible inferences

This section proposes a characterisation of plausible inference using forgetting variables. We first provide a symbolic computation of the inconsistency degree of a knowledge base, then we present some propositions that characterize the compiled possibilistic knowledge base.

5.1 A symbolic computation of inconsistency degrees

This section presents the characterization of the inconsistency degree of Σ using forgetting variables on K_Σ . We first start with the case where Σ is consistent. This is stated by the following proposition:

Proposition 1 Let Σ be a possibilistic knowledge base, and K_Σ be the propositional knowledge base associated with Σ using definition 4. Let NegS be the set of negative literals in K_Σ issued from S . Let $F = \text{ForgetVariable}(K_\Sigma, V)$. Then Σ is consistent if and only if $\text{ForgetLiteral}(F, \text{NegS})$ is a tautology.

Assume that Σ is consistent. The idea of the proof is first to note that $\{A_1 \vee p_1, \dots, A_n \vee p_n\}$ is equivalent to :

$$\bigvee_{I \subseteq \{1, \dots, n\}} (\wedge_{i \in I} A_i) (\wedge_{j \in \text{complement}(I)} p_j),$$

where $\text{complement}(I)$ is the set of elements in $\{1, \dots, n\}$ that are not in I .

In particular, this equivalent form of $\{A_1 \vee p_1, \dots, A_n \vee p_n\}$ contains the term $p_1 \wedge \dots \wedge p_n$. This also means that the equivalent form of Σ contains the term $\neg A_1 \wedge \dots \wedge \neg A_{n-1} \wedge p_1 \wedge \dots \wedge p_n$, which is consistent. Hence forgetting V and negated literals from this term leads to a tautology. Hence forgetting forgetting V and negated literals from K_Σ also leads to a tautology. The converse can also be shown in a similar way.

Now, let us analyse the case where Σ is inconsistent. The following proposition provides the characterisation:

Proposition 2 Let Σ be a possibilistic knowledge base, and K_Σ be a propositional knowledge base associated with Σ using definition 4. Let NegS be the set of negative literals in K_Σ issued from S . Let $F = \text{ForgetVariable}(K_\Sigma, V)$. Then Σ is inconsistent to a degree a_i if and only if $\text{ForgetLiteral}(F, \text{NegS})$ is equivalent to $A_i \wedge \dots \wedge A_n$.

The idea of the proof is the following: if Σ is inconsistent to a degree a_i , then this means that $\{p_1, \dots, p_i\}$ is inconsistent. Hence, $\{A_1 \vee p_1, \dots, A_i \vee p_i\}$ implies $\{A_1 \vee \dots \vee A_i\}$. From $\{A_1 \vee \dots \vee A_i\}$ and $\{\neg A_1 \vee A_2, \dots, \neg A_{i-1} \vee A_i\}$ we conclude A_i . And from A_i and $\{\neg A_i \vee A_{i+1}, \dots, \neg A_{n-1} \vee A_n\}$ we conclude $A_i \wedge \dots \wedge A_n$. Therefore, all formulas of the form $A_j \vee p_j$ for $j \geq i$ can be removed from K_Σ . And K_Σ is equivalent to : $\{\neg A_1 \vee A_2, \dots, \neg A_{i-2} \vee A_{i-1}, A_1 \vee p_1, \dots, A_{i-1} \vee p_{i-1}, A_i, \dots, A_n\}$.

This knowledge base is consistent. Hence, forgetting variables of V and negated literals of S leads to $A_i \dots A_n$.

Example 3 Let us consider again our example, where we have :

$\Sigma = \{(\neg q \vee r, .8), (q, .6), (e, .6), (\neg r, .5), (q, .3)\}$, and,
 $K_\Sigma = \{A \vee \neg q \vee r, B \vee q, B \vee e, C \vee \neg r, D \vee q, \neg A \vee B, \neg B \vee C, \neg C \vee D\}$.

We already showed that Σ is inconsistent and its inconsistency degree is equal to .5. Let us show that Forgetting variables of V and negative literals of S in K_Σ is equivalent to $C \wedge D$. Remember that the symbols A, B, C, D are associated respectively with the degrees .8, .6, .5, .3.

Note that $A \vee \neg q \vee r, B \vee q$ implies $A \vee r \vee B$. Moreover, $A \vee r \vee B$ and $C \vee \neg r$ implies $A \vee B \vee C$. Lastly, $A \vee B \vee C$ and $\{\neg A \vee B, \neg B \vee C\}$ gives C . Again : C and $\neg C \vee D$ gives D .

Therefore, K_Σ is equivalent to :

$$K_\Sigma \equiv \{A \vee \neg q \vee r, B \vee q, B \vee e, \neg A \vee B, C, D\}.$$

Let us compute the DNF form of K_Σ , we get:

$$\text{DNF}(K_\Sigma) \equiv (\neg A \wedge r \wedge C \wedge D \wedge q \wedge e) \vee (A \wedge B \wedge C \wedge D) \vee (\neg q \wedge B \wedge C \wedge D) \vee (r \wedge B \wedge C \wedge D)$$

Let us now forget symbols of V but also negative literals of S .

- Forgetting $\{r\}$ gives :

$$\text{ForgetVariable}(K_\Sigma, \{r\}) \equiv (\neg A \wedge C \wedge D \wedge q \wedge e) \vee (B \wedge C \wedge D).$$

- Forgetting $\{r, q\}$ gives :

$$\text{ForgetVariable}(K_\Sigma, \{r, q\}) \equiv (\neg A \wedge C \wedge D \wedge e) \vee (B \wedge C \wedge D).$$

- Forgetting $\{r, q, e\}$ gives :

$$\text{ForgetVariable}(K_\Sigma, \{r, q, e\}) \equiv (\neg A \wedge C \wedge D) \vee (B \wedge C \wedge D).$$

- Lastly, forgetting negative literals of S gives :

$$\begin{aligned} \text{ForgetLiteral}(\text{ForgetVariable}(K_\Sigma, \{r, q, e\}), \{\neg A, \neg B, \neg C\}) \\ \equiv (C \wedge D) \vee (B \wedge C \wedge D) \equiv C \wedge D. \end{aligned}$$

Hence, we get the expected result.

5.2 Characterizing compiled possibilistic knowledge bases

This section characterises the compiled possibilistic knowledge bases. More precisely, given a possibilistic knowledge base, we are interested in characterizing a propositional knowledge base, denoted by $\text{Compiled}(\Sigma)$ such that:

$$\Sigma \models_{\pi} p \text{ iff } \text{Compiled}(\Sigma) \vdash p.$$

Of course, we require that the inference from $\text{Compiled}(\Sigma)$ should be efficient (polynomial).

Again we start with the case where Σ is consistent. This is stated by the following proposition.

Proposition 3 *Let Σ be a consistent possibilistic knowledge base, and K_{Σ} be a propositional knowledge base associated with Σ using definition 4. Then: $\text{Compiled}(K_{\Sigma}) = \text{ForgetVariable}(\neg A_1 \wedge \dots \wedge \neg A_n \wedge \text{DNF}(K_{\Sigma}), S)$.*

The idea of the proof is quite immediate. Note first that $\text{DNF}(K_{\Sigma})$ contains a term $\neg A_1 \wedge \dots \wedge \neg A_n \wedge p_1 \wedge \dots \wedge p_n$. All other terms contain at least a positive symbol of S . Hence, adding $\neg A_1 \wedge \dots \wedge \neg A_n$ to $\text{DNF}(K_{\Sigma})$ is equivalent to the term : $\neg A_1 \wedge \dots \wedge \neg A_n \wedge p_1 \wedge \dots \wedge p_n$, since all other terms will become inconsistent.

The following proposition gives the case where Σ is inconsistent.

Proposition 4 *Let Σ be an inconsistent possibilistic knowledge base, and K_{Σ} be a propositional knowledge base associated with Σ using definition 2. Assume that Σ is consistent to a degree a_i . Then: $\text{Compiled}(K_{\Sigma}) = \text{ForgetVariable}(\neg A_1 \wedge \dots \wedge \neg A_{i-1} \wedge \text{DNF}(K_{\Sigma}), S)$.*

Example 4 Let us consider again our example.

We recall that :

$$\begin{aligned} \text{DNF}(K_{\Sigma}) &\equiv (\neg A \wedge r \wedge C \wedge D \wedge q \wedge e) \vee (A \wedge B \wedge C \wedge D) \\ &\vee (\neg q \wedge B \wedge C \wedge D) \vee (r \wedge B \wedge C \wedge D) \end{aligned}$$

Let us compute

$$\text{Compiled}(K_{\Sigma}) \equiv \text{ForgetVariable}(\neg A \wedge \neg B \wedge \text{DNF}(K_{\Sigma}), S).$$

We have $\neg A \wedge \neg B \wedge \text{DNF}(K_{\Sigma})$ is equivalent to : $(\neg A \wedge \neg B \wedge r \wedge C \wedge D \wedge q \wedge e)$

Hence, forgetting variables of S gives :

$$\text{Compiled}(K_{\Sigma}) \equiv r \wedge q \wedge e.$$

6 Procedure for computing compiled possibilistic base

The above propositions are very important since they provide an efficient way to draw possibilistic conclusions from Σ . The procedure for checking if a proposition p can be derived from Σ can be described as follows:

The following proposition shows that the compiled knowledge base obtained at step 6 allows us to recover all possibilistic consequences of Σ .

Procedure 1: Computation of the compiled possibilistic base

Data: A possibilistic knowledge base Σ .

Result: A compiled base $\text{Compiled}(\Sigma)$

begin

Step 1: Transform Σ into K_{Σ}

Step 2: Put K_{Σ} into a DNF (or d-DNNF) form

Step 3 Forget variables of V from K_{Σ}

Step 4 Forget negated atoms of S from K_{Σ} .

Step 5 Compute inconsistency degree A_i

Step 6

if Σ is consistent then

$\text{Compiled}(\Sigma) = \text{ForgetVariable}(\neg A_1 \wedge \dots \wedge \neg A_n \wedge \text{DNF}(K_{\Sigma}), S)$

else

/* Σ is inconsistent to a degree a_i

$\text{Compiled}(\Sigma) = \text{ForgetVariable}(\neg A_1 \wedge \dots \wedge \neg A_{i-1} \wedge \text{DNF}(K_{\Sigma}), S)$

end

Proposition 5 *Let $\text{Compiled}(\Sigma)$ be the propositional base obtained at end of step 6 of the above algorithm. p is a possibilistic consequence of Σ iff $\text{Compiled}(\Sigma) \vdash p$.*

The proof is immediate using Propositions 1-4.

Example 5 Let us consider again our example. From previous computations we have:

$$\text{Compiled}(K_{\Sigma}) \equiv r \wedge q \wedge e$$

We can check that for all propositional formula p , p is a possibilistic consequence of Σ if and only if p is classical consequence of $\text{compiled}(K_{\Sigma})$, with the advantage that $\text{compiled}(K_{\Sigma})$ is in DNF form, hence the inference is polynomial. For instance, we have already shown (example 1) that r is a possibilistic consequence of Σ . This obviously follows from $\text{compiled}(K_{\Sigma})$.

Proposition 6 Steps 3–6 of the above algorithm are achieved in a polynomial time, with respect to the number of terms (or conjuncts) in the compiled base (which is in DNF form).

Indeed, steps 3–4 can be obtained in a linear time, since the knowledge bases are in DNF form from which forgetting operations are polynomials [Darwiche and Marquis 2004]. Step 4 which concerns the computation of inconsistency degree can also be done in a polynomial time thanks to Propositions 1 and 2. Indeed, it is enough to check if $A_1 \wedge \dots \wedge A_n$ is equivalent $\text{ForgetLiteral}(F, \text{Neg}S)$ for $i = 1, \dots, n$ with $F = \text{ForgetVariable}(K_{\Sigma}, V)$.

7 Computing weighted consequences

This section proposes an algorithm to compute the degree of inference associated with a propositional formula p , once Procedure 1 has been used for compiling Σ and establishing p as a consequence of Σ . First, we need the following result:

Proposition 7 *Let p be a propositional formula that is a consequence of $\text{Compiled}(K_{\Sigma})$. Then: $\Sigma \models_{\pi} (p_i, a_i)$ iff*

- $\text{ForgetVariable}(\neg A_1 \wedge \dots \wedge \neg A_i \wedge A_{i+1} \dots \wedge A_n \wedge \text{DNF}(K_\Sigma), S) \vdash p_i$
- $\forall j = 1, \dots, i-1 :$
 $\text{ForgetVariable}(\neg A_1 \wedge \dots \wedge \neg A_j \wedge A_{j+1} \dots \wedge A_n \wedge \text{DNF}(K_\Sigma), S) \not\vdash p_i$

The idea of the proof is that when we add a positive literal A_i then all propositional formulas of levels $a_k \leq a_i$ are ignored. Indeed, we have A_i and $\{\neg A_i \vee A_{i+1}, \dots, \neg A_{n-1} \vee A_n\}$ implies $\{A_{i+1}, \dots, A_n\}$. Hence the set of formulas $\{A_{i+1} \vee p_{i+1}, \dots, A_n \vee p_n\}$ will be subsumed by $\{A_{i+1}, \dots, A_n\}$.

Given this proposition, the procedure for computing the degree associated with a possibilistic consequence is rather straightforward. It works iteratively, thanks to Proposition 7, since the level of p corresponds to the first A_i such that p can be proved from formulas with levels greater than a_i . So at the beginning, except those with level 1 (encoded by A_0) such as tautologies, are ignored. Then, adding $\neg A_i$ makes formulas in the corresponding stratum active in the inference process. Clearly, the procedure remains polynomial.

Procedure 2: Computing the symbolic weight associated with conclusions

Data: $F = \text{DNF}(K_\Sigma)$

A propositional formula p which is consequence of $\text{Compiled}(\Sigma)$

Result: A symbolic degree associated with p

begin

```

    k ← 0 ;
    X ← {A1, ..., An} ;
    while  $\text{ForgetVariable}(X \cup F, S) \not\vdash p$  do
        k ← k + 1;
        X ← X - {Ak} ;
        X ← X ∪ {¬Ak} ;
    return Ak
end

```

Example 6 Let us consider again our example. We already checked that r is a possibilistic consequence of Σ to a degree .6. We also checked that $\text{Compiled}(K_\Sigma) \vdash r$. Let us apply the above procedure to get the symbolic degree associated with r .

We recall that :

$$F = \text{DNF}(K_\Sigma) \equiv (\neg A \wedge r \wedge C \wedge D \wedge q \wedge e) (A \wedge B \wedge C \wedge D) \vee (\neg q \wedge B \wedge C \wedge D) \vee (r \wedge B \wedge C \wedge D)$$

- At the beginning, we have $k=0$ and $X=\{A, B, C, D\}$. Then we can check that $\text{ForgetVariable}(X \cup F, S)$ is equivalent to a tautology.
- At the next iteration, we have $k=1$ and $X=\{\neg A, B, C, D\}$. Then $X \cup F$ is equivalent to:
 $(\neg A \wedge r \wedge C \wedge B \wedge D \wedge q \wedge e)$
 $\vee (\neg A \wedge \neg q \wedge B \wedge C \wedge D) \vee (\neg A \wedge r \wedge B \wedge C \wedge D)$

Then $\text{ForgetVariable}(X \cup F, S)$ is equivalent to $a: \neg q \vee r$ from which r cannot be derived.

- At the second iteration, we have $k=1$ and $X=\{\neg A, \neg B, C, D\}$. Then $X \cup F$ is equivalent to:
 $(\neg A \wedge \neg B \wedge r \wedge C \wedge D \wedge q \wedge e)$
 $\vee (\neg A \wedge \neg B \wedge \neg q \wedge C \wedge D) \vee (\neg A \wedge \neg B \wedge r \wedge C \wedge D)$
- Then $\text{ForgetVariable}(X \cup F, S)$ is equivalent to $q \wedge r$ from which r can be derived. Hence, the symbolic degree associated with r is B , which is indeed associated with the degree 0.6.

Proposition 8 The above algorithm, which computes the degree associated with a possibilistic conclusion, is achieved in a polynomial time, with respect to the number of terms (or conjuncts) in the compiled base (which is in DNF form).

8 Conclusion

The paper has proposed an approach for handling possibilistic inference (including the computation of the formula levels) in polynomial time thanks to a compilation procedure that takes advantage of a propositional treatment of formula levels, and to the use of a forgetting variable procedure. Note also that the proposed compilation procedure cannot be derived from the one used by [Darwiche and Marquis2004] for penalty logic, which relies on summations and is quantitative in nature, while possibilistic logic is qualitative and uses max and min operations. Moreover, the results are also relevant for processing other inconsistency-tolerant inferences that extend possibilistic inference and are also based on the computation of inconsistency levels [Benferhat *et al.* 1999].

A line for further research is the handling of hypothetical reasoning in this framework. Indeed, by moving literals in the level slots, namely the possibilistic formula $(\neg p \vee q, a)$ is equivalent to $(q, \min(P, a))$ where $P = 1$ or 0 depending if p is assumed true or false, one can develop a possibilistic counterpart of ATMS [de Kleer1986]. It would be interesting to combine the ideas presented here, the handling of more general symbolic levels (as in [Benferhat and Prade2005]), and consequence-finding algorithms (e.g. [Inoue1991]) in that perspective.

Improving Bound Propagation

Bozhena Biduk¹ and Rina Dechter²

Abstract. This paper extends previously proposed bound propagation algorithm [11] for computing lower and upper bounds on posterior marginals in Bayesian networks. We improve the bound propagation scheme by taking advantage of the directionality in Bayesian networks and applying the notion of relevant subnetwork. We also propose an approximation scheme for the linear optimization subproblems. We demonstrate empirically that while the resulting bounds loose some precision, we achieve 10-100 times speedup compared to original bound propagation using a simplex solver.

1 Introduction

Using Bayesian networks to model the problems arising in practical applications requires answering queries regarding the probability of an outcome given observations, namely, computing posterior marginals. Computing exact posteriors is NP-hard. Computing bounds on posterior marginals is a special case of approximating posterior marginals with the desired degree of precision which is also NP-hard [6, 2]. Previously proposed methods include bounded conditioning [7], search with conflict-counting [14], "context-specific" bounds [15], *large deviation bounds* for layered networks [8, 9], bounds for goal directed queries [12], and a scheme bounding exact computation in bucket elimination [10]. None of the methods dominates the rest as they offer different accuracy and speed trade-offs.

We focus on a recently proposed **bound propagation** (*BdP*) algorithm [11], applicable to both Bayesian networks and Markov random fields. The algorithm iteratively solves a linear optimization problem for each variable such that the minimum and maximum of the objective function correspond to lower and upper bounds on the variable's posterior marginals. The lower and upper bounds are initialized to 0 and 1 respectively. When algorithm solves minimization/maximization LP problem, the lower and upper bounds are updated. The bounds are updated repeatedly until they converge. The performance of the scheme was demonstrated in [11] on the example of Alarm network, Ising grid, and regular bi-partite graphs.

The performance of bound propagation is tied to the network structure, namely, the Markov blanket of each variable. Its computation time increases exponentially with Markov blanket size. Hence, it is well suited for problems with regular network structure, having large induced width but bounded Markov blanket size (e.g., grids).

In our work here, we improve the performance of *BdP* by exploiting the global network properties, namely, restricting the Markov blanket of a node to its relevant subnetwork, resulting in substantial gains in accuracy and speed. Further, since bound propagation yields linear optimization subproblems that fall into a category of fractional packing and covering problems, known to be hard for simplex

method, we propose a fast approximate algorithm for solving the LP problems without using simplex method. Although many schemes have been developed for approximately solving linear programming problems [5], they usually solve packing-only or covering-only problems and do not include the additional constraints present in bound propagation. Hence, we propose our own solution obtained by relaxing the original problem until it can be solved exactly using a greedy algorithm. We investigate empirically the trade-offs in bounds interval length and time.

2 Background

2.1 Belief Networks

We use upper case letters without subscripts, such as \bar{X} , to denote sets of variables and an upper case letter with a subscript, such as X_i , to denote a single variable. We use a lower case letter with a subscript, such as x_i , to denote an instantiated variable. $\mathcal{D}(X_i)$ denotes the domain of the variable X_i . We will use \bar{x} to denote an instantiation of a set of variables $\bar{x} = \{x_1, \dots, x_i, \dots\}$ and $\bar{x}_{-i} = \bar{x} \setminus x_i$ to denote \bar{x} with element x_i removed.

Definition 1 (belief networks) Let $\bar{X} = \{X_1, \dots, X_n\}$ be a set of random variables over multi-valued domains $\mathcal{D}(X_1), \dots, \mathcal{D}(X_n)$. A belief network (BN) is a pair (G, P) where G is a directed acyclic graph on \bar{X} and $P = \{P(X_i|pa_i)\}$ is the set of conditional probability tables (CPTs) associated with each X_i . The parents of a variable X_i together with its children and parents of its children form a Markov blanket ma_i of node X_i . A network is **singly-connected** (also called a **poly-tree**), if its underlying undirected graph has no cycles. The queries over singly-connected network can be processed in time linear in the size of the network [13].

2.2 Bound Propagation

Bound propagation (*BdP*) [11] is an iterative algorithm that utilizes the local network structure to formulate a linear optimization problem. For each variable $X_i \in \bar{X}$ the minimum and maximum of the objective function correspond to the upper and lower bounds on posterior marginals $P(x_i|e)$. Let $\bar{Y} = \{Y_1, \dots, Y_k\}$ denote the Markov blanket of node X_i . The idea is to compute posterior marginals using decomposition:

$$P(x_i|e) = \sum_{\bar{y}} P(x_i|\bar{y}, e)P(\bar{y}|e) \quad (1)$$

Given its Markov blanket, the probability distribution of X_i is independent from the rest of the variables in the network so that $P(x_i|\bar{y}, e) = P(x_i|\bar{y})$. Hence, we can rewrite Eq. (1) as:

$$P(x_i|e) = \sum_{\bar{y}} P(x_i|\bar{y})P(\bar{y}|e) \quad (2)$$

¹ Donald Bren School of Information and Computer Science, University Of California Irvine, CA 92697-3425, USA, email: bbidyuk@ics.uci.edu

² email: dechter@ics.uci.edu

Here, $P(x_i|\bar{y})$ is an entry in the probability table of X_i conditioned on the instantiation of variables in its Markov blanket which can be computed as follows [13]:

$$P(x_i|pa_i, \cup_j(ch_j \cup pa_j)) = \alpha P(x_i|pa_i) \prod_j P(ch_j|pa_j)$$

where α is a normalization constant. The probabilities $P(\bar{y}|e)$ are unknown, but we know that the sum of all probabilities equals 1:

$$\sum_{y_1, \dots, y_k} P(y_1, \dots, y_k|e) = 1 \quad (3)$$

Further, $\forall Y_j \in \bar{Y}, \forall y_j \in \mathcal{D}(Y_j), \sum_{\bar{y}_j, Y_j=y_j} P(\bar{y}|e) = P(y_j|e)$. Denoting arbitrary lower and upper bounds on $P(y_j|e)$ by $P^L(y_j|e)$ and $P^U(y_j|e)$ respectively, we can write:

$$P^L(y_j|e) \leq \sum_{y \setminus y_j, Y_j=y_j} P(y_1, \dots, y_k|e) \leq P^U(y_j|e) \quad (4)$$

Hence, for each variable X_i , we have a linear optimization problem with the objective function $P(x_i|e)$ defined in Eq. (2) and constraints defined in Eq. (3) (sum-to-1 constraint) and Eq. (4). For each $\bar{y} \in \mathcal{D}(\bar{Y})$, the $P(x_i|\bar{y})$ is an objective function coefficient and $P(\bar{y}|e)$ is a variable. The number of variables is exponential in the size of the Markov blanket. The number of constraints equals $1 + \sum_j |\mathcal{D}(Y_j)|$ since there are $|\mathcal{D}(Y_j)|$ constraints for each Y_j .

Example 1 Let $ma_i = \{A, B\}$ where $\mathcal{D}(A) = \{0, 1\}$ and $\mathcal{D}(B) = \{0, 1, 2\}$. Let $P(x_i|A, B)$ be defined as follows: $P(x_i|0, 0) = 0.1$, $P(x_i|0, 1) = 0.2$, $P(x_i|0, 2) = 0.3$, $P(x_i|1, 0) = 0.4$, $P(x_i|1, 1) = 0.5$, and $P(x_i|1, 2) = 0.6$. Then, denoting $P_{pq} = P(x_i|p, q)$, the objective function of the LP problem for x_i can be defined as follows:

$$f = 0.1P_{00} + 0.2P_{01} + 0.3P_{02} + 0.4P_{10} + 0.5P_{11} + 0.6P_{12}$$

$$\text{s.t. } P_{00} + P_{01} + P_{02} + P_{10} + P_{11} + P_{12} = 1$$

$$\begin{aligned} P^L(a=0|e) &\leq P_{00} + P_{01} + P_{02} \leq P^U(a=0|e) \\ P^L(a=1|e) &\leq P_{10} + P_{11} + P_{12} \leq P^U(a=1|e) \\ P^L(b=0|e) &\leq P_{00} + P_{10} \leq P^U(b=0|e) \\ P^L(b=1|e) &\leq P_{01} + P_{11} \leq P^U(b=1|e) \\ P^L(b=2|e) &\leq P_{02} + P_{12} \leq P^U(b=2|e) \end{aligned}$$

Initializing all bounds $P^L(X_i|e)$ and $P^U(X_i|e)$ to 0 and 1, the algorithm solves the linear minimization and maximization problems for each value $x_i \in \mathcal{D}(X_i)$ of each variable $X_i \in \bar{X}$ and updates the bounds. With every iteration, the bounds get closer to the posterior marginals or do not change. The process is iterated until convergence. The variable processing order does not affect the results although it may affect the number of iterations needed to converge.

Since the number of variables in the LP problems grows exponentially with the size of the Markov blanket, algorithm *BdP* is feasible only for networks having bounded Markov blanket size e.g. Ising grid an regular two-layer networks explored in [11]. Applied to Alarm network without evidence, *BdP* obtained small bounds interval for several nodes but could not obtain good bounds for root nodes 11, 12, 13, 14, although their relative subnetworks are singly-connected and, hence, the posteriors equal the priors. The latter shows the weakness of *BdP* in that it may not compute tight bounds even in a singly-connected network.

3 Improving *BdP* Performance

In this section we describe how to improve the performance of *BdP* by exploiting global network structure and how to obtain quick bounds using a simple greedy algorithm instead of a simplex solver.

3.1 Exploiting Network Structure

The performance of bound propagation can be improved also by identifying the irrelevant child nodes and restricting the Markov blanket of X_i to its relevant subnetwork.

Definition 2 (Relevant Subnetwork) An irrelevant (barren) node of a node X_i is a child node Y_j that is not observed and does not have observed descendants. The relevant subnetwork of X_i is a subnetwork obtained by removing all irrelevant nodes in the network.

Removing irrelevant nodes (and their parents) from Markov blanket whenever possible yields a smaller effective Markov blanket and, thus, a smaller LP problem with fewer variables. Also, if the relevant subnetwork of node X_i is singly-connected then its posteriors should be computed exactly and fixed.

We denote as *BdP+* the bound propagation algorithm that takes advantage of the network structure as described above. Although proposed improvements are straight forward, the gains in accuracy and speed are significant in practice, as we show empirically.

3.2 Managing Resources

In order to limit *BdP* demands for memory and time, we can bound the maximum length of the Markov conditional probability table by a constant k and, thus, the maximum number of variables in a linear optimization problem. For variables, whose Markov blanket size exceeds the maximum, their lower and upper bound values remain equal to their input values (usually, 0 and 1). The resulting algorithm *BdP(k)* is then parametrized by k .

Since the bounds of variable X_i are used to define constraints of the neighboring variables, fixing the bounds of X_i to their input values will result in a more relaxed LP formulation. Thus, the bounds of neighboring nodes are likely to be less tight as well, affecting, in turn, the bounds of their neighbors. Hence, the effect of fixing bounds of X_i can propagate throughout the network resulting in the overall larger average bounds interval. As k increases, the computation time will increase, but the bounds will become tighter.

3.3 Approximating the LP in Bound Propagation

In this section, we propose an algorithm for solving the linear optimization problem approximately, instead of using a simplex solver.

In large Bayesian networks, we may need to solve linear optimization problems thousands of times. Using the simplex method then becomes impractical time-wise. In general, the linear optimize problems which are formulated in bound propagation fall into a class of linear packing and covering problems which are known to be especially challenging for the simplex method [5]. The standard fractional packing and covering problem can be defined as follows:

$$\min c^T \bar{x} \quad (5)$$

$$A\bar{x} \geq l \quad (6)$$

$$B\bar{x} \leq m \quad (7)$$

$$x \geq 0 \quad (8)$$

Without Eq. (7), it is a **fractional covering** problem. Without Eq. (6), it is a **fractional packing** problem. The BdP (and $BdP+$) linear optimization problems have both packing and covering components with the special properties that $A=B$ and A is a zero-one matrix. Still, the problem remains hard. Existing approximate algorithms solve either packing or covering problem, but not both [5]. The LP formulation in BdP is complicated further by having an additional sum-to-1 constraint. Hence, we resort to solving a relaxed problem.

We considered two relaxations of the LP formulation in BdP . First, we relaxed the problem to an instance of a fractional knapsack packing which can be solved exactly in a greedy fashion [16]. In this case, we maintain the sum-to-1 constraint, but drop the lower bound constraints completely and replace the upper bounds on sums of variables with the derived upper bounds on individual variables. Namely, for each variable $P(\bar{y}|e)$ participating in $|Y|$ constraints, we set:

$$P(\bar{y}|e) \leq UB_{\bar{y}} = \min_j P^U(y_j|e) \quad (9)$$

We obtain an optimal solution to the fractional knapsack packing by first ordering the variables by their coefficient (from maximum to minimum for maximization and from minimum to maximum for minimization) and then assigning each variables its maximum value until the sum of all values equals 1. The complexity of the algorithm is $O(n \log n)$, where n is the number of variables, due to the complexity of sorting.

The second relaxation is more constrained. We maintain the sum-to-1 constraint and the lower and upper bound constraint pertaining to one variable in the Markov blanket of X_i . We drop the remaining lower bounds and use remaining upper bounds to set upper bounds on individual variables. Consider the example presented previously with a Markov blanket consisting of two nodes A and B . Maintaining the constraints associated with variable A , the resulting relaxed optimization problem can be expressed as:

$$f = 0.1P_{00} + 0.2P_{01} + 0.3P_{02} + 0.4P_{10} + 0.5P_{11} + 0.5P_{12}$$

$$\text{s.t. } P_{00} + P_{01} + P_{02} + P_{10} + P_{11} + P_{12} = 1$$

$$\begin{aligned} P^L(a=0|e) &\leq P_{00} + P_{01} + P_{02} \leq P^U(a=0|e) \\ P^L(a=1|e) &\leq P_{10} + P_{11} + P_{12} \leq P^U(a=1|e) \\ 0 &\leq P_{00}, P_{10} \leq P^U(b=0|e) \\ 0 &\leq P_{01}, P_{11} \leq P^U(b=1|e) \\ 0 &\leq P_{02}, P_{12} \leq P^U(b=2|e) \end{aligned}$$

The domains of the constraints w.r.t. just one Markov variables Y_j are disjoint. Hence, the problem can be treated as an instance of the fractional packing with multiple knapsacks, each having a separate set of packing materials and an individual capacity bound. If it was not for the sum-to-1 constraint, we could solve each knapsack packing problem independently. Nevertheless, we can show that the problem can be solved optimally by a greedy algorithm.

We describe the idea of the algorithm on the example of maximization problem. Similar to fractional packing with 1 knapsack, we first order nodes by their objective function coefficient value from the largest to smallest. We initialize all node values to 0. Then, we make two passes through the list. The first time, we satisfy all lower bound requirements. Namely, we increment each node value until either its upper bound is reached or the lower bound $L(y_j)$ of the equation in which it participates is satisfied. During a second pass, we increment each variable value until either the variables' upper bound or the upper bound $U(y_j)$ of the equation in which it participates is reached or

the sum of all variables equals 1. Since we cannot predict which variable $Y_j \in Y$ will yield the LP relaxation with the smallest maximum of the objective function, we repeat computation for each $Y_j \in Y$ and pick the smallest maximum of the objective function.

The solution to the minimization problem is the same except nodes are ordered by their objective function coefficient value from smallest to largest. We prove formally that the algorithm finds an optimal solution in [4]. The total complexity is $O(|Y| \cdot n \log n)$, $n = |\mathcal{D}(Y)|$. We call the bound propagation scheme with an approximate LP algorithm as $ABdP+$.

4 Experiments

We compare empirically the performance of the original bound propagation algorithm BdP , modified $BdP+$ that restricts the Markov blanket of a node to its relevant subnetwork, and a modified bound propagation scheme using the approximate algorithm for solving linear programming subproblems, namely, $ABdP+$.

4.1 Methodology

We measure the quality of the bounds via the average length of the interval between lower and upper bound:

$$\bar{I} = \frac{\sum_i \sum_{D(x_i)} (P^U(x_i|e) - P^L(x_i|e))}{\sum_i |D(x_i)|} \quad (10)$$

We compute approximate posterior marginal as the midpoint between lower and upper bound in order to show whether the bounds are well-centered around the posterior marginal $P(x|e)$. Namely:

$$\hat{P}(x|e) = \frac{P^U(x|e) + P^L(x|e)}{2} \quad (11)$$

and then measure average absolute error Δ with respect to $\hat{P}(x|e)$:

$$\Delta = \frac{\sum_i \sum_{D(x_i)} |P(x_i|e) - \hat{P}(x_i|e)|}{\sum_i |D(x_i)|} \quad (12)$$

We control the time and memory of bound propagation by restricting the maximum length k of a conditional probability table over the Markov blanket of a variable. The maximum Markov CPT length tested was $k=2^{19}$ (the size of the CPT with 19 bi-valued variables) when the computation demands exceeded available memory.

We report all results for BdP , $BdP+$, and $ABdP+$ schemes "upon convergence" or after 20 iterations, whichever occurs first, so that the computation time is a function of k and number of iterations needed to converge. We implemented bounds propagation algorithm using simplex solver from COIN-OR libraries [1]. The experiments were conducted on 1.8Ghz CPU with 512 MB RAM.

Our benchmarks are 8 networks from Bayesian Network Repository (<http://www.cs.huji.ac.il/labs/compbio/> Repository/) and 3 networks for pedigree analysis, gen44, gen50, and gen51 (from <http://bioinfo.cs.technion.ac.il/superlink/ExpF.html>). Benchmarks' properties are specified in Table 4.1. In gen44, gen50, and gen51 evidence is pre-defined. In all other benchmarks, the results are averaged over 20 instances of each network instantiated with different evidence. In most networks the evidence variables are selected at random among leaf nodes. In cpcs422b, the evidence is selected at random among all variables.

Table 1. Benchmarks' characteristics: N -number of nodes, w^* -induced width, T_{BE} -exact computation time via bucket elimination.

network	N	w^*	T_{BE}
Alarm	37	4	0.01 sec
cpcs54	54	15	1 sec
cpcs179	179	8	2 sec
cpcs360b	360	21	20 min
cpcs422b	422	22	50 min
gen44	873	N/A	47 min
gen50	547	N/A	>6 hrs
gen51	1218	N/A	> 7 hrs

4.2 Results

4.2.1 BdP vs. BdP+

In Tables 2 and 3 we report the average error, average bounds interval, and computation times for BdP and $BdP+$ as a function of $k=2^m$ for $14 \leq m \leq 19$. Each row corresponds to a set of experiments with a single benchmark with a fixed k . Note that, as k increases, the computation time of both BdP and $BdP+$ increases fast, while the bounds interval decreases only a little.

Table 2. Average error Δ , length of the bounds interval \bar{I} , and computation time for $BdP(k)$ and $BdP+(k)$ in networks without evidence.

	k	BdP(k)			BdP+(k)		
		\bar{I}	Δ	time	\bar{I}	Δ	time

	32768	0.3287	0.1081	80	0.2034	0.0617	74
	65536	0.3171	0.1023	317	0.1815	0.0522	256

$BdP+$ always computes tighter bounds and requires less computation time than BdP . The performance gap is wider in the networks without evidence (Table 2), where the Markov blanket of each node,

restricted to its relevant subnetwork, contains node's parents only and $BdP+$ converges after one iteration when processing nodes in topological order. For the largest benchmark, cpcs422b, with 422 nodes and $w^*=21$, the average bounds interval length is 0.23 for BdP and 0.008 for $BdP+$. At the same time, BdP computations take 190 sec while $BdP+$ only takes 16 sec.

In benchmarks with evidence, reported in Table 3, $BdP+$ computation time increases but its bounds remain superior to BdP . Consider the results for cpcs360b network with 360 nodes and $|E|$ ranging from 11 to 23. For $k=16384$, $BdP+$ computes the average bounds interval of length 0.06 within 15 seconds. BdP average bounds interval equals 0.34 and requires 68 seconds. We observed similar results for other benchmarks.

4.2.2 Approximating LP

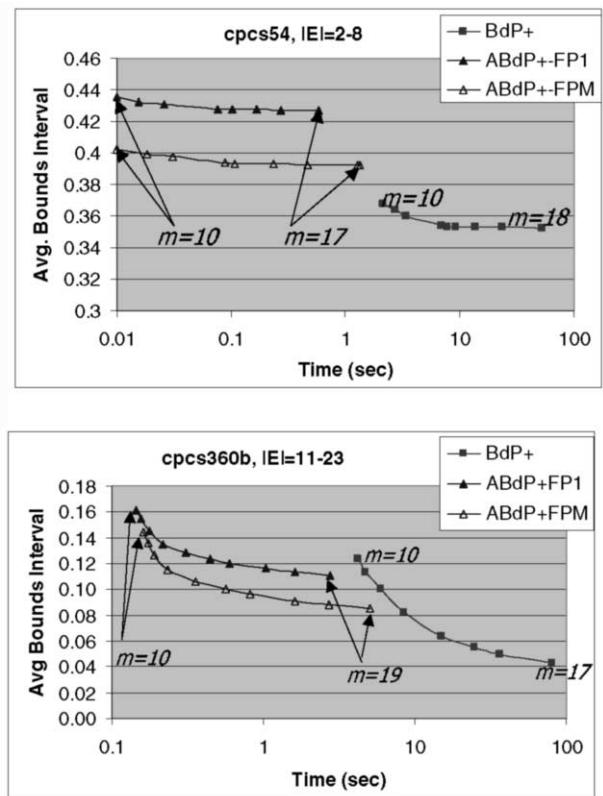

Figure 1. Bounds interval for $BdP+$ and $ABdP+$ optimizing LP by fractional packing with 1 ($ABdP+FP1$) and many ($ABdP+FPM$) knapsacks. Each data point corresponds to a value of input parameter m that bounds the maximum Markov table length $k=2^m$.

We compare the performance of $BdP+$ and $ABdP+$ with two different approximation schemes, $FP1$ and FPM . $FP1$ solves the fractional packing with 1 knapsack; FPM solves the fractional packing and covering problem with multiple knapsacks.

The results shown in Figure 1 for cpcs54 and cpcs360b are typical. The average bounds interval is shown as a function of time which, in turn, depends on the input parameter $k=2^m$. Hence, each point on the graph corresponds to a particular value of m . First, we observe that $ABdP+$ with FPM (denoted $ABdP+FPM$) substantially outperforms $ABdP+$ with $FP1$ (denoted $ABdP+FP1$) in

both benchmarks. *FPM* incurs negligible amount of computation overhead but computes considerably tighter bounds. *BdP+* outperforms both *ABdP+* with enough time, but *ABdP+* is more efficient at the start. For the same k , *BdP+* requires an order of magnitude more time than *ABdP+*. In cpcs54, for $k=2^{10}$, *ABdP+FPM* computes bounds in <0.01 seconds while *BdP+* requires a few seconds. We observe similar result in case of cpcs360b. Roughly, *BdP+* requires as much time to compute bounds for $k=2^{10}$ as *ABdP+FPM* for $k=2^{17}-2^{19}$. As a result, *BdP+* begins to outperform *ABdP+FPM* only after ≈ 2 seconds in cpcs54 and only after 10 seconds in cpcs360b. The overall improvement in *BdP+* bounds over *ABdP+FPM* in cpcs54 is minor; the difference between their average bounds intervals is only about 0.04 which is $\approx 1\%$ of the interval length. In cpcs360b, the *BdP+* bounds interval after 100 seconds is a factor of 2 smaller, but the computation time is an order of magnitude greater.

Table 4. The # of probabilities in each pedigree network (gen44, gen50, gen51) with bounds interval \bar{I} in different ranges, *BdP+* vs. *ABdP+FPM*.

	gen44		gen50		gen51	
	BdP+	ABdP+	BdP+	ABdP+	BdP+	ABdP+
time	54	0.8	66	8.4	140	0.7
$0.5 \leq \bar{I} < 1$	1312	1324	1114	1114	1428	1432
$0.4 \leq \bar{I} < 0.5$	14	6	6	6	36	36
$0.3 \leq \bar{I} < 0.4$	6	2	8	10	2	0
$0.2 \leq \bar{I} < 0.3$	2	2	6	4	4	2
$0.1 \leq \bar{I} < 0.2$	10	10	6	6	6	6
$0.01 \leq \bar{I} < 0.1$	0	0	10	10	12	12
$0.001 \leq \bar{I} < 0.01$	0	0	2	2	5	5
$0 \leq \bar{I} < 0.001$	14	14	18	18	174	174

In pedigree networks, both schemes performed poorly computing $\bar{I} < 0.5$ only for 5-15% of posteriors using maximum $k=2^{19}$. Yet, importantly, *ABdP+* obtained similar results to *BdP+* in a fraction of time. Table 4 specifies the number of posterior marginals with bounds in different ranges obtained by both algorithms. In gen44, both *BdP+* and *ABdP+FPM* computed $\bar{I} \in [0, 0.001]$ for 14 values and $\bar{I} \in [0.1, 0.2]$ for another 10 values. However, *BdP+* requires 54 sec whereas *ABdP+FPM* takes 0.8 sec. In gen50, the results only differ in that 2 values with *BdP+* bounds interval in range $[0.2, 0.3]$ have *ABdP+FPM* bounds interval in range $[0.3, 0.4]$, but *BdP+* takes 66 sec while *ABdP+FPM* computes bounds in 8.4 sec. Similarly, in gen51, algorithm *ABdP+FPM* computes only 4 values less with the bounds interval in range $[0.2, 0.4]$, but completes computation in 0.7 sec while *BdP+* requires 140 sec.

5 Conclusions and Future Work

In this paper, we proposed two improvements to the bound propagation algorithm [11]. First improvement exploits the directionality of Bayesian networks, restricting the Markov blanket of a variable to its relevant subnetwork. Although the idea is straight forward, it results in substantial improvement in the accuracy of bounds while the computation time is reduced which we demonstrated empirically.

Second improvement defines an approximation algorithm for the linear optimization problems in bound propagation scheme. Namely, we proposed a relaxation of the LP problem and a greedy algorithm that can solve it exactly. Although the bounds obtained by approximate LP solver are less accurate, we reduce computation time by an order of magnitude or more. Hence, bound propagation with approximate LP solver is more practical for real-time on-line applications

where speed is of critical importance while a small loss in accuracy may be acceptable. An efficient practical strategy may be also to select a threshold value k^* and use the simplex method to solve small LP problems (Markov blanket size $< k^*$) and use an approximate method to solve large LP problems.

We used the proposed bound propagation algorithm with approximate LP solver as a plug-in in the any-time framework for computing bounds on posterior marginals [3], where using *BdP+* with simplex solver was not feasible time-wise. The loss of bounds accuracy was not significant since the framework focuses on enumerating high-probability cutset-tuples and only uses *ABdP+FPM* to bound the remaining probability mass of $P(e)$. We showed in [3] that any-time framework with *ABdP+FPM* outperformed *BdP+* after exploring a few hundred to a few thousand cutset tuples.

Performance of bound propagation depends on the efficiency of the linear optimization algorithm. We have looked at only two approximation schemes. Other approximation algorithms, offering different time/accuracy trade-offs, need to be investigated.

Logic Programs with Multiple Chances

Francesco Buccafurri and Gianluca Caminiti and Domenico Rosaci¹

Abstract. In human-like reasoning it often happens that different conditions, partially alternative and hierarchically structured, are mentally grouped in order to derive some conclusion. The hierarchical nature of such knowledge concerns with the possible failure of a chance of deriving a conclusion and the necessity, instead of blocking the reasoning process, of activating a subordinate chance. Traditional logic programming (we refer here to Answer Set Programming) does not allow us to express such situations in a synthetic fashion, since different chances of deriving a conclusion must be distributed over different rules, and conditions enabling the switching among chances must be explicitly represented. We present a new language, relying on Answer Set Programming, which incorporates a new modality able to naturally express the above features. The merits of the proposal about the capability of representing knowledge are shown both by examples and by comparisons with other existing formalisms. A translation to plain ASP is finally provided in order to give a practical tool for computing our programs, since a number of optimized ASP evaluation systems are nowadays available.

1 INTRODUCTION

In human-like reasoning it often happens that different conditions are mentally grouped in order to derive some conclusion. Such conditions represent different chances, partially overlapped, exploitable as alternative ways for proceeding in the reasoning process. Moreover, following different kinds of ordering, like reliability, simplicity, cost, and so on, different chances are hierarchically structured, and the failure of a chance of deriving a conclusion, caused by uncertainty conditions, enables the application of a subordinate chance. This way, the reasoning process is not necessarily blocked by uncertainty. Consider for example the diagnostic medical reasoning. The doctor tries to recognize a classical clinical picture, in order to derive a diagnosis, but often such a picture is unclear and incomplete. In this case he typically adopts subordinate ways for reaching the same conclusion, like consulting, ex-adiuvantibus treatments, laboratory tests and so on. Traditional logic programming (we refer here to Answer Set Programming [8]) does not allow us to express such situations in a synthetic fashion, since different chances of deriving a conclusion must be distributed over different rules, and conditions enabling the switching among chances must be explicitly represented.

In this paper, we define a language extending Answer Set Programming (ASP) by including a new modality, allowing us to represent, in a compact and natural fashion, the multi-chances form of reasoning described above. Besides ASP, our programs, called *MC-programs*, are compared also with *Inheritance Logic Programming* [5] and *Nested Logic Programming* [12], that appear to us as the best candidates for representing multiple chances. The former is chosen

among languages allowing default reasoning with exceptions and prioritized rules [2, 15, 6, 4, 9], the latter is a powerful logic language allowing us to define rules with nested if-then-else constructs. A translation to plain ASP is finally provided in order to give a practical tool for computing our programs, since a number of optimized ASP solvers [10, 14] and optimization techniques [3] are available.

In order to give the flavor of our proposal, we illustrate the following simple MC-program, describing the diagnosis of appendicitis performed by a doctor:²

$app \leftarrow (\underline{fever}, pl, pf, \underline{nausea})[wbc_test]$

The structure of the above rule, which we call MC-rule, is the following. First, it embeds a standard logic rule, i.e., $app \leftarrow \underline{fever}, pl, pf, \underline{nausea}$, whose meaning is the usual one: If the conjunction $\underline{fever}, pl, pf, \underline{nausea}$ holds, where pl (resp. pf) means pain localization (resp. pain form), then the diagnosis app (appendicitis) is derived. The MC-rule contains also a subordinate condition, namely wbc_test (denoting the result of a laboratory test counting white blood cells), whose truth is required, in order to derive app , whenever the truth assignment of the elements of the conjunction $\underline{fever}, pl, pf, \underline{nausea}$ is recognized as *uncertain*. Such a machinery models the reasoning approach of the doctor, who adopts a subordinate strategy (i.e, the laboratory test) in order to derive the diagnosis, in case the clinical picture allows him neither to exclude such a diagnosis nor to conclude it (i.e., in case of an uncertain clinical picture).

More generally, through an MC-rule of the form $head \leftarrow body[sub_cond]$, our purpose is to represent a logic rule like $head \leftarrow body$ which is not blocked every time $body$ fails (like in standard ASP), but enables the evaluation of the subordinate condition sub_cond only in case the value of $body$ reflects an uncertain situation. In our example, following a standard approach, we could certainly recognize as uncertain truth assignments just those where at least one literal among $\underline{fever}, pl, pf, \underline{nausea}$ is undefined and the others are true³. However, the notion of uncertainty we are using now is strictly related to the intended meaning of the rule. As a consequence, it might happen that other truth assignments are recognizable as uncertain, and thus, the occurrence of such assignments has to enable the evaluation of the subordinate condition wbc_test . In particular, truth assignments including some false value, might be good candidates for activating the evaluation of the subordinate condition, whenever such false values actually contain uncertain knowledge (for example, *false negatives* of a test result). Consider for example the literal *fever*. The doctor knows that in case of absence of fever (i.e.,

¹ DIMET, Università Mediterranea di Reggio Calabria, Italy, email: {bucca, gianluca.caminiti, domenico.rosaci}@unirc.it

² The same example is encoded in Section 4 both in Answer Set Programming and in Nested Logic Programming.

³ Recall that, under ASP semantics, it may happen that an intended model contains neither a given literal nor its complementary literal. Throughout this paper the perspective we use in order to capture the above issue is allowing for literals three truth values: true, false and undefined.

whenever *fever* is false) he cannot exclude the diagnosis of appendicitis (if the rest of the clinical picture holds). The same happens to the symptom *nausea*. Conversely, whenever the localization of the pain is not compatible with the diagnosis of appendicitis (i.e., *pl* is false) the diagnosis can be excluded (the same happens to the pain form). As a consequence, we should include into the set of truth assignments reflecting uncertain situations (corresponding in our example to an uncertain clinical picture), also those in which *fever* and *nausea* are false. This is done, in our formalism, by underlining such literals in the body of the rule. Observe that in case of absence of underlined literals, a conjunction of literals is recognized as uncertain exactly when it is undefined according to the standard meaning (i.e., at least one literal in the conjunction is undefined and the others are true). For instance, according to the above statements, whenever the patient has both a normal temperature, a clear localization of the pain compatible with the diagnosis of appendicitis, an unclear form of pain and, further, he does not have nausea, then the doctor recognizes an uncertain situation not allowing him to exclude the diagnosis. However, such an unclear clinical condition together with the positive result of the laboratory test *wbc_test* (which is the subordinate condition activated in case of uncertainty), allows the doctor to conclude the diagnosis. The language provides the programmer with another important tool. Some uncertainty configurations, among all possible ones, could be considered non-admissible on the basis of possible relationships among the elementary conditions of a conjunction. In our example, even though the conditions *pl* and *pf* may appear separately in admissible uncertainty configurations, the doctor thinks that they cannot be missing simultaneously. In other words, he considers very improbable that neither the localization nor the form of the pain appear in a definite way. This is modeled in our language by defining some *admissibility constraints*, associated to the conjunction of literals. In our example we have just one admissibility constraint $\{pl, pf\}$ encoding what we have described above. The set of admissibility constraints is inserted just after the conjunction on which they operate. The resulting MC-program is the following:

$$app \leftarrow (\underline{fever}, pl, pf, \underline{nausea}) \{ \{pl, pf\} \} [wbc_test] \quad (1)$$

The plan of the paper is the following. Section 2 describes syntax and semantics of the language. In Section 3 the features of the language are shown by real-life examples. In Section 4 our capability of representing knowledge is compared with other existing approaches. Section 5 describes the translation of our language into Answer Set Programming. Finally, we draw our conclusions in Section 6.

2 SYNTAX AND SEMANTICS

In this section, after a brief recall of basic concepts about *Answer Set Programming* (ASP) [8], we introduce the syntax of logic programs with multiple chances, said *MC-programs*, and then we give its semantics, that is an adaptation of the notion of *answer sets*⁴.

An *atom* is an expression $p(t_1, \dots, t_n)$, where p is a *predicate* of arity n and t_1, \dots, t_n are constants. A *literal* is either a *positive literal* a or a *negative literal* $\neg a$, where a is an atom and \neg is the *classical negation symbol*. Given a literal a , $\neg a$ is defined as $\neg p$, if $a = p$ and p if $a = \neg p$. A set L of literals is *consistent* if $\forall l \in L, \neg l \notin L$. Given a literal a , the formula *not a* is the *negation as failure* (NAF) of a ⁵.

⁴ For the sake of presentation, we refer to variable-free (also said *ground*) programs. The extension to the general case is straightforward.

⁵ Observe that the NAF of negative literals is allowed.

Definition 1 Given $m \geq 0$ and $k \geq 0$, an *MC-formula* β is a formula $(\alpha_1[\gamma_1], \dots, \alpha_m[\gamma_m])\{T_1, \dots, T_k\}$, where (1) α_j ($1 \leq j \leq m$) is (possibly the NAF of) a literal and may appear underlined (2) T_i ($1 \leq i \leq k$) is a subset of $\{\alpha_j \mid (\alpha_j \text{ is either underlined, or is not the NAF of a literal}) \wedge 1 \leq j \leq m\}$, and (3) γ_j ($1 \leq j \leq m$) is a (possibly empty) conjunction of MC-formulas. Each set T_i ($1 \leq i \leq k$) is called *admissibility constraint* and the (possibly empty) set $\{T_1, \dots, T_k\}$ of admissibility constraints of β is denoted by $S(\beta)$. γ_j ($1 \leq j \leq m$) is said the *second-chance* of α_j .

The recursive definition above is a generalization of the standard definition of the conjunction of (possibly the NAF of) literals occurring in the body of an ASP logic rule, where both (1) a second-chance is (possibly) associated to each literal, (2) literals may appear underlined and (3) a set of admissibility constraints is associated to the conjunction. As we will explain in the following, the second-chance may be viewed like a substitution of the α_j to which is applied. Such a substitution is executed only when α_j is *uncertain* (the notion of uncertainty will be introduced in the following – the underlining is relating with this notion). Due to the recursive structure of the above definition, a second-chance is, in turn, a conjunction of MC-formulas, and thus may contain further subordinate chances (i.e., the nesting of chances is allowed). Intuitively, second-chances are subordinate conditions that are required, in order to satisfy the MC-formula, whenever the basic conditions α_i s are uncertain. Actually, not all the possible configurations of values making α_i s uncertain are allowed, in order to activate the substitution of the second-chance, but only those satisfying the admissibility constraints.

Given a conjunction of MC-formulas Δ , in favor of simplicity, we often write $(\alpha_1[\gamma_1], \dots, \alpha_m[\gamma_m])\{T_1, \dots, T_k\}[\Delta]$ to denote $(\alpha_1[\gamma_1[\Delta]], \dots, \alpha_m[\gamma_m[\Delta]])\{T_1, \dots, T_k\}$. In particular, if $\gamma_1 = \dots = \gamma_m = \Delta$, we write $(\alpha_1, \dots, \alpha_m)\{T_1, \dots, T_k\}[\Delta]$ to denote $(\alpha_1[\Delta], \dots, \alpha_m[\Delta])\{T_1, \dots, T_k\}$. Clearly, square brackets of empty second-chances are omitted. Examples of MC-formulas are $\beta_1 = (a, \text{not } b)[c]$ (denoted also by $(a[c], \text{not } b[c])$), where $S(\beta_1) = \emptyset$ and $\beta_2 = (a, b)\{a, b\}[c]$, (denoted also by $(a[c], b[c])\{a, b\}$), where $S(\beta_2) = \{a, b\}$.

Definition 2 An *MC-rule* r is a formula $a \leftarrow \beta_1, \dots, \beta_n$ ($n \geq 0$), where a is a positive literal and β_i is an MC-formula, for each $1 \leq i \leq n$. The set $\{a\}$, denoted by *head(r)*, is called the *head* of r , and the set $\{\beta_1, \dots, \beta_n\}$, denoted by *body(r)*, is called the *body* of r . An *MC-program* is a finite set of MC-rules.

Note that since an MC-formula is a generalization of a standard conjunction of (the NAF of) literals, a standard ASP rule is a special case of an MC-rule r . Informally, an MC-rule is a logic rule allowing in the body the substitution of some literal with its second-chance (under uncertainty conditions). An example of MC-rule is the expression (1) reported in Section 1. Another example of MC-rule is: $a \leftarrow b[c[d]], f[\text{not } g]$.

We introduce now the intended models of our semantics. First we need some preliminary definitions. Given an (MC-)program P , Lit^P is the set of literals occurring in P . An *interpretation* I of an (MC-)program P is a consistent subset of Lit^P . A literal a is *true* w.r.t. I if $a \in I$, it is *false* w.r.t. I if $\neg a \in I$. A literal a is *undefined* w.r.t. I if it is neither true nor false w.r.t. I . Given a literal a , a formula *not a* is *true* w.r.t. I if $a \notin I$, it is *false* w.r.t. I otherwise (observe that the NAF of a literal cannot be undefined w.r.t. a given interpretation). From now on in this section, consider given an (MC-)program P and an interpretation I of P .

We introduce now a basic notion of our framework, that is the notion of *uncertainty* of an element of an MC-formula. Indeed the mechanism of substitution of an element of an MC-formula with its second-chance is founded on this property (this will be explained in detail in the following).

Given an MC-formula $\beta = (\alpha_1[\gamma_1], \dots, \alpha_m[\gamma_m])\{T_1, \dots, T_k\}$, we say that α_j ($1 \leq j \leq m$) is *uncertain* w.r.t. the interpretation I if either (i) $\alpha_j = a \mid a \in \text{Lit}^P \wedge \{a, \neg a\} \cap I = \emptyset$, (ii) $\alpha_j = \underline{a} \mid a \in \text{Lit}^P \wedge a \notin I$, or (iii) $\alpha_j = \underline{\text{not } a} \mid a \in \text{Lit}^P \wedge a \in I$.

The definition of uncertainty introduced above arises from the following reasoning. We expect that an element α_j is uncertain if it is undefined. This is captured by the item (i) of the definition. Note that, correctly, this item does not include the case of the NAF of a literal, since such a formula cannot be undefined. Now, when we want to interpret as uncertain also the false value of α_j , we require that α_j is underlined (items (ii) and (iii)). Thanks to this mechanism, also the NAF of a literal can be uncertain, whenever it appears in an underlined element $\alpha_j = \underline{\text{not } a}$, and a is true.

Consider again the MC-formula β introduced above. $S(\beta)$ is *true* w.r.t. I if for each $T_i \in S(\beta)$ ($1 \leq i \leq k$), there exists $\alpha \in T_i$ such that α is not uncertain w.r.t. I . In words, an admissibility constraint T_i states that literals occurring in it cannot appear simultaneously in uncertainty configurations. Now we define the intended models of our semantics. First, we introduce a transformation for MC-programs which produces an ASP program.

Definition 3 We define the *MC-transformation* of the program P w.r.t the interpretation I as the ASP program \bar{P}^I , obtained from P by executing Algorithm 1.

Algorithm 1 (The MC-transformation algorithm)

```

repeat
  for each MC-rule  $r \in P$  do
    if  $\exists \beta \in \text{body}(r) \mid S(\beta)$  is false w.r.t.  $I$  then delete  $r$ 
    else for each  $\beta = (\alpha_1[\gamma_1], \dots, \alpha_m[\gamma_m])\{T_1, \dots, T_k\} \in \text{body}(r)$  do
      delete  $S(\beta)$ 
      for each  $1 \leq j \leq m$  do
        if  $\alpha_j$  is uncertain w.r.t.  $I$  then remove from  $\alpha_j$  the underlining (if any)
        if  $\gamma_j$  is not empty then replace  $\alpha_j[\gamma_j]$  by  $\gamma_j$ 
        end if
      else remove from  $\alpha_j$  the underlining (if any); replace  $\alpha_j[\gamma_j]$  by  $\alpha_j$ 
      end if
    end for
  end for
  end if
end for
until  $\forall r \in P, \forall \beta \in \text{body}(r) \exists a \in \text{Lit}^P \mid \beta = a \vee \beta = \text{not } a$ 
```

The MC-transformation of P consists of both (i) deleting all MC-rules of P whose body includes some MC-formula with false admissibility constraint, (ii) deleting all admissibility constraints from the remaining MC-formulas, (iii) for each uncertain element α_j in the body of every MC-rule, removing the underlining (if any), and replacing α_j by its second-chance (if any); (iv) for each remaining element α_j , removing the underlining (if any) and discarding its second-chance. The loop ends when only (possibly the NAF of) literals occur in P .

Definition 4 An interpretation J of the program P is an *answer set* of P if J is an answer set⁶ of \bar{P}^J .

For instance, consider the following MC-program P :

⁶ The definition of *answer sets* of an ASP program can be found in [8]. We do not report it here for space limitations. Note that, according to the definition of interpretation, we want to limit our focus only on consistent answer sets.

$$\begin{array}{ll} r_1 : a \leftarrow (b, c, e)\{\{c, e\}, \{\underline{b}, c\}\}[\text{not } d] & r_3 : \neg b \leftarrow a \\ r_2 : d \leftarrow \text{not } a & r_5 : e \leftarrow \\ r_4 : c \leftarrow \text{not } d & \end{array}$$

The intended answer sets of P are: $\{a, \neg b, c, e\}, \{d, e\}$. Indeed, given $I_1 = \{a, \neg b, c, e\}$, the MC-transformation of P w.r.t. I_1 is $\bar{P}^{I_1} = \{r'_1, r_2, r_3, r_4, r_5\}$, where r'_1 is $a \leftarrow \text{not } d, c, e$. Observe that I_1 is an answer set of \bar{P}^{I_1} thought as an ASP program. Likewise, it is easy to see that $I_2 = \{d, e\}$ is an answer set of $\bar{P}^{I_2} = \{r_2, r_3, r_4, r_5\}$ (r_1 is deleted due to the constraint $\{\underline{b}, c\}$).

Remark. Our formalism can be viewed as an extension of the ASP negation by failure. Indeed, the rule $h \leftarrow \text{not } b$ can be rewritten in our setting as $h \leftarrow \neg b[\text{true}]$. According to our semantics, h is derived if either b is false (i.e., $\neg b$ is true) or b is undefined (since, in this case the subordinate condition is activated and it corresponds to the constant *true*), exactly as the ASP rule $h \leftarrow \text{not } b$.

3 KNOWLEDGE REPRESENTATION BY MC-PROGRAMS

In this section, we show how our language can be used for naturally representing real-life situations. We show two examples, where we do not make explicit the answer sets of the programs, because they depend on the value of a number of literals, which we assume as “external variables”. However, the purpose of this section is to make evident the merits of the multi-chance constructs. Therefore in the following description we just stress the aspect of the meaning of MC-rules, instead of considering the issues typically occurring in the context of answer sets (like their multiplicity), which our language completely preserves.

A Medical Example. We consider here a fragment of a diagnostic reasoning process in a medical setting. We model, by means of the following MC-program, the reasoning steps leading to both the diagnosis of *ischemic cardiopathy* (rules $r_1 - r_4$) and the consequent therapy (rules $r_5 - r_8$).

$$\begin{array}{lll} r_1 : & \text{clin_pict} \leftarrow & \text{complete_set_of_symptoms} \\ r_2 : & \neg \text{clin_pict} \leftarrow & \text{absent_symptoms} \\ r_3 : & \text{ECG_test} \leftarrow & \text{ST_segment_anomaly} \\ r_4 : & \text{isch_cardio} \leftarrow & (\text{clin_pict}, \text{N_test}, \underline{\text{ECG_test}}[\text{PPI_test}]) \\ & & \{\{\text{clin_pict}, \text{N_test}\}\}[\text{enz_test}[\text{echo}]] \\ r_5 : & \text{active_ulcer} \leftarrow & \text{recent_symptoms}, \text{pos_case_history} \\ r_6 : & \neg \text{active_ulcer} \leftarrow & \neg \text{pos_case_history} \\ r_7 : & \text{risk_patient} \leftarrow & \text{smoker}, \text{diabetic}, \text{hypertensive} \\ r_8 : & \text{aspirin} \leftarrow & \text{isch_cardio}, \\ & & \neg \text{active_ulcer}[\text{risk_patient}] \end{array}$$

In particular, rules r_1 and r_2 specify that the patient’s clinical picture (*clin_pict*) is either (i) true, if there exists a complete set of symptoms, or (ii) false, if all symptoms are absent. Otherwise *clin_pict* is considered uncertain. Rule r_3 describes that the electrocardiogram (ECG) test (*ECG_test*) is positive if it reveals a typical anomaly of its ST-segment. Thus, by means of rule r_4 , the doctor concludes the diagnosis of ischemic cardiopathy (*isch_cardio*) in case of both a complete clinical picture, the patient’s positive reaction to a nitrate treatment (*N_test*), and a positive result of the ECG. In this case, rule r_4 behaves as the following standard ASP rule: $\text{isch_cardio} \leftarrow \text{clin_pict}, \text{N_test}, \text{ECG_test}$.

However, a possible uncertainty situation might arise from a negative ECG: The doctor knows that there are cases of ischemic cardiopathy not altering the ST-segment of the ECG (i.e. *ECG_test* is false). In such cases he applies a second-chance approach, by substituting the information given by the ECG test with that given by

another ex-adiuvantibus treatment, i.e. the administration of a protonic pump inhibitor (*PPI*_test). The patient's positive reaction to such a test, reveals a different kind of pathology. Thus, *PPI*_test is assumed true whenever symptoms persists after the administration of the inhibitor. After such a substitution, rule r_4 behaves as: $\text{isch_cardio} \leftarrow \text{clin_pict}, N_test, PPI_test$.

Unfortunately, there are other situations that may appear still unclear: (i) The clinical picture might be not complete (*clin_pict* may be undefined)⁷. (ii) The nitrate treatment might give either an unclear result (i.e., symptoms may weakly persist) or false negatives (*N_test* may be either undefined or false, respectively). (iii) Symptoms might weakly persist after the protonic-pump-inhibitor-based treatment (i.e., *PPI*_test may be undefined).

Observe that the admissibility constraint $\{\{\text{clin_pict}, N_test\}\}$ in rule r_4 means that the simultaneous occurrence of both case (i) and (ii) is not compatible with the diagnosis of ischemic cardiopathy.

In either case (i), (ii) or (iii), the doctor decides to perform a laboratory test, which is aimed to detect specific enzymes in the blood. The result of such a test is represented by *enz*_test. Accordingly, rule r_4 behaves as: $\text{isch_cardio} \leftarrow \text{enz_test}$.

However, since this test might give false negatives, the doctor evaluates the nested second-chance (*echo*), corresponding to the result of a echocardiogram. Thus, rule r_4 behaves as: $\text{isch_cardio} \leftarrow \text{echo}$.

In order to apply the therapy, the doctor reasons about the patient's history. In particular, he is interested in the possible presence of an active ulcer (rules r_5 and r_6). Rule r_5 states that the patient is affected by an active ulcer (*active_ulcer*), if both the doctor recognizes the occurrence of recent symptoms and the patient's history clearly reveals previous cases of ulcer. Rule r_6 excludes the occurrence of an active ulcer in case of a clearly negative patient's history. However, it may happen that the history reported by the patient is unclear, so that the information about such a pathology remains undefined. Moreover, rule r_7 specifies under which conditions the patient has to be considered a patient with a high cardiovascular risk (*risk_patient*).

Finally, rule r_8 describes the therapy (*aspirin*) to be administered in case of both ischemic cardiopathy and in absence of an active ulcer ($\neg\text{active_ulcer}$). However, if the latter information is undefined, then the doctor replaces the condition $\neg\text{active_ulcer}$ by *risk_patient*, i.e. he decides to administer the aspirin to the patient only if both the diagnosis is certain and the patient has a high cardiovascular risk. Accordingly, rule r_8 behaves as: $\text{aspirin} \leftarrow \text{isch_cardio}, \text{risk_patient}$. Observe that, in this case, the doctor judges the risk of a both non-adequate and non-immediate therapy for the ischemic cardiopathy to be more relevant than the probability of side effects due to the interaction of aspirin and a (possible, but not evident) active ulcer.

The Driving Licence. A guy must go to a far town for renewing his driving license. The renewal takes a few minutes, but in order to apply for it, two documents *A* and *B* are required by the administration office. Moreover, *A* and *B* are issued by two different offices, say O_A and O_B , that are placed in that town. He is told that *A* and *B* will be available in about 15 days. Meanwhile, he can check by phone for both *A* and *B* to be ready. However, it is possible that either both O_A and O_B phone lines are busy, or the officers cannot answer. The guy wants to go to the administration office only if he knows that both offices O_A and O_B have issued the respective documents. However, if after 20 days he is sure about the availability of at least one document, and he was not informed of the contrary about the other document, then he goes. This example may be represented

by the following MC-program:

```
go ← (rdy_A, rdy_B){{rdy_A, rdy_B}}[waiting(20)]
```

where we assume that *rdy_A* (resp. *rdy_B*) is derived as a fact if the guy has been told by phone that *A* (resp. *B*) is ready, $\neg\text{rdy}_A$ (resp. $\neg\text{rdy}_B$) is derived as a fact if the guy has been told by phone that *A* (resp. *B*) is not ready and *waiting(20)* is derived as a fact if the guy has waited for 20 days.

4 COMPARISON WITH OTHER APPROACHES

In this section first we compare by examples our language with plain ASP, in order to show that the introduction of the new modality in ASP gives real benefits. Then, we compare our programs also with *Inheritance Logic Programming* [5] and *Nested Logic Programming* [12], that appear, to our knowledge, as the best candidates among logic programming languages for representing multiple chances.

Plain ASP. Consider now the MC-program (1) presented at the end of Section 1 and encode the same real-life situation using Answer Set Programming. Since we need to make explicit all the possible combinations of uncertain elements of the conjunction (which number grows exponentially with the number of uncertain cases), the resulting ASP program is the following:

```
app ← fever, pl, pf, nausea
app ← not fever, pl, pf, nausea, wbc_test
app ← not fever, pl, pf, not nausea, wbc_test
app ← not fever, pl, not pf, not \pf, nausea, wbc_test
app ← not fever, not pl, not \pl, pf, nausea, wbc_test
app ← not fever, not pl, not \pl, pf, not nausea, wbc_test
app ← not fever, pl, not pf, not \pf, not nausea, wbc_test
app ← fever, pl, pf, not nausea, wbc_test
app ← fever, pl, not pf, not \pf, nausea, wbc_test
app ← fever, not pl, not \pl, pf, nausea, wbc_test
app ← fever, not pl, not \pl, pf, not nausea, wbc_test
app ← fever, pl, not pf, not \pf, not nausea, wbc_test
```

This example shows that even though our formalism does not extend the expressive power of ASP (and does not introduce asymptotic computational cost), it has evident merits as far as its capability of representing multi-chance reasoning is concerned. Concerning the complexity and the expressiveness of logic programming, see [7].

Nested Logic Programming. *Nested Logic Programming* [12] (NLP) is a class of logic programs, where arbitrarily nested expressions – formed from literals by using negation as failure, conjunction and disjunction (\wedge) – are allowed in both the bodies and heads of rules. Given an MC-program P , a suitable translation P' into the non-disjunctive fragment of NLP (with no NAF in heads of rules) exists, but we show that P' is extremely tedious to write and difficult to read. For instance, if we translate the MC-program (1) of Section 1, we obtain the following NLP program:

```
app ← (fever; not fever, wbc_test),
      (pl; not pl, not \pl, (pf; \pf), wbc_test),
      (\pf; not pf, not \pf, (pl; \pl), wbc_test),
      (nausea; not nausea, wbc_test)
```

Disjunctive Logic Programs with Inheritance. *Disjunctive Logic Programs with Inheritance* [5] ($\text{DLP}^<$) is a knowledge representation language extending disjunctive logic programming (with strong negation) by inheritance. The addition of inheritance allows us a natural representation of default reasoning with exceptions. Thus, one could argue that $\text{DLP}^<$ may be used to represent default conditions being evaluated whenever previously required conditions are uncertain. We have compared by examples our language with $\text{DLP}^<$. For space limitations we do not report details of such a comparison here.

⁷ Observe that if $\neg\text{clin_pict}$ holds, then such a case is not considered as a font of uncertainty. That is, if no symptom is present, then the doctor is able to exclude the diagnosis of ischemic cardiopathy.

Synthetically, we have tested that DLP $^<$, compared to our language, is not suitable to represent multi-chance reasoning. Indeed base conditions must be thought as exceptions and (nested) chances as defaults and, further, programs are time-wasting to write and difficult to read, since all the combinations, i.e. those resulting from the possible uncertainty of the literals enclosed in an MC-formula, must be individually considered.

5 TRANSLATION TO ASP

In this section we show that for any MC-program P , an ASP program $\Gamma(P)$ exists such that there is a one-to-one correspondence between the answer sets of P and the answer sets of $\Gamma(P)$. Such a translation allows us to evaluate any MC-program by exploiting one of the existing answer set solvers (DLV [10], Smodels [14], etc).

Given an MC-program P , we define $\Gamma(P)$ as the ASP program obtained from P by executing Algorithm 2.

Algorithm 2 (The translation algorithm)

```
for each MC-rule  $r \in P$  do
  for each MC-formula  $\beta \in body(r) \mid \beta$  is not (the NAF of) a literal do
    RESOLVE_FORMULA( $r, \beta, \bar{\beta}$ )
  end for
end for
```

The core of Algorithm 2 is the recursive procedure described by Algorithm 3, where MC-formulas are of the form $(\alpha_1[\gamma_1], \dots, \alpha_m[\gamma_m])\{T_1, \dots, T_k\}$ ($m \geq 0, k \geq 0$).

Algorithm 3 (The procedure RESOLVE_FORMULA)

```
procedure RESOLVE_FORMULA( $r, \beta, \bar{\beta}$ )
  body( $r$ ) = body( $r$ ) \ { $\beta$ } \ { $\bar{\beta}$ }
   $P = P \cup \{\bar{\beta} \leftarrow \rho_1, \dots, \rho_m, \text{not } \tau_1, \dots, \text{not } \tau_k\} \cup$ 
     $\cup \{\tau_i \leftarrow \sigma_1, \dots, \sigma_{|T_i|} \mid 1 \leq i \leq k\}$ 
  for  $1 \leq j \leq k$  do let  $c_1, \dots, c_{|T_j|}$  be a permutation of  $T_j$ 
    for  $1 \leq l \leq |T_j|$  do
      if  $(c_l = b) \wedge (b \in Lit^P)$  then  $P = P \cup \{\sigma_l \leftarrow \text{not } b, \text{not } \neg b\}$ 
      else if  $(c_l = \underline{b}) \wedge (b \in Lit^P)$  then  $P = P \cup \{\sigma_l \leftarrow \text{not } b\}$ 
      else if  $(c_l = \underline{\text{not } b}) \wedge (b \in Lit^P)$  then  $P = P \cup \{\sigma_l \leftarrow b\}$ 
      end if
    end for
  end for
  for  $1 \leq j \leq m$  do
    if  $(\alpha_j = b \vee \alpha_j = \underline{b}) \wedge (b \in Lit^P)$  then  $P = P \cup \{\rho_j \leftarrow b\}$ 
    if  $\gamma_j$  is not empty then
      if  $(\alpha_j = b) \wedge (b \in Lit^P)$  then let  $t : \rho_j \leftarrow \text{not } b, \text{not } \neg b, \gamma_j$ 
      else if  $(\alpha_j = \underline{b}) \wedge (b \in Lit^P)$  then let  $t : \rho_j \leftarrow \text{not } b, \gamma_j$ 
      end if
       $P = P \cup \{t\}; \text{ RESOLVE\_FORMULA}(t, \gamma_j, \bar{\gamma}_j)$ 
    end if
    else if  $(\alpha_j = \text{not } b \vee \alpha_j = \underline{\text{not } b}) \wedge b \in Lit^P$  then
       $P = P \cup \{\rho_j \leftarrow \text{not } b\}$ 
      if  $(\gamma_j \text{ is not empty}) \wedge (\alpha_j = \underline{\text{not } b}) \wedge (b \in Lit^P)$  then
        let  $t : \rho_j \leftarrow b, \gamma_j; \ P = P \cup \{t\}; \text{ RESOLVE\_FORMULA}(t, \gamma_j, \bar{\gamma}_j)$ 
      end if
    end if
  end for
end procedure
```

Note that for each call of the procedure, $\rho_i, \tau_i, \sigma_i, \bar{\gamma}_i(\forall i)$ and $\bar{\beta}$ are fresh literals (not already included in Lit^P). Observe that the Algorithm 2 is exponential in the maximum number, say c , of nested chances. However, c is typically bound (informally, the number of nested chances is small). Therefore it becomes meaningful the complexity analysis w.r.t. n , that is the number of literals occurring in the program, keeping constant c . It is easy to see that such a complexity is $O(n)$. Moreover, in such a case, the computational complexity still remains linear w.r.t. both the number of program rules and the maximum number of elements in the body of an MC-rule.

In the next theorem we state the equivalence between the original MC-program P and its translation $\Gamma(P)$. The proof of the theorem is omitted for space limitations.

Theorem 1 Given an MC-program P and an interpretation I of P , then I is an answer set of P iff $I \in AS^{dep}(\Gamma(P))$, where $AS^{dep}(\Gamma(P))$ is the set of answer sets of $\Gamma(P)$ where all working literals $\bar{\beta}, \rho_i, \tau_i, \sigma_i, \bar{\gamma}_i(\forall i)$ are discarded.

6 CONCLUSIONS

The paper presents a new language relying on Answer Set Programming and including some new constructs useful for naturally representing some forms of reasoning where multiple chances of deriving a given conclusion occur. Examples described in the previous sections as well as comparisons with other languages show that the above goal is satisfactorily reached. The general KR point of view adopted in this work could represent a starting point for designing more specific solutions, once a particular research setting is chosen (for example, planning [13, 16, 11, 1]). We feel this is a very interesting direction for our future research.

Reasoning with Inconsistencies in Propositional Peer-to-Peer Inference Systems¹

Ph. Chatalic² and G.H. Nguyen³ and M.Ch. Rousset³

Abstract.

In a peer-to-peer inference system, there is no centralized control or hierarchical organization: each peer is equivalent in functionality and cooperates with other peers in order to solve a collective reasoning task. Since peer theories model possibly different viewpoints, even if each local theory is consistent, the global theory may be inconsistent. We exhibit a distributed algorithm detecting inconsistencies in a fully decentralized setting. We provide a fully distributed reasoning algorithm, which computes only *well-founded* consequences of a formula, i.e., with a consistent set of support.

1 Introduction

Recently peer-to-peer (P2P) systems have received considerable attention because their underlying infrastructure is appropriate to scalable and flexible distributed applications over Internet. In P2P systems, there is no centralized control or hierarchical organization: each peer is equivalent in functionality and cooperates with other peers in order to solve a collective task. P2P systems have evolved from simple keyword-based file sharing systems like Napster [2] and Gnutella [1] to semantic data management systems like EDUTELLA [22], PIAZZA [18] or SOMEWHERE [5]. Reasoning in P2P Inference Systems (P2PIS) has been considered very recently (e.g., [3, 12, 4]). The dynamicity of P2PIS imposes to revisit many reasoning problems in order to address them in a decentralized manner. In particular, it is neither feasible to bring all the information to a single server and use standard reasoning algorithms, nor to compute its best partitioning for using partition-based reasoning like in [15, 8].

The local theories of the P2PIS considered in [3, 4] are sets of clauses defined upon sets of propositional variables (the local vocabularies of the peers). A new peer joins an existing P2PIS by establishing *mappings* with other peers, called its *acquaintances*. Mappings are clauses involving variables of distinct peers that state semantic correspondences between different vocabularies. The decentralized algorithm DECA [6] computes the consequences (in some target language) of an input formula w.r.t. the global theory of the P2PIS (i.e. the union of all peer theories). The point is to compute those consequences, without having access to the global theory. DECA is anytime, sound, and complete (under some conditions). It has been implemented in the SOMEWHERE platform and experiments on synthetic data have shown its scalability [4, 6].

This paper focuses on the problem of reasoning with inconsistencies in a P2PIS. Since peer theories model possibly different view-

points, the global theory may be inconsistent even if each local theory is consistent. Given the lack of centralized control, all peers should be treated equally. It would be unfair to refuse the join of a new peer just because the resulting P2PIS becomes inconsistent. Our choice is to accept the presence of inconsistency. The problem is first to *detect* inconsistencies, second to *reason* in spite of them in a satisfactory way. We thus compute only *well-founded* consequences of a formula, i.e., consequences of the formula w.r.t. to a consistent subset of the global theory. Such an approach is not novel in the centralized case but raises new algorithmic issues in the decentralized case because the computation and the storage of *nogoods* (accounting for inconsistencies) are distributed. One has to be able to check the consistency of distributed sets of formulas, w.r.t. distributed sets of nogoods.

We assume each local theory to be consistent. Therefore, the possible inconsistencies result from interactions between local theories and are caused by *mappings*. Before adding a mapping, a peer checks whether this mapping (possibly with other mappings) can be the cause of some inconsistency, i.e., if the empty clause can be produced as one of its consequences. In that case, the peer stores locally as a *nogood* the set of mappings involved in the corresponding proof. At reasoning time, the concerned distributed nogoods must be collected to check whether the proof under construction is well-founded.

In Section 2, we formally define the considered P2PIS. In Section 3, we present a decentralized algorithm for detecting inconsistencies and computing the corresponding nogoods. Section 4 provides a decentralized reasoning algorithm which is well-founded despite possible inconsistencies. In Section 5, we conclude by relating our approach w.r.t. existing work.

2 Peer-to-peer inference systems

The P2PIS that we consider are networks of peer clausal theories $\mathcal{P} = \{P_i\}_{i=1..n}$, such that each peer has a proper *vocabulary* (denoted by \mathcal{V}_{P_i}). We suppose that each peer has a unique identifier (for example, its IP address) and that variable names use in some way this identifier. For simplicity, we just use the index i as the peer identifier and denote a variable A of the peer P_i by A_i . Each local theory of a peer P_i is a set of clauses without duplicated literals. We denote by \mathcal{L}_{P_i} the language of clauses involving only variables of \mathcal{V}_{P_i} .

Definition 1 (Mappings, shared variables and acquaintances)

A mapping is a clause of a peer involving at least a variable of the vocabulary of another peer. A variable of some peer is said to be shared if it appears in a mapping of another peer. The acquaintances of a peer are the peers in the network with which it shares variables.

The global theory $\mathcal{T}(\mathcal{P})$ of a P2PIS $\mathcal{P} = \{P_i\}_{i=1..n}$ is: $\bigcup_{i=1..n} P_i$. Since mappings play a special role in our approach, we distinguish $\mathcal{M} = \bigcup_{i=1..n} M_i$, where M_i is the set of mappings of P_i from

 {Gia-Hien.Nguyen,Marie-Christine.Rousset}@imag.fr

$\mathcal{O} = \bigcup_{i=1..n} O_i$, where each O_i is the complementary of M_i . In addition, we assume that each mapping of P_i has a unique identifier prefixed by P_i .

A shared literal is a shared variable or its negation. For a clause c , we denote by $S(c)$ the disjunction of its shared literals and by $L(c)$ the disjunction of its other literals. We suppose that each peer P knows its acquaintances, and given a shared literal l we denote by $ACQ(l, P)$ the set of peers with which P shares the variable of l .

In contrast with other approaches [17, 12], we do not adopt an epistemic or modal semantics for interpreting a P2PIS but we interpret it with the standard semantics of propositional logic. In particular, a variable shared by two peer theories of a given P2PIS is interpreted by the same value in the two peers.

Definition 2 (Semantics of a P2PIS) Let $\mathcal{P} = \{P_i\}_{i=1..n}$ be a P2PIS, an interpretation I of \mathcal{P} is an assignment of the variables of $T(\mathcal{P})$ to true or false. I is a model of a clause c iff one of the literals of c is evaluated to true in I . I is a model of a set of clauses iff it is a model of all the clauses of the set.

- \mathcal{P} is consistent iff $T(\mathcal{P})$ has a model.
- The consequence relation is the standard one: $\mathcal{P} \models c$ iff every model of \mathcal{P} is a model of c . We say that c is an implicate of \mathcal{P} .

Example

Let us consider the P2PIS corresponding to Figure 1. P_1 can be asked by researchers for choosing where to submit their results (demos or papers). For instance, part of its knowledge can model that: $PODS06$ is open for submission; submitting to $PODS06$ entails submitting to $PODS$; only theoretical results are submitted to $PODS$; a demo cannot be submitted to JAIR. P_2 distinguishes proceedings from journals and knows that: submitting to $PODS$ entails submitting to a conference with proceedings; submitting to JAIR entails submitting to a journal; a same result cannot be submitted in a conference and in a journal; patented results cannot be submitted to a journal. P_3 has some knowledge about research valorization policy: software should be patented or presented as demos; theoretical results should be submitted to journals. The knowledge expressed separately by P_1 , P_2 and P_3 using their respective vocabularies can be respectively modelled by the set of clauses O_1 , O_2 and O_3 .

The set M_2 of mappings stored at P_2 states the equivalence between $PODS_1$ and $PODS_2$ (reps. $JAIR_1$ and $JAIR_2$) through the mappings identified by $P_2.1$, $P_2.2$, $P_2.3$ and $P_2.4$. The set M_3 of mappings stored at P_3 also establishes equivalences between variables of P_3 and variables of the two other peers. Note however that mappings clauses do not necessarily result from equivalences.

The reasoning problem

For each peer P_i , we consider a set $\mathcal{TV}_{P_i} \subseteq \mathcal{V}_{P_i}$ of target variables, supposed to represent the variables of interest for the application, (e.g., observable facts in a model-based diagnosis application, or classes storing data in an information integration application). For a set SP of peers of a P2PIS, we define its target language $Target(SP)$ as the language of clauses (including the empty clause) involving only variables of $\bigcup_{P \in SP} \mathcal{TV}_P$.

Definition 3 (P2PIS consequence finding problem)

Given a P2PIS \mathcal{P} , a peer P of \mathcal{P} and a clause $q \in \mathcal{L}_P$, the P2PIS consequence finding problem is to find the set of proper prime implicates of q w.r.t. $T(\mathcal{P})$ that belong to $Target(\mathcal{P})$.

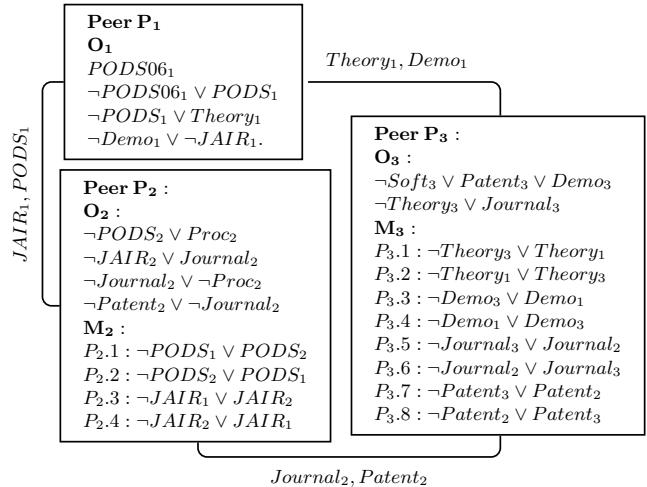

Figure 1. Example P2PIS network (edges labelled by shared variables).

A proper prime implicate of q w.r.t. a (distributed) theory T is a prime implicate of $T \cup \{q\}$, which is not a prime implicate of T .

DECA [3, 6] is the first fully decentralized algorithm being able to solve this problem without having a global view of the system. Details and illustrations of DECA behavior may be found in [6]. Roughly summarized, when running at a peer P and asked to compute the proper prime implicants of a literal q , it first computes all proper prime implicants of this literal w.r.t. the local theory of P , selects those of interest w.r.t. the target language and then split each clause c obtained in this way in two subclauses : $L(c)$ and $S(c)$. $S(c)$ is in turn splitted and for each shared literal l of $S(c)$ DECA asks its appropriate acquaintances (which are running the very same algorithm) to further propagate l in the P2PIS and to return the corresponding results. As soon as consequences are obtained for all literals of $S(c)$ they are recombined together, as well as with $L(c)$, to produce consequences of the splitted clause c . Different branches of reasoning are thus developed throughout the network, following the shared variables, and thus the mappings. In order to ensure termination in presence of cycles as well as to handle the transmission of the results back to the appropriate peers, an *history* is associated to each propagated literal and updated each time that the corresponding reasoning branch goes out from one peer into another peer.

3 P2P detecting inconsistencies and nogoods

As outlined in the introduction, even if each P_i is locally consistent, this is not necessarily the case for $T(\mathcal{P})$. We assume that the causes of inconsistencies are only due to mappings and define a **nogood** ng as a set of mappings such that $\mathcal{O} \cup ng$ is inconsistent. Note that in a nogood ng there necessarily exists some mapping m from which one can derive the empty clause (i.e., with a proof rooted in m). We exploit this property in the decentralized algorithm P2P-NG to detect nogoods accounting for inconsistencies. P2P-NG runs at each peer and is used before adding a new mapping m to a peer P , to check whether the propagation of m into the existing P2PIS produces the empty clause. If that is the case, P stores locally as new nogoods the mappings (including m) involved in the corresponding derivations. We call the set of mappings used in a derivation, its **mapping support**. The P2P-NG algorithm computes the (possibly empty) set of mapping supports of the derivations of the empty clause rooted in

m , starting at the peer P . Since mappings have a unique identifier, mapping supports can efficiently be encoded as sets of mapping identifiers (and similarly for nogoods computed from mapping supports).

P2P-NG is an adaptation of the DECA consequence finding algorithm. It follows the same split-recombine strategy but it has the following significant differences:

- The stopping conditions **must** be changed. The ones in the original DECA algorithm were designed for the computation of *proper prime* implicants only. Here we need to find all the possible ways of deriving the empty clause, we cannot stop the reasoning as soon as we produce the empty clause, or as soon as we find a unit clause in a local peer which is the same as the literal under processing.

- Because we are only looking for \square as a consequence, locally produced consequences c such that $L(c) \neq \square$ can be filtered out.

- While DECA would return $\{\square\}$ as its result if there exists a derivation of the empty clause, P2P-NG returns as many mapping supports as different ways of deriving \square .

We use the following notations:

- For a clause c , $Resolvent+SMS(c, P)$ computes the couples of pairs $(r, SMS(r, P))$ such that r is a local consequence of c w.r.t. P and $SMS(r, P)$ is its corresponding set of local mapping supports.

- For a literal q , \bar{q} denotes its complementary literal.

- A history $hist$ is a sequence of tuples (l, P, c) where l is a literal, P a peer, and c a clause which is a consequence of l on the peer P . A history $[(l_n, P_n, c_n), \dots, (l_1, P_1, c_1), (l_0, P_0, c_0)]$ represents a branch of reasoning initiated by the propagation of the literal l_0 within the peer P_0 , which either has produced locally the clause c_0 in P_0 (in that case, c_0 may have been splitted into its different literals among which l_1 is propagated in P_1), or not (in that case l_0 is simply propagated from P_0 to P_1 and $l_0 = c_0 = l_1$). For every $i \in [0..n-1]$, c_i is a consequence of l_i and P_i , and l_{i+1} is a literal of c_i , which is propagated in P_{i+1} .

- \otimes is the distribution union operator on sets of sets:

$SS_1 \otimes \dots \otimes SS_n = \{S_1 \cup \dots \cup S_n \mid S_1 \in SS_1, \dots, S_n \in SS_n\}$. If $L = \{l_1, \dots, l_p\}$, $\otimes_{l \in L} SS_l$ denotes $SS_{l_1} \otimes \dots \otimes SS_{l_p}$.

Each literal resulting from the splitting of a clause (Line (4) of the P2P-NG algorithm) is processed independently by the P2P-NG $_l$ algorithm. P2P-NG $_l(q, SP, hist)$ checks whether there exists a derivation of \square rooted in the literal q , starting with the computation of local consequences of q , and then recursively following the acquaintances of the visited peers. To ensure termination, it is necessary to keep track of the literals already processed by peers. This is done thanks to $hist$, where $hist$ is the history of the reasoning branch ending up to the propagation of the literal q in SP , which is the set of acquaintances of the last peer added to the history.

Theorem 1 states that the result of P2P-NG(m, P) can be used to characterize nogoods involving the mapping m (by assimilating mappings to their corresponding index).

Theorem 1 Let m be a mapping and P be a peer such that P2P-NG(m, P) $\neq \emptyset$. $\forall ms \in$ P2P-NG(m, P), $ms \cup \{m\}$ is a nogood.

Before adding a new mapping m to its local theory, each peer P first computes P2P-NG(m, P) and stores locally all the nogoods $\{m\} \cup ms$, such that $ms \in$ P2P-NG(m, P) is minimal (for inclusion).

Theorem 2 states that the P2P-NG algorithm is complete, i.e., it enables to find the mapping supports of all the irredundant derivations of the empty clause from a given mapping added to a P2PIS. The proof of Theorem 2 relies on Lemma 1.

Definition 4 (Irredundant derivation) A derivation is irredundant if it does not involve two identical applications of the resolution rule.

Algorithm 1: Detection of the nogoods caused by adding a mapping P2P-NG(m, P)

```

(1) LOCAL( $P$ )  $\leftarrow$  Resolvent+SMS( $m, P$ )
(2) RESULT  $\leftarrow \emptyset$ 
(3) foreach ( $c$  sms)  $\in$  LOCAL( $P$ ) s.t.  $S(c) \neq \square$  and  $L(c) = \square$ 
(4)   foreach literal  $q \in S(c)$ 
(5)     NOGOODS( $q$ )  $\leftarrow$  P2P-NG $_l(q, ACQ(q, P), \emptyset)$ 
(6)     if for every  $q \in S(c)$  NOGOODS( $q$ )  $\neq \emptyset$ 
(7)       UNIONCOMB  $\leftarrow$  sms  $\otimes (\otimes_{q \in S(c)} NOGOODS(q))$ 
(8)     RESULT  $\leftarrow$  RESULT  $\cup$  UNIONCOMB
(9)   return RESULT

```

P2P-NG $_l(q, SP, hist)$

```

(1) if for every  $P \in SP$ ,  $(q, P, \_) \in hist$ 
(2)   return  $\emptyset$ 
(3) else
(4)   SMS( $q$ )  $\leftarrow \{\emptyset\}$ 
(5)   RESULT  $\leftarrow \emptyset$

Theorem 2 Let \mathcal{P} be a P2PIS and m a mapping of a given peer P of \mathcal{P} . Let ms be a mapping support of an irredundant derivation of \square rooted in m . It will be returned by P2P-NG(m, P).

Lemma 1 Let ms be the mapping support of an irredundant derivation of \square rooted in a clause $c: c_1 \vee \dots \vee c_n$ where every c_i is a clause (which can be a unit clause or not) such that there is no literal common to c_i and c_j for $i \neq j$. There exists ms_1, \dots, ms_n where, for every i , ms_i is a mapping support of an irredundant derivation of \square rooted in c_i , such that: $ms = ms_1 \cup \dots \cup ms_n$.

Corollary 1 results directly from Theorem 2. It guarantees that all the minimal nogoods are computed and stored in the P2PIS. It is the key for proving that the reasoning algorithm presented in the next section is well-founded.

Corollary 1 Let $T(\mathcal{P}) = \mathcal{O} \cup \mathcal{M}$ be the global theory of a P2PIS and let S be a set of mappings of \mathcal{M} . If S is a minimal nogood then it is stored at some peer P of \mathcal{P} .

Example (cont.): In the example of Section 2, let us suppose that the different peers join in the following order: P_1 , then P_2 , then P_3 and that their respective mappings are added according to their numbering. At the join of P_2 , the successive adding of the 4 mappings causes no inconsistency. When P_3 joins, the 4 first mappings cause no inconsistency. Let us focus on the 5th one. P2P-NG($\neg Journal_3 \vee Journal_2, P_3$) is triggered where P_3 is the theory containing the clauses of P_3 that are not mappings, and the 4 first mappings (which have been added since they have been checked as not deriving inconsistencies). $\neg Theory_1 \vee Journal_2$ is produced

locally at P_3 as a local consequence of $\neg Journal_3 \vee Journal_2$, with a set of local mapping support equal to $\{\{P_3.2\}\}$. Then, $\neg Theory_1 \vee Journal_2$ is splitted (Line (4) of P2P-NG): $\neg Theory_1$ is processed by P_1 , while $Journal_2$ is processed by P_2 . The propagation of $\neg Theory_1$ produces \square as a local consequence in P_1 with a local set of mapping support equal to $\{\emptyset\}$. Thus $\{\emptyset\}$ is returned to P_3 as the set of mapping supports of the derivation of \square from $Theory_1$. The propagation of $Journal_2$ produces $\neg PODS_1$ as a local consequence in P_2 , with a local set of mapping supports equal to $\{\{P_2.1\}\}$, as well as $\neg Patent_2$ with a local set of mapping support equal to $\{\emptyset\}$. $\neg PODS_1$ is in turn propagated in P_1 , where it produces \square as a local consequence with a local set of mapping supports equal to $\{\emptyset\}$. It is transmitted back to P_2 which, after combination of $\{\emptyset\}$ and $\{\{P_2.1\}\}$ (Line 15) of P2P-NG $_l$ ($Journal_2, \{P_2\}, \emptyset$), transmits back to P_3 the set of mapping supports $\{\{P_2.1\}\}$ for the derivation \square from $Journal_2$. By combination (Line 7) P2P-NG($\neg Journal_3 \vee Journal_2, P_3$) returns $\{\{P_3.2, P_2.1\}\}$. The nogood $\{P_3.5, P_3.2, P_2.1\}$ is thus obtained and stored at P_3 . No other nogood is obtained from the last mappings of P_3 .

4 Peer-to-peer well-founded reasoning

First, we have to define the notion of *well-founded* consequences that can be derived from a given input clause and a possibly inconsistent P2PIS. Many semantics have been proposed and studied for reasoning with (centralized) inconsistent theories ([14] for a survey). We adopt the following one (which is one of the simplest ones), because it makes sense in a decentralized and dynamic setting.

Definition 5 (P2P well-founded implicate) Let \mathcal{P} be an inconsistent P2PIS: r is a well-founded implicate of c w.r.t. \mathcal{P} if r is an implicate of c w.r.t. a consistent subset of $\mathcal{T}(\mathcal{P})$.

The WF-DECA(q, P) algorithm computes well-founded consequences of the (unit) clause q , starting at the peer P . This algorithm extends the original DECA consequence finding algorithm [3, 6] by computing the set of mapping supports of the derivations for each consequence, and by collecting the nogoods encountered during the reasoning. Because of the split/recombination technique used by the algorithm, mapping supports of derivations are only known after the recombination step, and the set of possibly relevant nogoods must be available at this step: if some mapping support includes a nogood, it is discarded; consequences that get an empty set of mapping supports after nogoods filtering are discarded as well.

We use the following notations :

- $LocalConsSSNG(q, P)$ is a local procedure that computes the set of triples $(c \text{ sms } sng)$ such that c is a local consequence of q w.r.t. P , sms is its corresponding set of local mapping supports, and sng is the set of nogoods stored at the peer P that contain a mapping m of some mapping support ms of c .
- \uplus denotes the *merged union* of sets of consequences, i.e. the union of sets of triples of the form $(c \text{ sms } sng)$, where triples corresponding to a same consequence c are merged together, by computing the union of their respective sms and sng .
- \oslash is the distribution union operator on sets of triples of the form $(c \text{ sms } sng)$: $S_1 \oslash \dots \oslash S_n = \{(c_1 \vee \dots \vee c_n \text{ sms}_1 \otimes \dots \otimes \text{sms}_n \text{ sng}_1 \cup \dots \cup \text{sng}_n) / (c_1 \text{ sms}_1 \text{ sng}_1 \in S_1, \dots, (c_n \text{ sms}_n \text{ sng}_n) \in S_n)\}$.

Theorem 3 states that the WF-DECA(q, P) algorithm terminates and returns only well-founded consequences. Its proof relies on showing that each triple $(c \text{ sms } sng)$ returned by WF-

Algorithm 2: Well Founded Distributed Consequence Finding Algorithm

(18)      UNIONCOMB  $\leftarrow \{(L(c) \text{ sms } sng)\} \oslash (\oslash_{l \in S(c)} ANSWER(l))$ 
(19)      foreach  $(c \text{ sms } sng) \in UNIONCOMB$ 
(20)        nsms  $\leftarrow \{ms \in sms / \forall ng \in sng, ng \not\subseteq ms\}$ 
(21)        if  $nsms \neq \emptyset$ 
(22)          RESULT  $\leftarrow$  RESULT  $\uplus \{(c \text{ nsms } sng)\}$ 
(23) return RESULT

```

DECA($q, SP, hist$) is such that either c is a local consequence of q w.r.t. some peer $P \in SP$, or for every $ms \in sms$, $\mathcal{O} \cup ms$ is consistent (using Corollary 1) and c is the result of a derivation rooted in q that only uses clauses from $\mathcal{O} \cup \{l_0, l_1, \dots, l_n, q\} \cup ms$, where l_0, l_1, \dots, l_n are the literals in $hist$.

Theorem 3 Let P be a peer of a P2PIS \mathcal{P} and q a literal belonging to the vocabulary of P . WF-DECA(q, P) terminates and for all triples $(c \text{ sms } sng)$ returned by WF-DECA(q, P), c is a well-founded consequence of q w.r.t. \mathcal{P} .

Example (cont.): Let us illustrate the behaviour of WF-DECA($Soft_3, P_3$), assuming that the only target variables are $PODS_1$ and $JAIR_1$. $Patent_2 \vee Demo_1$ is the only clause produced locally on P_3 with a local part of which (i.e. \square) in $Target(P_3)$. Its local sms is $\{\{P_3.7, P_3.3\}\}$. The only nogood stored at P_3 contains neither $P_3.7$ nor $P_3.3$. The corresponding sng returned by $LocalConsSSNG(Soft, P_3)$ is thus empty. $Patent_2 \vee Demo_1$ is then splitted. When $Patent_2$ is transmitted to P_2 , $\neg JAIR_1$ is the only clause produced locally with a local part (i.e. \square) in $Target(P_2)$. Its local sms is $\{\{P_2.3\}\}$ and its sng is empty. The further propagation of $\neg JAIR_1$ returns an empty result. So the triple $(\neg JAIR_1 \{\{P_2.3\}\} \emptyset)$ is sent back to P_3 as a consequence of $Patent_2$. When $Demo_1$ is transmitted to P_1 the only clause produced locally is $\neg JAIR_1$, which is in $Target(P_1)$. Its local sms is empty, as well as its sng . So the triple $(\neg JAIR_1 \{\emptyset\} \emptyset)$ is sent back to P_3 as a consequence of $Demo_1$. P_3 then combines these two triples obtained from P_2 and P_1 giving $(\neg JAIR_1 \{\{P_2.3\}\} \emptyset)$, which is the only final consequence of $Soft_3$ being in the target language. Since the corresponding sng is empty, it is trivially a well-founded consequence.

5 Conclusion and Related Work

We have presented a fully decentralized approach for reasoning with inconsistencies in propositional P2PIS. Nogoods are discovered each time a new mapping is added. Though these are stored in a completely distributed way, the WF-DECA algorithm guarantees that all consequences it returns are well-founded. For lack of place, many optimization details have been omitted. In particular, calculating *all* possible mapping supports of each consequence is not necessary. Computing only the minimal ones is sufficient. The implementation of this approach is currently under process. An extensive experimental study in the spirit of that of [4, 6] is planned for the near future.

For efficiency reasons our approach for P2P reasoning with more powerful languages is to approximate the peer theories and the queries into propositional logic and to exploit the current infrastructure to compute the corresponding propositional answers. The actual answers are then computed by focusing on the relevant peers.

Reasoning under inconsistency has been widely studied in artificial intelligence, but mainly in the centralized case. There are two kinds of strategies for dealing with inconsistent knowledge bases. The first one is to restore consistency as in belief revision [7, 16]. In the context of peer-to-peer interconnected databases, although not strictly restoring consistency, the work of [9] characterizes consistent answers as those that can be drawn from all minimal repairs of all peer databases and that satisfy as well a set of data exchange constraints (similar to mappings) relating the different peer schemes.

The alternative is just to tolerate inconsistency [10]. In a fully decentralized setting, all peers playing the same role, this seems far more preferable. A wide range of paraconsistent logics have been proposed [20] to avoid the trivialization problem of classical logic. Our approach is closer to coherence systems and argumentative approaches [14], since we consider consequences that can be produced from consistent subsets of $\mathcal{T}(\mathcal{P})$. Since \mathcal{O} is known to be consistent, mapping supports can be considered as justifications supporting the consequences. Our approach is a credulous one, since any subset of \mathcal{M} consistent with \mathcal{O} is considered. Well-founded consequences can also be viewed as either local consequences or as the formulas of some extension of the supernormal default theory [11] $\Delta = (\mathcal{O}, \mathcal{M})$.

The work of [19] on reasoning from inconsistent ontologies is another kind of coherence-based approach. For a given query, it aims at finding a specific consistent subset of the global theory, in which the query (or its negation) classically holds. If it is not possible, the answer is undetermined. The set is constructed by successive consistent expansions, according to some selection function measuring some relevance criterion with the query. They use a syntactical criteria, that selects only formulas sharing some variable with those already selected during the previous iterations. Limiting the choice for the consistent subset clearly reduces the set of accepted consequences.

An epistemic semantics has been proposed in [13] to deal with possible inconsistencies in a P2P Data Inference Systems formalized in a first order multi modal language. It considers the case of local inconsistency (a point not addressed by our approach) as well as global inconsistency. Mapping are formalised in such a way that they cannot be used to propagate information from some locally inconsistent theory. Moreover mappings can only be used to propagate information to a peer, as far as they do not contradict either local information or other non-local information that may be deduced on that peer.

Distributed CSP techniques [24, 23] aim at finding consistent assignments of a set of variables, satisfying a set of distributed constraints. They also propagate nogoods corresponding to invalid partial affectations, that are further stored on the peer that receives them.

This tends to replicate among all agents some global knowledge. This is also the case in distributed ATMS [21]. In comparison, we exploit nogoods only at reasoning time. Only those that may interfere with some mapping support of a related *sms* are transmitted in the *sng*.

Conceptual hierarchies matching: an approach based on discovery of implication rules between concepts

Jérôme David and Fabrice Guillet and Régis Gras and Henri Briand¹

Abstract. Most research works about ontology or schema matching are based on symmetric similarity measures. By transposing the association rules paradigm, we propose to use asymmetric measures in order to enhance matching. We suggest an extensional and asymmetric matching method based on the discovery of significant implications between concepts described in textual documents. We use a probabilistic model of deviation from independence, named implication intensity. Our method is divided into two consecutive stages: (1) the extraction in documents of relevant terms for each concept; (2) the discovery of significant implications between the concepts. Our method is tested on two benchmarks. The results show that some relevant relations, ignored by a similarity-based matching, can be found thanks to our approach.

Keywords: ontology matching, term extraction, implication intensity, extensional matching, association rules.

1 Introduction

With the increase of electronic data and knowledge on the Internet or in companies, the hierarchical categorization of data through ontological forms as taxonomies has been widely used. Web directories such as Yahoo.com and OpenDirectory, the Electronic Document Management, or the Semantic Web with its OWL ontology are examples of such taxonomies.

In the literature, a lot of works deals with schema/ontology matching. The schema or ontology matching aims at finding semantic relations (i.e. equivalence, subsomption, etc) between entities (i.e. concepts, properties) of two schemas/ontologies. These approaches use various techniques such as machine learning [7], FCA-Analysis [17], database schema matching [12], graph matching [13]. These approaches are commonly based on similarity measures for discovering equivalence relations between concepts.

However, the extracted matchings can be enhanced by using asymmetric measures, which deliver more accurate information in the form of implications between concepts. In knowledge discovery in databases (KDD), asymmetric measures, called interestingness measures, are widely used for association rules discovery [1]. Association rules are expressions of the type "if *antecedant* then *consequent*" representing implicative tendencies between conjunctions of attributes in databases. In this paper, we evaluate the use of such asymmetric measures for matching concepts of schemas or ontologies by using the Implication Intensity [9, 2], a probabilistic model of deviation from statistical independence.

Our matching method is both extensional and terminological. It is designed to be used on taxonomies of concepts associated with

textual documents. The idea underlying our approach considers that one concept is more specific than another, if the vocabulary used in the documents associated to the first concept tends to be included in the vocabulary of the other one.

Our method is divided into two consecutive stages: (1) The extraction of concept-relevant terms; (2) The discovery of association rules between concepts.

This paper is organized as follows. In a first section we give an overview of matching approaches. Then, we introduce the Implication Intensity measure, and the concept hierarchy model, and the used formalism. Next, we apply the two stages of our method focusing on rule extraction. Finally, we experiment our method on two datasets and discuss the results obtained.

2 Related works

Many surveys about ontology and schema matching have been proposed in litterature [10], [15], [16]. The two last ones propose a classification and a comparative study of matching approaches. The survey [15] focuses on the database schema matching approaches, while [16] reuses this classification for ontology matching. From these surveys we can distinguish: the extensional approaches (or element-based), and the intensional approaches (or only-schema-based). The matching approaches can be also discriminated regarding the kind of relations that they are based on. Some consider symmetric (equivalence) relations, while other ones also use asymmetric relations such as the subsomption or implication.

The main part of these works propose to process the concept name by using string-similarities (Anchor-PROMPT [14], Cpuid [12], Coma [5], S-MATCH [8]) or/and external oracles such as Wordnet ([8]). They can also use the schema or ontology structure (Similarity Flooding [13], Artemis [3], [5], [14], [12]).

Most of these approaches are intensional and symmetric. None of them are both asymmetric and extensional. Among extensional approaches, we can cite GLUE [6]. This symmetric approach uses Bayesian learners in order to classify instances of the first ontology into the other and vice-versa in order to estimate the joint probability distribution and then predict concept similarities.

We can also notice that there is only one intensional method considering asymmetric relations. The method S-MATCH [8] searches equivalence (=) relation between concepts but also the more general (\sqsupseteq), less general (\sqsubseteq), mismatch (\perp) and overlapping (\sqcap) relations. This method uses a lot of single matchers: 13 linguistic-based matchers and 3 logic-based matchers.

3 The definition of the Implication Intensity

Let us now consider a finite set T of n individuals described by a set I of p items. Each transaction t can be considered as an itemset so that $t \subseteq I$. $A = \{t \in T; a \subseteq t\}$ is the extension of itemset a and $\bar{B} = T - \{t' \in T; b \subseteq t'\}$ is the extension of \bar{b} . Then, we introduce the quantities $n_a = \text{card}(A)$, $n_{\bar{b}} = \text{card}(\bar{B})$ and $n_{a \wedge \bar{b}} = \text{card}(A \cap \bar{B})$.

An association rule [1] is an implication of the form $a \rightarrow b$, where a and b are disjoined itemsets. In practice, it is quite common to observe a few transactions which contain a and not b without having the general trend to have b when a is present. Therefore, the number $n_{a \wedge \bar{b}}$ of counter-examples must be taken into account to statistically accept to retain or not the rule $a \rightarrow b$.

More precisely, we compare the observed number of counter-examples $n_{a \wedge \bar{b}}$ to a probabilistic model noted $N_{a \wedge \bar{b}}$. Let us assume that we randomly draw two subsets X and Y in T which respectively contain n_a and n_b transactions, i.e. $N_{a \wedge \bar{b}} = \text{card}(X \cup \bar{Y})$.

The implication intensity of the association rule $a \rightarrow b$ is defined by:

$$\varphi(a \rightarrow b) = 1 - \Pr(N_{a \wedge \bar{b}} \leq n_{a \wedge \bar{b}}) \quad (1)$$

The distribution of the random variable $N_{a \wedge \bar{b}}$ depends on the drawing mode [9]. It is established that, under some conditions, the random variable $N_{a \wedge \bar{b}}$ follows a Poisson law with $\lambda = n_a n_{\bar{b}} / n$.

4 Concept hierarchy model and formalisms used

Our approach (figure 1) is designed for conceptual hierarchies of concepts organized by a partial order relation, connected to a set of textual documents.

We define a conceptual hierarchy \mathcal{H} as a quadruplet:

$$\mathcal{H} = (C, \leq, D, \sigma_0) \quad (2)$$

where C is a set of concepts, \leq represents the partial order, D is the set of documents, and σ_0 is the relation which associates a set of documents to each concept (i.e. for a concept $c \in C$, $\sigma_0(c)$ represents the documents associated to c). From the partial order \leq , we extend the relation σ_0 to σ , where:

$$\sigma(c) = \bigcup_{c' \leq c} \sigma_0(c') \quad (3)$$

Then, we transform the hierarchy \mathcal{H} defined on documents in a hierarchy \mathcal{H}' defined on terms as follows:

$$\mathcal{H}' = (C, \leq, T, \gamma_0) \quad (4)$$

where T is the set of relevant terms extracted from D , and $\gamma_0 \subseteq C \times T$ is the relation associating terms to concepts (i.e. $\gamma_0(c)$ represents the set of relevant terms selected for the concept c). Technically, γ_0 is deduced from σ and the relation δ linking terms to documents (i.e. $\delta(t)$ is the set of documents in which the term t appears). From the partial order \leq , we extend the relation γ_0 to γ , where:

$$\gamma(c) = \bigcup_{c' \leq c} \gamma_0(c') \quad (5)$$

The common term set of two hierarchies $\mathcal{H}'_1 = (C_1, \leq_1, T_1, \gamma_1)$ and $\mathcal{H}'_2 = (C_2, \leq_2, T_2, \gamma_2)$ is noted $T_{1 \cap 2} = T_1 \cap T_2$. Next, we define the relation $\gamma_{1 \cap 2}$ which associates a subset of $T_{1 \cap 2}$ for each concept $c \in C_1 \cup C_2$:

$$\gamma_{1 \cap 2}(c) = \begin{cases} \gamma_1(c) \cap T_2 & \text{if } c \in C_1 \\ \gamma_2(c) \cap T_1 & \text{if } c \in C_2 \end{cases} \quad (6)$$

An implicative match set between two hierarchies \mathcal{H}'_1 and \mathcal{H}'_2 is a set of implicative rules. A rule $a \rightarrow b$ between the concepts $a \in C_1$ and $b \in C_2$ represents a quasi-implication from the set of terms $\gamma_{1 \cap 2}(a)$ to the set of terms $\gamma_{1 \cap 2}(b)$.

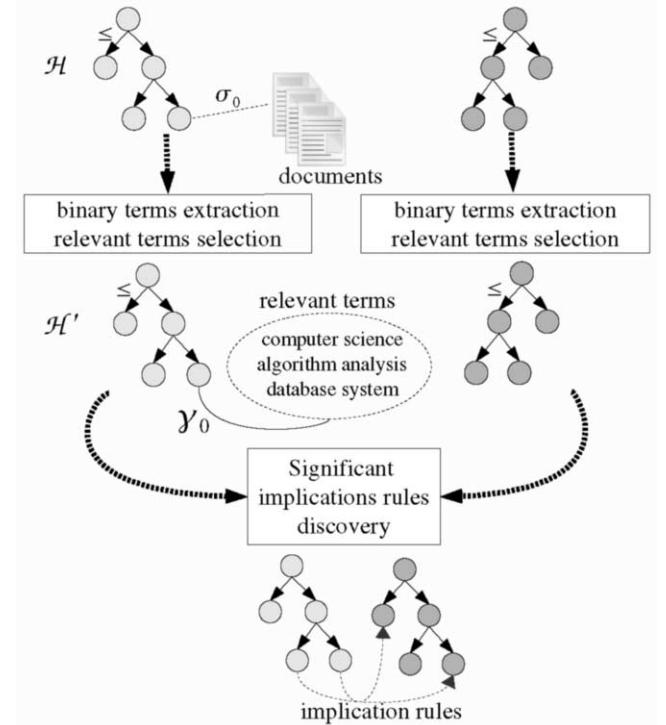

Figure 1. Methodology scheme

5 Extraction and selection of relevant terms

The goal of this process is to extract terms from the documents and then select relevant terms for each concept of the two hierarchies. A term t will be relevant for concept c if t tends to appear in the documents associated with concept c . We choose to associate the term t with concept c if the rule $t \rightarrow c$ has an implication intensity value greater than a given threshold φ_t .

In order to evaluate the rules $t \rightarrow c$, we first extract T_0 , the set of the binary terms (terms composed of two meaningful words) and of the verbs contained in the documents. Binary terms have the advantage to be less ambiguous than simple words. The acquisition of binary terms is performed by software program ACABIT [4]. The textual data are firstly POS-tagged and stemmed by the software program Montylingua [11]. The figure 2 summarizes the term extraction process.

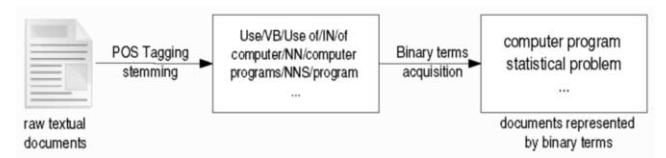

Figure 2. Terms extraction process

Next, we compute all the rules $t \rightarrow c$ and the selection of the relevant terms set of a concept c (noted $\gamma_0(c)$) is defined as follows:

$$\gamma_0(c) = \{t \in T_0 \mid \varphi(t \rightarrow c) \geq \varphi_t\} \quad (7)$$

where φ_t is the implication intensity threshold value and $\varphi(t \rightarrow c)$ is the implication intensity values of the rule $t \rightarrow c$ defined by:

$$\varphi(t \rightarrow c) = 1 - \Pr(N_{t \wedge \bar{c}} \leq n_{t \wedge \bar{c}}) \quad (8)$$

$n_{t \wedge \bar{c}} = \text{card}(\delta(t) - \sigma(c))$ is the observed number of counter-examples, that is to say documents which contain the term t and which are not associated with the concept c . And $N_{t \wedge \bar{c}}$ is the expected number of counter-examples under independence hypothesis.

6 Discovery of significant rules between concepts

6.1 Selection criteria of significant rules

In section 4, we have defined a match result as a set of implication rules between concepts issued from two hierarchies \mathcal{H}_1 and \mathcal{H}_2 . Nevertheless, a lot of rules can be discovered. In this section, we define the implication intensity of a rule between concepts, and then we give two criteria defining the notion of significant rule.

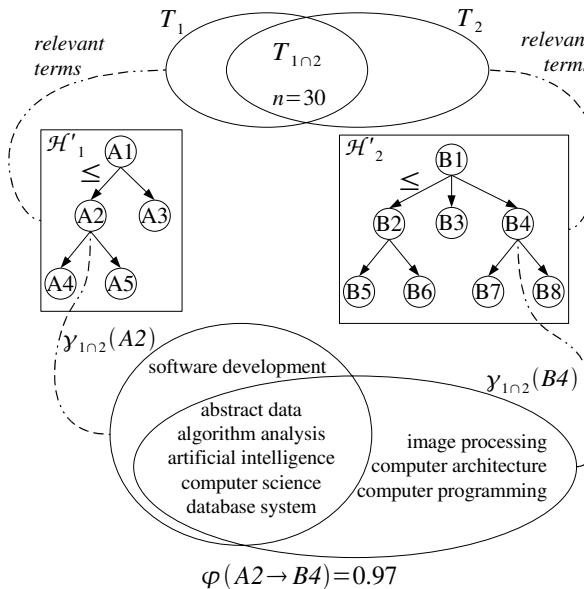

Figure 3. Evaluation of significant rules

The implication intensity of a rule $a \rightarrow b$ (with $a \in C_1$ and $b \in C_2$) is defined by:

$$\varphi(a \rightarrow b) = 1 - \Pr(N_{a \wedge \bar{b}} \leq n_{a \wedge \bar{b}}) \quad (9)$$

where $n_{a \wedge \bar{b}} = \text{card}(\gamma_{1 \cap 2}(a) - \gamma_{1 \cap 2}(b))$ is the number of relevant terms for concept a which are not relevant for concept b . $N_{a \wedge \bar{b}}$ is the expected number of relevant terms for concept a which are not relevant for concept b . On figure 3, the rule $A2 \rightarrow B4$ has $n_{A2 \wedge \bar{B}4} = 1$ counter-examples. Its implication intensity value is:

$$\varphi(A2 \rightarrow B4) = \sum_{k=0}^{n_{A2 \wedge \bar{B}4}} e^{-\lambda} \cdot \frac{\lambda^k}{k!} = 0,97$$

where $\lambda = n_{A2} \cdot n_{\bar{B}4} / n = 6 \times 22 / 30$ (see figure 3).

Thus, the two criteria defining a significant rule are, first, its implication intensity value and, second, the specificity of its consequent combined with the generality of its antecedent. A rule $a \rightarrow b$ (with $a \in C_1$ and $b \in C_2$) will be significant if:

$$\varphi(a \rightarrow b) \geq \varphi_r \quad (10)$$

$$\text{and } \forall x \geq a, \forall y \leq b, \varphi(x \rightarrow y) \leq \varphi(a \rightarrow b) \quad (11)$$

The second criterion (equation 11) selects only generative rules and then permits to reduce redundancy in the extracted rules set. Indeed, from a significant rule $a \rightarrow b$, we can deduce all the rules of the form $u \rightarrow v$ (with $u \leq_1 a$ and $b \leq_2 v$) because at the term level: $\gamma_{1 \cap 2}(b) \subseteq \gamma_{1 \cap 2}(v)$ and $\gamma_{1 \cap 2}(u) \subseteq \gamma_{1 \cap 2}(a)$. We say that the rule $a \rightarrow b$ is generative of the rules set $u \rightarrow v$. For example (figure 3), the rule $A2 \rightarrow B4$ is generative of the rules set $\{A2 \rightarrow B1, A4 \rightarrow B4, A5 \rightarrow B4, A4 \rightarrow B1, A5 \rightarrow B1\}$.

6.2 Algorithms for rule extraction

During the rule extraction step, we can reduce the computation time with the help of the partial order. A top-down search phase enables us to avoid the evaluation of rules having too specific antecedents. This section presents our selection strategy divided into two algorithms.

```

Inputs :
  a : a concept of  $\mathcal{H}_1$ .
Input/Output variables :
   $\mathcal{B}_{current}$  : a set of concepts taking from  $\mathcal{H}_2$ .
  ruleList : the list of selected rules.
Procedure specializeAntecedent( $a, \mathcal{B}_{current}, ruleList$ )
Begin
  ForEach  $b_x \in \mathcal{B}_{current}$  Do
    specializeConsequent( $a, b_x, \mathcal{B}_{current}, 0.0, ruleList$ )
  End Do
  ForEach child  $\in children(a)$  do
     $\mathcal{B}'_{current} := \mathcal{B}_{current}$ 
    specializeAntecedent(child,  $\mathcal{B}'_{current}, ruleList$ )
  End Do
End

```

Figure 4. Algorithm specializing the antecedent

Our first algorithm (figure 4) takes in a concept a from the hierarchy \mathcal{H}_1 and a set of concepts $\mathcal{B}_{current} \subset C_2$ from \mathcal{H}_2 . For each concept of $\mathcal{B}_{current}$, the second algorithm (figure 5) searches and selects valid consequents. It also updates the set $\mathcal{B}_{current}$. And then, this first procedure is recursively launched over the children of a and with a copy of the set $\mathcal{B}_{current}$. The set $\mathcal{B}_{current}$ contains the subtrees of \mathcal{H}_2 with concepts that were selected during the previous recursion steps.

The second algorithm (figure 5) searches a set of valid consequents for the current antecedent a . The search is performed over the set candidate consequents $\{B_x \mid B_x \leq_2 B\}$. A consequent b_s will be selected if the rule $a \rightarrow b_s$ satisfies the two criteria 10 and 11.

This algorithm provides a top-down search of rules in \mathcal{H}_2 , and then explores all branches of the hierarchy. We choose to stop the descent in a branch if $\forall b'_x \leq_2 b_x, \varphi(a \rightarrow b'_x) < \varphi_r$. For a rule $x \rightarrow y$, a property of implication intensity defines $x \cup y$ as the best specialization of the consequent. We exploit this property in order to avoid the evaluation of all rules $a \rightarrow b'_x$.

The describing search method does not consider the roots of hierarchies because all selected terms are associated to root-concepts. The implication intensity value of such rules (i.e. rules which contain root-concepts) is either undefined or equals to 0.

```

Global variable :
 $\varphi_r$  : The Implication Intensity threshold
Inputs :
  a : a concept of  $\mathcal{H}_1$ .
  b : a concept of  $\mathcal{H}_2$ .
   $\varphi_{max}$  : The best value  $\varphi(a \rightarrow b_p)$  with  $b \leq b_p$ 
Input/Output variables :
   $\mathcal{B}_{current}$  : the list of "current" concepts taking from  $\mathcal{H}_2$ .
  ruleList : the list of selected rules.
return value :
  The value  $\varphi$  of the best rule  $a \rightarrow b_x$  with  $b_x \leq b$ 

Function specializeConsequent( $a, b, \mathcal{B}_{current}, \varphi_{max}, ruleList$ )
Begin
  bestChild := FALSE
   $\varphi_{current} := \varphi(a, b)$ 
  returnVal :=  $\varphi_{current}$ 
  If ( $\varphi_{current} < \varphi_r$ ) then
     $\varphi' := \varphi(a, a \cap b)$ 
    If ( $\varphi' < \varphi_r$ ) then
      return  $\varphi_{current}$ 
    EndIf
  EndIf
  ForEach child  $\in children(b)$  do
     $\varphi_{child} := specializeConsequent(a, child, \mathcal{B}_{current}, ruleList)$ 
    If ( $\varphi_{child} \geq \varphi_{current}$ ) then
      bestChild := TRUE
       $\mathcal{B}_{current} := \mathcal{B}_{current} - \{b\}$ 
      If ( $returnVal < \varphi_{child}$ ) then
        returnVal :=  $\varphi_{child}$ 
      EndIf
    EndIf
    If ( $\varphi_{current} > \varphi_r$ ) and  $\neg(bestChild)$  and ( $\varphi_{current} \geq \varphi_{max}$ ) then
      ruleList := ruleList  $\cup (a \rightarrow b)$ 
       $\mathcal{B}_{current} := \mathcal{B}_{current} \cup \{b\}$ 
       $\varphi_{max} := \varphi_{current}$ 
    EndIf
  EndDo
  return returnVal
End

```

Figure 5. Algorithm specializing consequent

7 Experiments

In this section, we choose to compare our method results with a benchmark which is manually matched. We do not confront our results with those provided by other approaches because among the few extensional approaches proposed in the litterature, none are asymmetric. This fact implies that we must "symmetrize" our results before making any experimental comparison with other extensional approaches. This "symmetrization" introduces a strong bias.

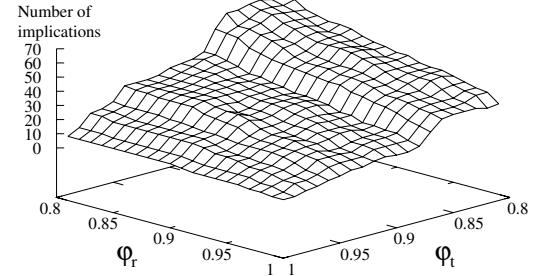

7.1 The analysed data

We experimented our algorithms on two benchmarks proposed in [7]. The first benchmark "Course catalog" describes courses which are proposed at the Cornell and Washington universities. The courses descriptions are hierarchically organised. These two hierarchies contain respectively 166 and 176 concepts to which are associated 4360 and 6957 textual course descriptions. The second benchmark "Company profiles" is issued from the web directories Yahoo.com and Standard.com. These hierarchies describe respectively 13634 and 9504 companies. These company profiles are respectively organised into 115 and 333 sectors and industries.

7.2 Results

We perform both a quantitative test and a qualitative test over the datasets. First, we vary the term threshold φ_t and the rule threshold φ_r in order to analyse their influence over the amount of discovered rules. Secondly, we compare our experimental results with manual matching reference. We vary the thresholds values from 0.8 to 1 for the two tests.

Number of implications between Cornell and Washington course catalogs

Number of implications between Yahoo.com and Standard.com directories

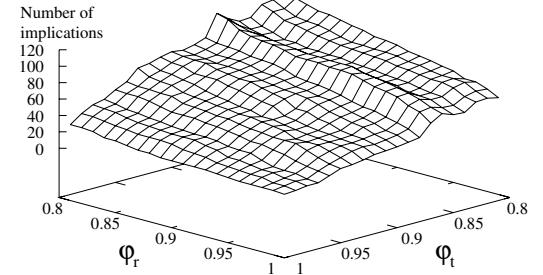

Figure 6. Influence of threshold values over the amount of selected rules

The two graphs of figure 6 shows that the terms selection threshold φ_t has a greater influence than the rule selection threshold φ_r . For example, a φ_t increase of 0.1 unit entails a decrease of 2.15 rules while the same increase of 0.1 unit for φ_r only entails a decrease of 1.2 rules.

Secondly, we perform the qualitative test of precision and recall with the "course catalog" dataset. We compare the results produced by our approach with a reference matching pair set provided by [7]. However their relations are symmetric while ours are asymmetric. Consequently we only retain equivalence relations from ours results (If $a \rightarrow b$ and $b \rightarrow a$ then $a \leftrightarrow b$). Finally, we built the two following graphs respectively representing the evolution of the precision value and the evolution of the recall value in function of chosen threshold values φ_t and φ_r . These two measures issued from information retrieval are defined as follows: let us consider F the set of matching pairs found using our approach and R the set of "reference" matching pairs. The precision ($precision = card(F \cap R)/card(F)$) measures the share of real matching pairs among all found ones. The recall ($recall = card(F \cap R)/card(R)$) measures the share of real correspondances that is found.

Figure 7 shows that the term selection threshold φ_t has a greater influence than the rule selection threshold φ_r . We obtain good precision values (from 0.71 to 1). Nevertheless, the recall values are quite bad: we notice an average recall value equals to 0.29. The best value is equal to 0.54. Our method seems to be too selective.

We found two arguments explaining these recall results. The former is related to the term selection phase. Indeed, a lot of leaves-concepts of the hierarchies cannot be compared to other concepts because they do not have relevant terms selected. Leaves-concepts are not associated with a lot of documents, so it is difficult to assign relevant terms to those concepts. The latter reason, is due to the kind of studied relations. We consider in our approach implicative relations from which we deduce equivalence relations. For example, if

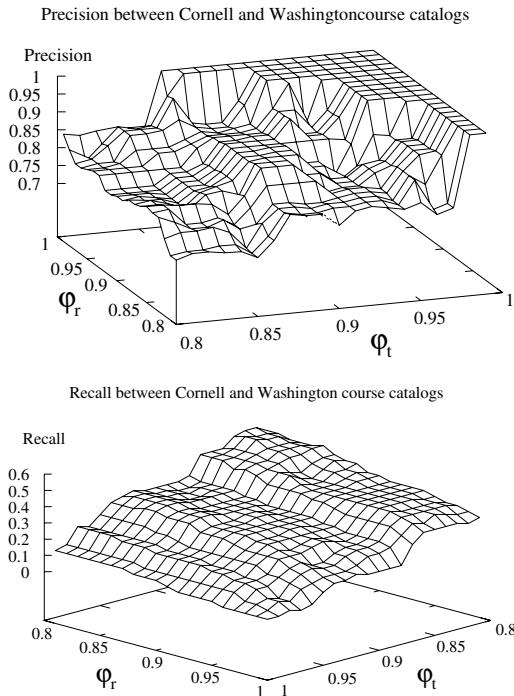

Figure 7. Thresholds values influence over the precision and the recall

we hold the term selection threshold φ_t to 0.83 and the rule selection threshold φ_r to 0.82, we obtain 24 false positives. Among them, 6 are considered as simple implications and not equivalence.

However, our method discovered some meaningful rules which are not in the manual matching reference. For example, we have obtain : From Cornell to Washington :

City and Regional Planning → Urban Planning URBDP
Cognitive Studies Program → Psychology PSYCH

Department of Aerospace Studies → Aerospace Studies A S
Electrical and Computer Engineering → Electrical Engineering E E

From Washington to Cornell :

Atmospheric Sciences ATM S → Earth and Atmospheric Sciences

Our approach is not sensitive to concept name: it led to the following rule "Cognitive Studies Program → Psychology PSYCH" that would not be found with an approach based on string similarity. The selection of relevant terms for concepts permits to take into account the semantics of the concepts.

8 Conclusion

In this paper, we proposed an extensional matching method based on the discovery of significant implication rules between concepts. Our approach takes in two hierarchies of concepts to be matched and the textual corpus indexed to these concepts. The matching task is divided into two stages: (1) the extraction and selection of relevant terms for each concepts; (2) the discovery of significant rules between concepts by using their relevant terms set. The main advantages of this method are the consideration of semantic by using binary terms contained in the corpus and the discovery of rules allowing to enhance the produced matching results only regarding

similarity-based matching systems. We implemented and tested our algorithms with two real catalogs respectively related to company profiles and course catalogs. The results show that we distinguish implication and equivalence relations. We can also notice that our prototype has found several relevant relations not considered by the manual reference matching pair set.

In our point of view, and after a study of related works, our method seems really novel and unique because: (1) it works on terminological level and not on the document level, (2) it is based on asymmetric relations (which offer a stronger semantic for user), (3) it operates an original reduction of rule redundancies.

Currently, we propose an extensional individual matcher. In the near future, we will propose a schema based matcher and combine the two approaches in order to enhance the ontology matching task.

CTL Model Update: Semantics, Computations and Implementation

Yulin Ding and Yan Zhang¹

Abstract. Minimal change is a fundamental principle for modeling system dynamics. In this paper, we study the issue of minimal change for Computational Tree Logic (CTL) model update. We first propose five primitive operations which capture the basic update of the CTL model, and then define the minimal change criteria for CTL model update based on these primitive operations. We provide essential semantic and computational characterizations for our CTL model update approach. We develop a formal algorithm to implement this update that employs the underlying minimal change principle. We also present a CTL model update example using the well known microwave oven scenario.

1 Introduction

Over the past decade, automated formal verification tools, such as model checkers, have shown their ability to provide a thorough automatic error diagnosis in complex designs, e.g. [10]. The current state of the art model checkers, such as SMV [4], NuSMV [3] and Cadence SMV [9], employ SMV specification language for both CTL and Linear Temporal Logic (LTL) model checking. Other model checkers such as SPIN [7] use Promela specification language for on the fly LTL model checking. Also, the MCK [5] model checker was developed by integrating a knowledge operator to verify the knowledge related properties in security protocols.

Along with model checking, error repair has begun to employ a formal methods approach. Buccafurri et al. [2] used abductive model revision techniques to repair errors in concurrent programs. They aimed at using techniques and concepts from model checking by combining them with AI principles. In the paper of Harris and Ryan [6], model checking is formalized with a belief updating operator to satisfy classical proposition knowledge update KM postulates U1-U8. Baral and Zhang [1] presented a formal approach of knowledge update based on single agent S5 Kripke structures. As they argued, their approach of knowledge update could be integrated with model checking technology towards a more general automatic system modification. In this paper, we consider the problem of CTL model update from both theoretical and implementational perspectives. We first consider five primitive CTL model update operations, and based on these operations, we define a minimal change principle for CTL model update. We then investigate the essential semantic and computational properties of CTL model update. Based on these findings, we develop an algorithm to perform CTL model update. By presenting a case study, we also show how our system prototype is applied for system modification.

2 CTL Syntax and Semantics: An Overview

To begin with, we briefly review the syntax and semantics of CTL. Readers are referred to [4] and [8] for details.

Definition 1 [4] Let AP be a set of atomic propositions. A Kripke model M over AP is a three tuple $M = (S, R, L)$ where

1. S is a finite set of states,
2. $R \subseteq S \times S$ is a transition relation,
3. $L : S \rightarrow 2^{AP}$ is a function that assigns each state with a set of atomic propositions.

Definition 2 [8] Computation tree logic (CTL) has the following syntax given in Backus naur form:

$$\begin{aligned} \phi ::= & \top \mid \perp \mid p \mid (\neg\phi) \mid (\phi \wedge \psi) \mid (\phi \vee \psi) \mid \phi \supset \psi \mid AX\phi \mid EX\phi \\ & \mid AG\phi \mid EG\phi \mid AF\phi \mid EF\phi \mid A[\phi \cup \psi] \mid E[\phi \cup \psi] \end{aligned}$$

where p is any propositional atom.

A CTL formula is evaluated on a Kripke model M . A path in M from a state s is an infinite sequence of states $\pi \stackrel{\text{def}}{=} [s_0, s_1, \dots, s_{i-1}, s_i, s_{i+1}, \dots]$ such that $s_0 = s$ and $(s_i, s_{i+1}) \in R$ holds for all $i \geq 0$. We write $(s_i, s_{i+1}) \subseteq \pi$ and $s_i \in \pi$. If we express a path as $\pi = [s_0, s_1, \dots, s_i, \dots, s_j, \dots]$ and $i < j$, we say that s_i is a state *earlier* than s_j in π as $s_i < s_j$. For simplicity, we may use $\text{succ}(s)$ to denote state s' if there is a relation (s, s') in R .

Definition 3 [8] Let $M = (S, R, L)$ be a Kripke model for CTL. Given any s in S , we define whether a CTL formula ϕ holds in state s . We denote this by $(M, s) \models \phi$. The satisfaction relation \models is defined by structural induction on all CTL formulas:

1. $(M, s) \models \top$ and $M, s \not\models \perp$ for all $s \in S$.
2. $(M, s) \models p$ iff $p \in L(s)$.
3. $(M, s) \models \neg\phi$ iff $(M, s) \not\models \phi$.
4. $(M, s) \models \phi_1 \wedge \phi_2$ iff $(M, s) \models \phi_1$ and $(M, s) \models \phi_2$.
5. $(M, s) \models \phi_1 \vee \phi_2$ iff $(M, s) \models \phi_1$ or $(M, s) \models \phi_2$.
6. $(M, s) \models \phi_1 \rightarrow \phi_2$ iff $(M, s) \not\models \phi_1$, or $(M, s) \models \phi_2$.
7. $(M, s) \models AX\phi$ iff for all s_1 such that $(s, s_1) \in R$, $(M, s_1) \models \phi$.
8. $(M, s) \models EX\phi$ iff for some s_1 such that $s \rightarrow s_1$, $(M, s_1) \models \phi$.
9. $(M, s) \models AG\phi$ holds iff for all paths $[s_0, s_1, s_2, \dots]$, where $s_0 = s$, and all s_i along the path, $(M, s_i) \models \phi$.
10. $(M, s) \models EG\phi$ holds iff there is a path $[s_0, s_1, s_2, \dots]$, where $s_0 = s$, and for all s_i along the path, $(M, s_i) \models \phi$.
11. $(M, s) \models AF\phi$ holds iff for all paths $[s_0, s_1, s_2, \dots]$, where $s_0 = s$, there is some s_i in the path such that $(M, s_i) \models \phi$.
12. $(M, s) \models EF\phi$ holds iff there is a path $[s_0, s_1, s_2, \dots]$, where $s_0 = s$, and for some s_i along the path, $(M, s_i) \models \phi$.

13. $(M, s) \models A[\phi_1 \cup \phi_2]$ holds iff for all paths $[s_0, s_1, s_2, \dots]$, where $s_0 = s$, the path satisfies $\phi_1 \cup \phi_2$, i.e. there is some s_i along the path, such that $(M, s_i) \models \phi_2$, and, for each $j < i$, $(M, s_j) \models \phi_1$.
 14. $(M, s) \models E[\phi_1 \cup \phi_2]$ holds iff there is a path $[s_0, s_1, s_2, \dots]$, where $s_0 = s$, the path satisfies $\phi_1 \cup \phi_2$, i.e. there is some s_i along the path, such that $(M, s_i) \models \phi_2$, and, for each $j < i$, $(M, s_j) \models \phi_1$.

In the rest of this paper, without explicit declaration, we will assume that all CTL formulas occurring in our context will be satisfiable. For instance, when we consider to update a Kripke model with a CTL formula ϕ , we already assume that ϕ is satisfiable.

3 Minimal Change for CTL Model Update

Given a CTL kripke model and a (satisfiable) CTL formula, we consider how this model can be updated in order to satisfy the given formula. We first give the following general definition on CTL model update.

Definition 4 (CTL Model Update) Given a CTL Kripke model $M = (S, R, L)$ and a CTL formula ϕ . An update of $M = (M, s_0)$ where $s_0 \in S$ with ϕ is a CTL Kripke model $M' = (S', R', L')$ such that $M' = (M', s'_0) \models \phi$ where $s'_0 \in S'$. We use $\text{Update}(M, \phi)$ to denote the result M' and $\text{Update}(M, \phi) = M$ if $M \models \phi$.

Definition 4 only presents an essential requirement for a CTL model update and does not tell how such update should be conducted. Basically, as in traditional knowledge base update [11], we would expect that a CTL model update obeys an underlying minimal change principle. Furthermore, this minimal change should be defined based on some operational process so that a concrete algorithm for CTL model update can be implemented. To this end, we first consider five primitive operations on the CTL model that provide a basis for all complex CTL model updates.

3.1 Primitive Operations

The operations to update the CTL model can be decomposed into five types identified as PU1, PU2, PU3, PU4 and PU5. These primitive updates are defined in their simplest forms as follows.

PU1: Adding a relation only

Given $M = (S, R, L)$, its updated model $M' = (S', R', L')$ is the result of M having only added one new relation. That is $S' = S$, $L' = L$, and $R' = R \cup \{(s_{ar}, s_{ar2})\}$ where $(s_{ar}, s_{ar2}) \notin R$ for one pair of $s_{ar}, s_{ar2} \in S$.

PU2: Removing a relation only

Given $M = (S, R, L)$, its updated model $M' = (S', R', L')$ is the result of M having only removed one existing relation. That is, $S' = S$; $L' = L$, and $R' = R - \{(s_{rr}, s_{rr2})\}$ where $(s_{rr}, s_{rr2}) \in R$ for one pair of $s_{rr}, s_{rr2} \in S$.

PU3: Substituting a state and its associated relation(s) only

Given $M = (S, R, L)$, its updated model $M' = (S', R', L')$ is the result of M having only substituted one existing state and its associated relation(s). That is, $S' = S[s/s_{ss}]$ (i.e. S' is the set of states where one state s in S is substituted by s_{ss}), $R' = R \cup \{(s_i, s_{ss}), (s_{ss}, s_j) \mid (s_i, s), (s, s_j) \in R\} - \{(s_i, s), (s, s_j) \mid (s_i, s), (s, s_j) \in R\}$, and $L'(s) = L(s)$ for all $s \in S \cap S'$ and $L'(s_{ss}) = \tau(s_{ss})$, where τ is a truth assignment on s_{ss} .

PU4: Adding a state and its associated relation(s) only

Given $M = (S, R, L)$, its updated model $M' = (S', R', L')$ is the

result of M having only added one new state and its associated relation(s). That is, $S' = S \cup \{s_{as}\}$, $R' = R \cup \{(s_i, s_{as}), (s_{as}, s_j) \mid$ for some $s_i, s_j \in S \cap S'\}$, and $L'(s) = L(s)$ for all $s \in S \cap S'$ and $L'(s_{as}) = \tau(s_{as})$, where τ is the truth assignment on s_{as} .

PU5: Removing a state and its associated relation(s) only

Given $M = (S, R, L)$, its updated model $M' = (S', R', L')$ is the result of M having only removed one existing state and its associated relation(s). That is, $S' = S - \{s_{rs} \mid s_{rs} \in S\}$, $R' = R - \{(s_i, s_{rs}), (s_{rs}, s_j) \mid$ for some $s_i, s_j \in S\}$, and $L'(s) = L(s)$ for all $s \in S \cap S'$ (note $S' \subset S$).

We call the above five operations *atomic* since all changes on a CTL model can be expressed by these five operations. It may be argued that PU3 can be expressed by PU4 and PU5. However, we will treat state substitution differently from a combination of state addition and state deletion. That is, in our context, whenever a state substitution is needed, we will apply PU3 directly rather than PU4 followed by PU5. This will simplify our definition on CTL model minimal change (see next).

3.2 Defining Minimal Change

In order to define the minimal change criteria for CTL model update, we need to consider changes on both states and relations for the underlying CTL models. We achieve this by specifying the differences of states and relations on CTL models through primitive operations. First we introduce some useful notions.

Given any two sets X and Y , the *symmetric difference* between X and Y is denoted as $\text{Diff}(X, Y) = (X - Y) \cup (Y - X)$. Given two CTL models $M = (S, R, L)$ and $M' = (S', R', L')$, for each primitive operation PU_i ($i = 1, \dots, 5$), $\text{Diff}_{\text{PU}_i}(M, M')$ denotes the differences between two CTL models where M' is a resulting model from M , that make clear that several operations of this type may occur. Since PU1 and PU2 only change relations, we define $\text{Diff}_{\text{PU}_i}(M, M') = (R - R') \cup (R' - R)$ ($i = 1, 2$). For operations PU3, PU4 and PU5, on the other hand, we define $\text{Diff}_{\text{PU}_i}(M, M') = (S - S') \cup (S' - S)$ ($i = 3, 4, 5$). Although any changes on states caused by PU3-PU5 will also imply corresponding changes on relations, we only count changes on states and take state changes as the primitive factor to measure the difference between M and M' ². For operation PU3, we should also consider the case that when a state is substituted by a new state, we require the difference between these two states to be minimal under the condition of satisfying the updated formula. Finally, we specify

$$\text{Diff}(M, M') = (\text{Diff}_{\text{PU}_1}(M, M'), \dots, \text{Diff}_{\text{PU}_5}(M, M')).$$

Let M , M_1 and M_2 be three CTL models. We denote $\text{Diff}(M, M_1) \preceq \text{Diff}(M, M_2)$ iff (1) for each i ($i = 1, \dots, 5$), $\text{Diff}_{\text{PU}_i}(M, M_1) \subseteq \text{Diff}_{\text{PU}_i}(M, M_2)$; or (2) $\text{Diff}_{\text{PU}_i}(M, M_1) \subseteq \text{Diff}_{\text{PU}_i}(M, M_2)$ for $i = 1, 2, 4, 5$, and $|\text{Diff}_{\text{PU}_3}(M, M_1)| = |\text{Diff}_{\text{PU}_3}(M, M_2)|$ implies for each state s in M substituted by s_1 and s_2 in M_1 and M_2 respectively, $\text{Diff}(s, s_1) \subseteq \text{Diff}(s, s_2)$.

Definition 5 (Closeness Ordering) Given three CTL Kripke models M , M_1 and M_2 , where M_1 and M_2 are obtained from M by applying PU1-PU5 operations. We say that M_1 is closer or as close to M as M_2 , denoted as $M_1 \leq_M M_2$, iff $\text{Diff}(M, M_1) \preceq \text{Diff}(M, M_2)$.

² In our full paper, we justify this principle by showing that as long as a state change is fixed, associated relation changes do not play a crucial role to influence the resulting CTL model.

$\text{Diff}(M, M_2)$. We denote $M_1 <_M M_2$ if $M_1 \leq_M M_2$ and $M_2 \not\leq_M M_1$.

Definition 6 (Admissible Update) Given a CTL Kripke model $M = (S, R, L)$, $\mathcal{M} = (M, s_0)$ where $s_0 \in S$, and a CTL formula ϕ , $\text{Update}(\mathcal{M}, \phi)$ is called admissible if the following conditions hold:
(1) $\text{Update}(\mathcal{M}, \phi) = (M', s'_0) \models \phi$ where $M' = (S', R', L')$ and $s'_0 \in S'$; and (2) there does not exist another resulting model $M'' = (S'', R'', L'')$ and $s''_0 \in S''$ such that $(M'', s''_0) \models \phi$ and $M'' <_M M'$.

4 Semantic Characterizations

From Definition 6, we observe that for a given CTL Kripke model M and a formula ϕ , there may be many admissible updates to satisfy ϕ , where some updates are simpler than others. In this section, we provide various semantic characterizations on CTL model update that present possible solutions to achieve admissible updates under certain conditions. In general, in order to achieve admissible update results, we may have to combine various primitive operations during an update process. Nevertheless, as will be shown in the following, for many situations, a single type primitive operation will be enough to achieve an admissible updated model. These characterizations also play an essential role to simplify CTL model update implementations.

Theorem 1 Let $M = (S, R, L)$ be a Kripke model and s_0 be an initial state in S and $\mathcal{M} = (M, s_0) \not\models EX\phi$, where ϕ is a propositional formula. Then an admissible updated model $\mathcal{M}' = \text{Update}(\mathcal{M}, EX\phi)$ can be obtained by doing one of the following operations:

1. PU3 is applied to any $\text{succ}(s_0)$ once to substitute it with a new state $s^* \models \phi$ and $\text{Diff}(\text{succ}(s_0), s^*)$ to be minimal, or PU4 is applied one time after adding a new state $s^* \models \phi$ and a new relation (s_0, s^*) ;
2. if there exists some $s_i \in S$ such that $s_i \models \phi$ and $s_i \neq \text{succ}(s_0)$, PUI is applied one time to add a new relation (s_0, s_i) .

Theorem 1 provides two cases where admissible CTL model update results can be achieved for formula $EX\phi$. The first case says that we can either select one of s_0 's successor states and substitute it with a new state satisfying ϕ (i.e. applying PU3 one time), or simply add a new state that satisfies ϕ as a successor of s_0 (i.e. applying PU4 one time). The second case indicates that if there is some state s_i in S that already satisfies ϕ , then it is enough to simply add a new relation (s_0, s_i) to make it as a successor of s_0 . It is easy to see that both cases will yield new CTL models that satisfy $EX\phi$. The theorem shows that such new models are also minimal with respect to the original CTL model.

Theorem 2 Let $M = (S, R, L)$ be a Kripke model and $\mathcal{M} = (M, s_0) \not\models AG\phi$, where $s_0 \in S$ and ϕ is a propositional formula. Then an admissible updated model $\mathcal{M}' = \text{Update}(\mathcal{M}, AG\phi)$ can be obtained by the following: for each path starting from s_0 : $\pi = [s_0, \dots, s_i, \dots]$:

1. if for all $s < s_i$ in π , $s \models \phi$ but $s_i \not\models \phi$, PU2 is applied to remove relation (s_{i-1}, s_i) , or PU5 is applied to remove s_i and its associated relations;
2. PU3 is applied to all states s in π not satisfying ϕ to substitute s with $s^* \models \phi$ and $\text{Diff}(s, s^*)$ to be minimal.

In Theorem 2, Case 1 considers a special form of path π where the first i states starting from s_0 already satisfy formula ϕ . Under this situation, we can simply cut off the path (i.e. applying PU2 or PU5 one time) to disconnect all other states not satisfying ϕ . Case 2 is straightforward.

Theorem 3 Let $M = (S, R, L)$ be a Kripke model, $\mathcal{M} = (M, s_0) \not\models EG\phi$, where $s_0 \in S$ and ϕ is a propositional formula. Then an admissible updated model $\mathcal{M}' = \text{Update}(\mathcal{M}, EG\phi)$ can be obtained by the following: Select a path $\pi = [s_0, s_1, \dots]$ from M which contains minimal number of states not satisfying ϕ , and then

1. if for all $s' \in \pi$ such that $s' \not\models \phi$, there exist $s_i, s_j \in \pi$ satisfying $s_i < s' < s_j$ and $s_i \models \phi$ and $s_j \models \phi$, then PUI is applied to add a relation (s_i, s_j) , or PU4 is applied to add a state $s^* \models \phi$ and new relations (s_i, s^*) and (s^*, s_j) ;
2. if there exists some $s_i \in \pi$ ($i > 1$) such that for all $s' < s_i$, $s' \models \phi$ and $s_i \not\models \phi$, then PU2 is applied to remove relation (s_{i-1}, s_i) , or PU5 is applied to remove state s_i and its associated relations;
3. for all $s' \in \pi$, $s' \not\models \phi$, then PU3 is applied to substitute all s' with new state $s^* \models \phi$ and $\text{Diff}(s, s^*)$ to be minimal.

Proof: We prove case 1 here while proofs for the other two cases are presented in our full paper. Without loss of generality, we assume for the selected path π , there exists one state s' that does not satisfy ϕ , and all other states in π satisfy ϕ . We also assume that such s' is in the middle of path π . Therefore, there are two other states s_i, s_j in π such that $s_i < s' < s_j$. That is, $\pi = [s_0, \dots, s_{i-1}, s_i, \dots, s', \dots, s_j, s_{j+1}, \dots]$. We first consider to apply PU1. It is clear that by applying PU1 to add a new relation (s_i, s_j) , a new path is formed: $\pi' = [s_0, \dots, s_{i-1}, s_i, s_j, s_{j+1}, \dots]$. Note that each state in π' is also in path π and $s' \notin \pi'$. According, we know $EG\phi$ is held in the new model $M' = (S, R \cup \{(s_i, s_j)\}, L)$ at state s_0 . On the other hand, we consider $\text{Diff}(M, M')$. Clearly, $\text{Diff}(M, M') = (\{(s_i, s_j)\}, \emptyset, \emptyset, \emptyset, \emptyset)$, which implies M' must be a minimal model with respect to \leq_M that satisfies $EG\phi$.

Now we consider to apply PU4. In this case, we will have a new model $M' = (S \cup \{s^*\}, R \cup \{(s_i, s^*), (s^*, s_j)\}, L')$ where L' is an extension of L on new state s^* that satisfies ϕ . We can see that $\pi' = [s_0, \dots, s_i, s^*, s_j, \dots]$ is a path in M' which shares all states with path π except the state s' in π and those states between s_{i+1} and s_{j-1} including s' in π . So we also have $(M', s_0) \models EG\phi$. On the other hand, we have $\text{Diff}(M, M') = (\emptyset, \emptyset, \emptyset, \{s^*\}, \emptyset)$. Obviously, M' is a minimal model with respect to \leq_M that satisfies $EG\phi$. \square

Theorem 3 characterizes three typical situations for the update with formula $EG\phi$. Basically, this theorem says that in order to make formula $EG\phi$ be true, we first select a path, then we can either make a new path based on this path so that all states in the new path satisfy ϕ (i.e. Case 1), trim the path from the state where all previous states satisfy ϕ (i.e. Case 2); or simply substitute all states not satisfying ϕ in the path with new states satisfying ϕ (i.e. Case 3). Our proof shows that resulting models from these operations are admissible.

In our full paper, we also provide semantic characterizations for updates with other CTL formulas such as $EF\phi$, $AX\phi$, $AF\phi$, $E[\phi \cup \psi]$ and $A[\phi \cup \psi]$. All these results have been proved to be useful in simplifying the implementation and improving the efficiency of the CTL model update performance.

5 Computational Properties

In this section, we study the computational complexity of our approach for CTL model update. We first present the following general result.

Theorem 4 *Given two CTL Kripke models $M = (S, R, L)$ and $M' = (S', R', L')$, where $s_0 \in S$ and $s'_0 \in S'$, and a CTL formula ϕ . Deciding whether (M', s'_0) is an admissible result of $\text{Update}((M, s_0), \phi)$ is co-NP-complete. The hardness holds even if ϕ is of the form $\text{EX}\psi$ where ψ is a propositional formula.*

Proof: Membership proof. First from [4], we know that checking whether $(M', s'_0) \models \phi$ can be done in time $\mathcal{O}(|\phi| \cdot (|S| + |R|))$. In order to check whether (M', s'_0) is an admissible update result, we need to check whether M' is minimal with respect to ordering \leq_M . To do so, we consider the complement of the problem. That is to check whether M' is not a minimal model. Therefore, we do two things: (1) guessing a CTL model $M'' = (S'', R'', L'')$ satisfying ϕ for some $s'' \in S''$; and (2) testing whether $M'' <_M M'$. Step (1) can be done in polynomial time. To check $M'' <_M M'$, we first compute $\text{Diff}(S, S')$, $\text{Diff}(S, S'')$, $\text{Diff}(R, R')$ and $\text{Diff}(R, R'')$. All these can be computed in polynomial time. Then according to these sets, we identify, through PU1 to PU5, $\text{Diff}_{PU_i}(M, M')$ and $\text{Diff}_{PU_i}(M, M'')$ ($i = 1, \dots, 5$). Again, these can also be done in polynomial time. Finally, by checking $\text{Diff}_{PU_i}(M, M'') \subseteq \text{Diff}_{PU_i}(M, M')$ ($i = 1, \dots, 5$) we can decide whether $M'' <_M M'$. So both steps (1) and (2) can be achieved in polynomial time with a non-deterministic Turing machine.

Hardness proof. It is well known that the validity problem for a propositional formula is co-NP-complete. Given a propositional formula ϕ , we construct in polynomial time a transformation from the problem of deciding ϕ 's validity to a CTL model update. Let X be the set of all variables occurring in ϕ , and a, b two new variables not occurring in X . We denote $\neg X = \bigwedge_{x_i \in X} \neg x_i$. We specify a CTL Kripke model based on the variable set $X \cup \{a, b\}$: $M = (\{s_0, s_1\}, \{(s_0, s_1), (s_1, s_1)\}, L)$, where $L(s_0) = \emptyset$ (i.e. all variables are assigned false), $L(s_1) = X$ (i.e. variables in X are assigned true, while a, b are assigned false). Now we define a new formula $\mu = \text{EX}((\phi \supset a) \wedge (\neg X \wedge b)) \vee (\neg \phi \wedge a)$. Clearly, formula $((\phi \supset a) \wedge (\neg X \wedge b)) \vee (\neg \phi \wedge a)$ is satisfiable and $s_1 \not\models ((\phi \supset a) \wedge (\neg X \wedge b)) \vee (\neg \phi \wedge a)$. So $(M, s_0) \not\models \mu$. Consider the update $\text{Update}((M, s_0), \mu)$. We define $M' = (\{s'_0, s'_1\}, \{(s'_0, s'_1), (s'_1, s'_1)\}, L')$, where $L'(s'_0) = L(s_0)$ and $L'(s'_1) = \{a, b\}$. Now we show that ϕ is valid iff (M', s'_0) is an admissible update result from $\text{Update}((M, s_0), \mu)$.

Case 1. We show that if ϕ is valid, then (M', s'_0) is an admissible update result from $\text{Update}((M, s_0), \mu)$. Since ϕ is valid, we have $\neg X \models \phi$. So we have $s'_1 \models (\phi \supset a) \wedge (\neg X \supset b)$. This follows $(M', s'_0) \models \mu$. Also note that M' is obtained by applying PU3 to substitute s_1 with s'_1 . $\text{Diff}(s_1, s'_1) = X \cup \{a, b\}$ which presents a minimal change from s_1 in order to satisfy $(\phi \supset a) \wedge (\neg X \supset b)$.

Case 2. Suppose that ϕ is not valid. Then there exists $X_1 \subseteq X$ such that $X_1 \models \neg \phi$. We construct $M'' = (\{s''_0, s''_1\}, \{(s''_0, s''_1), (s''_1, s''_1)\}, L'')$, where $L''(s''_0) = L(s_0)$ and $L''(s''_1) = X_1 \cup \{a\}$. It is easy to see that $s''_1 \models (\neg \phi \wedge a)$, and hence $(M'', s''_0) \models \mu$. Now we show that $(M', s'_0) \models \mu$ implies $M'' <_M M'$. Suppose $(M', s'_0) \models \mu$. Clearly, both M' and M'' are obtained from M by applying PU3 one time on s_1 respectively. But we have $\text{Diff}(s_1, s'_1) = (X - X_1) \cup \{a\} \subset X \cup \{a, b\} = \text{Diff}(s_1, s''_1)$. This concludes that (M', s'_0) is not an admissible update model. \square

Theorem 4 implies that it is probably not feasible to develop a polynomial time algorithm to implement our CTL model update. Indeed, our algorithm described in the next section, generally runs in exponential time. Nevertheless, we can identify certain typical update cases that may be achieved in polynomial time.

Theorem 5 *Let $M = (S, R, L)$ be a CTL Kripke model and ϕ a CTL formula. If an admissible update result $\text{Update}((M, s_0), \phi)$ ($s_0 \in S$) can be obtained by only applying PU1, PU2, PU4 and PU5 without path selection in M (i.e. ϕ does not involve $\text{EG}\psi$, $\text{EF}\psi$ or $E[\psi_1 \cup \psi_2]$), then this result can be computed in polynomial time.*

6 The Algorithm and a Case Study

A prototype for the CTL model update addressed in previous sections has been implemented recently. The algorithm is designed following a similar style of CTL model checking algorithm SAT [8], where an updated formula is parsed through its structure and recursive calls to proper functions are made to its sub-formulas.

$\text{CTLUpdate}(\mathcal{M}, \phi) / \mathcal{M} = (M, s_0) \not\models \phi$. Update \mathcal{M} to satisfy ϕ . /
Input: $M = (S, R, L)$, $\mathcal{M} = (M, s_0)$, where $s_0 \in S$ and $\mathcal{M} \not\models \phi$
Output: $M' = (S', R', L')$, $\mathcal{M}' = (M', s'_0)$, $s'_0 \in S'$, $\mathcal{M}' \models \phi$;
{ case
 ϕ is \perp : return $\{\mathcal{M}\}$;
 ϕ is atomic p : return $\{\text{Update}_p(\mathcal{M}, p)\}$;
 ϕ is $\neg \phi_1$: return $\{\text{Update}_{\neg}(\mathcal{M}, \phi_1)\}$;
 ϕ is $\phi_1 \vee \phi_2$:
return $\{\text{CTLUpdate}(\mathcal{M}, \phi_1) \text{ or } \text{CTLUpdate}(\mathcal{M}, \phi_2)\}$;
 ϕ is $\phi_1 \wedge \phi_2$: return $\{\text{Update}_{\wedge}(\mathcal{M}, \phi_1, \phi_2)\}$;
 ϕ is $\text{EX}\phi_1$: return $\{\text{Update}_{\text{EX}}(\mathcal{M}, \phi_1)\}$;
 ϕ is $\text{AX}\phi_1$: return $\{\text{Update}_{\text{AX}}(\mathcal{M}, \phi_1)\}$;
 ϕ is $\text{EF}\phi_1$: return $\{\text{Update}_{\text{EF}}(\mathcal{M}, \phi_1)\}$;
 ϕ is $\text{AF}\phi_1$: return $\{\text{Update}_{\text{AF}}(\mathcal{M}, \phi_1)\}$;
 ϕ is $\text{EG}\phi_1$: return $\{\text{Update}_{\text{EG}}(\mathcal{M}, \phi_1)\}$;
 ϕ is $\text{AG}\phi_1$: return $\{\text{Update}_{\text{AG}}(\mathcal{M}, \phi_1)\}$;
 ϕ is $E(\phi_1 \cup \phi_2)$: return $\{\text{Update}_{\text{EU}}(\mathcal{M}, \phi_1, \phi_2)\}$;
 ϕ is $A(\phi_1 \cup \phi_2)$: return $\{\text{Update}_{\text{AU}}(\mathcal{M}, \phi_1, \phi_2)\}$;
}

Due to a space limit, here we only outline the main idea of implementing functions Update_{\neg} and $\text{Update}_{\text{AG}}$.

$\text{Update}_{\neg}(\mathcal{M}, \phi) / \mathcal{M} \not\models \phi$. Update \mathcal{M} to satisfy ϕ . /
{ case
 ϕ is $\neg p$: return $\{\text{Update}_{\neg p}(\mathcal{M}, p)\}$;
 ϕ is $\neg(\phi_1 \wedge \phi_2) = \neg \phi_1 \vee \neg \phi_2$:
return $\{\text{Update}_{\neg}(\mathcal{M}, \phi_1)\} \text{ or } \{\text{Update}_{\neg}(\mathcal{M}, \phi_2)\}$;
 ϕ is $\neg \text{EF}(\phi_1) = \text{AG}(\neg \phi_1)$: return $\{\text{Update}_{\text{AG}}(\mathcal{M}, \neg \phi_1)\}$;
}

$\text{Update}_{\text{AG}}(\mathcal{M}, \phi) / \mathcal{M} \not\models \text{AG}\phi$. Update \mathcal{M} to satisfy $\text{AG}\phi$. /
{ if $\mathcal{M}_0 = (M, s_0) \not\models \phi$, then PU3 is applied to s_0
such that $\mathcal{M}' = \text{CTLUpdate}(\mathcal{M}_0, \phi)$;
else select a path $\pi = [s_0, s_1, \dots]$, where $\exists s \in \pi$ such that
 $\mathcal{M}_i = (M, s) \not\models \phi$;
select the earliest state $s_i \in \pi$ such that $(M, s_i) \not\models \phi$;
perform one of the following three operations:
(1) applying PU2 to remove relation (s_{i-1}, s_i) ,
obtain result \mathcal{M}' ;
(2) applying PU5 to remove state s_i and
its associated relations, obtain result \mathcal{M}' ;
(3) applying PU3: $\mathcal{M}' = \text{CTLUpdate}(\mathcal{M}_i, \phi)$;

```

if  $\mathcal{M}' \models AG\phi$ , return  $\mathcal{M}'$ ;
else return  $\{Update_{AG}(\mathcal{M}', \phi)\}$ ;
}

```

Theorem 6 Given a Kripke model $M = (S, R, L)$ and a satisfiable CTL formula ϕ such that $(M, s) \not\models \phi$ for some $s \in S$. Then $CTLUpdate((M, s), \phi)$ will return a resulting Kripke model $M' = (S', R', L')$ such that $(M', s') \models \phi$ for some $s' \in S'$ and it is admissible.

In the rest of this section, we will describe some details of our algorithm implementation by applying the model modification to the well known microwave oven scenario [4]. The microwave oven model is described as in Figure 1.

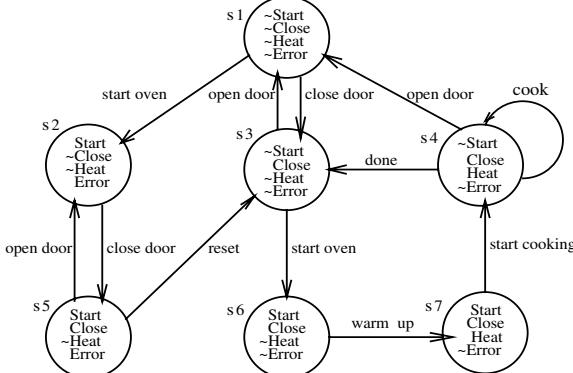

Figure 1. The CTL Kripke structure of a microwave oven.

The Kripke model has 7 states and propositional variables are from the set $\{Start, Close, Heat, Error\}$. It is observed that this model does not satisfy a desirable property $\phi = \neg EF(Start \wedge EG\neg Heat)$ [4]. What we would like to do is to apply our CTL model update program to minimally modify this kripke model to satisfy property ϕ . First, we parse ϕ into $AG(\neg(Start \wedge EG\neg Heat))$ to remove the front \neg . The translation is done by function $Update_{\neg}$. Then we check for each state whether it satisfies $\neg(Start \wedge EG\neg Heat)$. This string is parsed before it is checked. We pick out $EG\neg Heat$ to feed through the model checking function for EG . In this model, any path that has any state with $\neg Heat$ is picked out. Here we find paths $[s_1, s_2, s_5, s_3, s_1, \dots]$ and $[s_1, s_3, s_1, \dots]$ which are strongly connected component loops [4] satisfying $EG\neg Heat$. Then we identify all states with $Start$, they are $\{s_2, s_5, s_6, s_7\}$. Now we select those states with both $Start$ and $\neg Heat$, they are $\{s_2, s_5\}$. Since formula $AG(\neg(Start \wedge EG\neg Heat))$ identifies that the model should not have any states with both $Start$ and $\neg Heat$, we should perform model update related to states s_2 and s_5 .

Now function $Update_{AG}$ starts to perform update as described in the above pseudo code and Theorem 2 (see section 3). It turns out that there are three possible minimal updates: (1) applying PU2 to remove relation (s_1, s_2) ; (2) applying PU5 to remove state s_2 and its associated relations (s_1, s_2) , (s_2, s_5) and (s_5, s_2) ; and (3) applying PU3 on s_2 and s_5 . To perform option (3), our program first converts $\neg(Start \wedge EG\neg Heat)$ to $\neg Start \vee \neg EG\neg Heat$, then s_2 and s_5 are updated with either $\neg Start$ or $\neg EG\neg Heat$ by the main function $CTLUpdate$ to deal with \vee and function $Update_{\neg}$. In our program, updating $\neg Start$ is chosen since formula $\neg Start$ is simpler than $\neg EG\neg Heat$. After the update, we will obtain a resulting model $(M, s_1) \models \phi$. For instance, by choosing update (1) operation above, we will obtain a new Kripke model as shown in Figure 2, which simply states that no state transition from s_1 to s_2 is allowed.

Our algorithm will generate one of the three resulting models without specific indication, because under our criteria they are all minimally changed from the original model. However, in our prototype implementation, we have considered the computational cost of an update upon users' request, which may affect the system efficiency. For instance, in the above example, with three possible updates, if the user requires a low computational cost, our system will select the simplest operation (1) to achieve the goal.

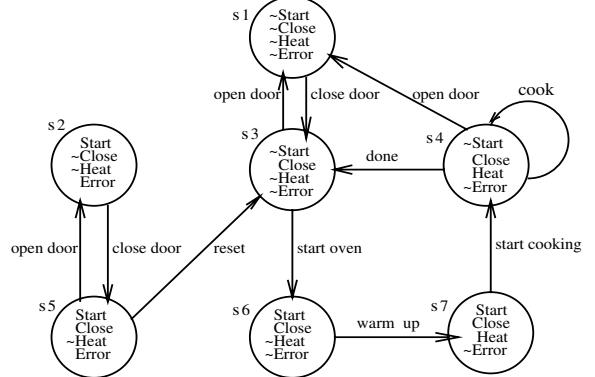

Figure 2. An updated CTL Kripke structure for the microwave oven.

7 Conclusion

In this paper, we presented a formal approach to update CTL models. By specifying five primitive operations on CTL Kripke models, we defined the minimal change criteria for CTL model update. We also investigated the semantic and computational properties of our approach in detail. Based on our formalization, we developed a CTL model update algorithm and implemented a system prototype to perform CTL model updating. Our case study showed an application of this work.

Resolving Conflicts in Action Descriptions

Thomas Eiter and Esra Erdem and Michael Fink and Ján Senko¹

Abstract. We study resolving conflicts between an action description and a set of conditions (possibly obtained from observations), in the context of action languages. In this formal framework, the meaning of an action description can be represented by a transition diagram—a directed graph whose nodes correspond to states and whose edges correspond to transitions describing action occurrences. This allows us to characterize conflicts by means of states and transitions of the given action description that violate some given conditions. We introduce a basic method to resolve such conflicts by modifying the action description, and discuss how the user can be supported in obtaining more preferred solutions. For that, we identify helpful questions the user may ask (e.g., which specific parts of the action description cause a conflict with some given condition), and we provide answers to them using properties of action descriptions and transition diagrams. Finally, we discuss the computational complexity of these questions in terms of related decision problems.

1 INTRODUCTION

Action languages [3] are a formal tool for reasoning about actions, where an agent's knowledge about a domain in question is represented by a declarative action description that consists of logical formulas. Consider for instance a light bulb with a switch. When the light is off, then toggling the switch turns the light on; this can be expressed in the action description language \mathcal{C} [4] by the formula

$$\text{caused Light after Toggle} \wedge \neg\text{Light}. \quad (1)$$

On the other hand, at every state, if the light bulb is broken then the light is off. This can be expressed by the formula

$$\text{caused } \neg\text{Light if Broken}. \quad (2)$$

Other pieces of knowledge, like laws of inertia, may be also included. The meaning of such an action description can be represented by a transition diagram—a directed graph whose nodes correspond to the states of the world and the edges to the transitions describing action occurrences. For instance, see Figure 1 for the transition diagram of the action description above (consisting of (1), (2), and inertia laws).

Note that the action description above is “buggy”, since the effects of toggling the switch are not completely specified. Our goal is to “repair” such descriptions taking into account some additional information, such as observations or axioms about the action domain, which can be represented in an action query language [3], expressing conditions on the transition diagram.

For example, when the light bulb is broken, toggling the switch may lead to a state where the light is off; this information is possibly obtained from some observations of the agent, and can be expressed in an action query language, e.g., by the statement

$$\text{possibly } \neg\text{Light after Toggle if Broken}. \quad (3)$$

¹ Institut für Informationssysteme 184/3, Technische Universität Wien, 1040 Wien, Austria, email: {eiter, esra, michael, jan}@kr.tuwien.ac.at

Some of the additional information may conflict with the action description. For instance, condition (3) does not hold relative to the action description above, since at the state where the light bulb is broken and the light is off, toggling the light switch is not possible. Thus, there is a conflict between the action description and this condition.

In this paper, we consider such conflicts, and how the agent's action description can be modified to resolve them. This may be accomplished in many different ways, and there is no canonical method which works satisfactorily in all cases. According to [2], one might aim at dropping a smallest set of candidate formulas to resolve the conflict. In our example, dropping (1) would work. However, under further conditions, like

$$\text{necessarily } \neg\text{Light after Toggle if Light}, \quad (4)$$

the conflict cannot be resolved just by dropping formulas: removing any of (1), (2) and inertia laws will not lead to an edge from a state where the light is on to a state where the light is off. A refined approach is needed which, semantically, modifies the transition diagram by suitable changes of the formulas to “repair” the action description such that the given queries (i.e., conditions) hold.

This paper makes two main contributions in this direction:

- 1) It provides a precise *notion of conflict* between an action description and a set of queries, and presents a basic algorithm to resolve such conflicts. The idea is to modify the transition diagram of the action description by adding or deleting transitions so that all given conditions are satisfied; such a modification of the transition diagram is possible by adding, deleting or modifying some formulas in the action description. Based on this idea, our algorithm calculates a repair whenever it is possible.
- 2) Intuitive repair preferences might be difficult to formalize (e.g., both syntactic and semantic aspects might play a role) and thus to achieve with the basic algorithm above. In such cases, the designer might want to *ask questions* about the action description, the transition diagram, and the extra information, whose answers could guide her to come up with an appealing repair in an iterative repair process. For that, we explore several kinds of such questions and determine properties of action descriptions, transition diagrams, and extra information which are helpful in answering them. We also analyze the computational complexity of related problems.

2 PRELIMINARIES

Transition diagrams. We start with a *propositional action signature* $\mathcal{L} = \langle \mathbf{F}, \mathbf{A} \rangle$ that consists of a set \mathbf{F} of fluent names, and a set \mathbf{A} of action names. Satisfaction of a propositional formula G over atoms $At \subseteq \mathbf{F} \cup \mathbf{A}$ by an interpretation $P \mapsto I(P) \in \{t, f\}$ for all $P \in At$ as usual, is denoted by $I \models G$. An *action* is an interpretation of \mathbf{A} , denoted by the set of action names that are mapped to t .

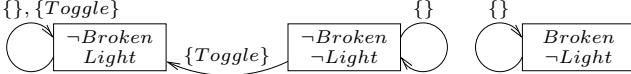

Figure 1. Transition diagram of the action description $\{ (1), (2), (7) \}$.

A transition diagram of \mathcal{L} consists of a set S of states, a function $V : \mathbf{F} \times S \rightarrow \{f, t\}$ such that each state s in S is uniquely identified by the interpretation $P \mapsto V(P, s)$, for all $P \in \mathbf{F}$, and a subset $R \subseteq S \times 2^{\mathbf{A}} \times S$ of transitions. We say that $V(P, s)$ is the value of P in s . The states s' such that $\langle s, A, s' \rangle \in R$ are the possible results of the execution of the action A in the state s . We can think of a transition diagram as a labeled directed graph. Every state s is represented by a vertex labeled with the function $P \mapsto V(P, s)$ from fluent names to truth values; we denote by s the set of fluent literals satisfied by this function. Each triple $\langle s, A, s' \rangle \in R$ is represented by an edge from s to s' and labeled A . See Figure 1 for an example.

Action descriptions. We consider a subset of the action description language \mathcal{C} [4] that consists of two kinds of expressions (called *causal laws*): *static laws* of the form

$$\text{caused } L \text{ if } G, \quad (5)$$

where L is a fluent literal or *False*, and G is a propositional combination of fluent names; and *dynamic laws* of the form

$$\text{caused } L \text{ if } G \text{ after } U, \quad (6)$$

where L and G are as above, and U is a propositional combination of fluent names and action names. In (5) and (6) the part **if** G can be dropped if G is *True*.² An *action description* is a set of causal laws. For instance, one formalization of the light domain described in the introduction can be expressed in this language by the causal laws (1), (2), and the inertia laws

$$\text{inertial } \text{Light}, \neg\text{Light}, \text{Broken}, \neg\text{Broken}. \quad (7)$$

Here an expression of the form **inertial** L_1, \dots, L_k stands for the causal laws **caused** L_i **if** L_i **after** L_i for $i \in \{1, \dots, k\}$.

The meaning of an action description can be represented by a transition diagram as follows. We say that a causal law l is *applicable* to a transition $\langle s, A, s' \rangle$ in a transition diagram, if

- l is a static law (5), such that $s' \models G$; or
- l is a dynamic law (6), such that $s' \models G$ and $s \cup A \models U$.³

We denote by $D(\text{tr})$ the set of all causal laws in an action description D that are applicable to a transition tr ; by $H_D(\text{tr})$ the set of the heads of all causal laws in $D(\text{tr})$; and by $\text{sat}(H_D(\text{tr}))$ the set of interpretations of \mathbf{F} that satisfy $H_D(\text{tr})$.

Let D be an action description with a signature $\mathcal{L} = \langle \mathbf{F}, \mathbf{A} \rangle$. Then the transition diagram $\langle S, V, R \rangle$ described by D , denoted $T(D)$, is defined as follows:

- S is the set of all interpretations s of \mathbf{F} such that, for every static law (5) in D , $s \models G \supseteq L$,
- $V(P, s) = s(P)$,
- R is the set of all $\langle s, A, s' \rangle$ such that $\text{sat}(H_D(\langle s, A, s' \rangle)) = \{s'\}$.

We denote by $S(D)$ (resp. $R(D)$) the set of states (resp. transitions) of $T(D)$. For instance the transition diagram described by the action description consisting of (1), (2), (7) is shown in Figure 1.

² *True* (resp. *False*) is the empty conjunction (resp. disjunction).

³ We identify states s with the interpretations $P \mapsto V(P, s)$.

Conditions. For expressing extra conditions, we consider here a language with two kinds of statements (“queries”) about an action description: *possibility* and *necessity queries* of the respective forms

$$\text{possibly } \psi \text{ after } A \text{ if } \phi \quad (8)$$

$$\text{necessarily } \psi \text{ after } A \text{ if } \phi \quad (9)$$

where ϕ and ψ are propositional combinations of fluent names, and A is an action. These queries are syntactically different from the ones presented in [3] and [2]; on the other hand, semantically they constitute a fragment of an extension of the action query language \mathcal{P} [3] (from which we draw the term “query”) and the condition language in [2] (see Related and Further Work for a discussion).

A query q of form (8) (resp., (9)) is *satisfied at state s in a transition diagram T* , denoted $T, s \models q$, if either $s \not\models \phi$, or for some (resp., every) transition $\langle s, A, s' \rangle$ of T $s' \models \psi$ holds. We say that T *entails* a set Q of queries (denoted $T \models Q$), if $T, s \models q$ for every $q \in Q$ and for every state s in T . Accordingly, an action description D *entails* Q (denoted $D \models Q$) if $T(D) \models Q$.

Example 1 Let us consider the light domain described in the introduction as our running example. Let D be the action description consisting of (2), (1), and (7); and Q be the set of two queries: possibility query (3) and the necessity query (4), denoted by q_p and q_n respectively. Figure 1 shows $T(D)$ (i.e., the transition diagram of D). Then it can be easily verified that, at state $\{\neg\text{Light}, \text{Broken}\}$, since there is no transition from this state with action *Toggle*, the query q_n is trivially satisfied while q_p is not satisfied.

What a query describes is different from what a causal law does: action descriptions allow us to describe a transition diagram, based on causal explanations (what “is caused”), whereas queries allow us to state assertions (what “holds”) about transition diagrams. These assertions may, e.g., be observations or axioms about the action domain. (See [3] for a discussion on action query languages.)

3 CONFLICTS IN ACTION DESCRIPTIONS

Given an action description D and a set Q of queries, we say that there is a *conflict* between D and Q , if $D \not\models Q$. Our goal is to resolve these conflicts by modifying the action description.

Conflicts can be characterized, from a semantic point of view, in terms of states and transitions “violating” some queries. We assume that the states of the world are correctly described by the given action description. Thus conflicts are existing transitions (for the violation of a necessity query) and non-existing transitions (for the violation of a possibility query) that cause such conflicts. The idea is then to “repair” an action description by a syntactic modification, such as adding, deleting, or modifying some of its causal laws, so that the detected conflicts are resolved by adding and/or deleting some transitions in the transition diagram.

For an action description D and a set Q of queries, the states and transitions violating possibility and necessity queries in Q , respectively, are as follows.

- A state s of $T(D)$ violates a possibility query q of form (8) in Q , if $T(D), s \not\models q$.
- A transition $\text{tr} = \langle s, A, s' \rangle$ of $T(D)$ violates a necessity query q of form (9) in Q (denoted $\text{tr} \not\models q$), if $s \models \phi$ and $s' \not\models \psi$.

Example 2 (cont’d) From $T(D)$ we can identify the following conflicts: the single state violating the possibility query q_p is $\{\neg\text{Light}, \text{Broken}\}$, and the single transition violating the necessity query q_n is $\{\text{Light}, \neg\text{Broken}\}, \{\text{Toggle}\}, \{\text{Light}, \neg\text{Broken}\}$.

Since we suppose that states of the world are correctly described by D , we do not need to modify the static laws in D for a repair.

Algorithm RESOLVE(D, Q) : $Mod, Incon$ **Input:** An action description, D , and a set of queries, Q .**Output:** A repair, Mod , and a set of queries, $Incon$.

```

 $Mod := \emptyset; Incon := \emptyset;$ 
for all  $(q, tr) \in conf_n(D, Q)$  do
     $Mod := Mod \cup Delete(tr);$ 
 $D' := Mod(D); Ins := \emptyset;$ 
for all  $(q, s) \in conf_p(D', Q)$  do
     $(q = \text{possibly } \psi \text{ after } A \text{ if } \phi)$ 
     $Cands := \{\langle s, A, s' \rangle \mid s' \in S(D), s' \models \psi,$ 
     $\langle s, A, s' \rangle \models q', \forall q' \in Q_n\};$ 
    if ( $Cands \neq \emptyset$ ) then
        select  $tr \in Cands;$ 
         $Ins := Ins \cup \{tr\};$ 
    else
         $Incon := Incon \cup \{q\};$ 
return  $Mod \cup Insert(Ins, D'), Incon;$ 

```

Figure 2. An algorithm to resolve conflicts.

4 A METHOD FOR RESOLVING CONFLICTS

Under the assumption above, we can resolve conflicts between an action description D and a set Q of queries by the algorithm presented in Figure 2. Before we explain how this algorithm works, let us describe the notation used in it.

For a set Q of queries, we denote by Q_p (resp. Q_n) the set of possibility (resp. necessity) queries in Q . Then

$$\begin{aligned} conf_p(D, Q) &= \{(q, s) \mid q \in Q_p, s \in S(D), T(D), s \not\models q\} \\ conf_n(D, Q) &= \{(q, tr) \mid q \in Q_n, tr \in R(D), tr \not\models q\}. \end{aligned}$$

For a triple $tr = \langle s, A, s' \rangle$, where s and s' are states and A is an action, and a dynamic causal law $l = \text{caused } L \text{ if } U \text{ after } G$, $\langle s, A, s' \rangle \models l$ if either l is not applicable to tr , or $s' \models l$.

A *repair item* is an expression of form $(modify, l, l')$, or (add, l) , where l and l' are dynamic causal laws. A *repair* is a set of repair items. For an action description D and a repair M , we denote by $M(D)$ the action description obtained from D by applying the modifications specified by the repair items in a repair M : (add, l) modifies D by adding l ; $(modify, l, l')$ modifies D by replacing l with l' ; all repair items are executed in parallel, i.e., if M comprises several *modify* items for the same law l , all corresponding modifications l' are generated and eventually replace l . The repairs used by the algorithm RESOLVE(D, Q) are as follows (in causal laws, a state s stands for $\bigwedge_{L \in s} L$, and an action A for $\bigwedge_{X \in A} X \wedge \bigwedge_{X \in A \setminus A} \neg X$):

$$\begin{aligned} Delete(\langle s, A, s' \rangle) &= \{(add, \text{caused } False \text{ if } s' \text{ after } A \wedge s)\} \\ Insert(Tr, D) &= \{(add, \text{caused } L \text{ if } s' \text{ after } A \wedge s) \mid \langle s, A, s' \rangle \in Tr, L \in s'\} \cup \\ &\quad \{(modify, l, \text{caused } L \text{ if } G \text{ after } U \wedge \alpha(Tr, l)), \\ &\quad (modify, l, \text{caused } L \text{ if } G \wedge L \text{ after } U \wedge A \wedge s) \mid \\ &\quad l = \text{caused } L \text{ if } G \text{ after } U, l \in D, \langle s, A, s' \rangle \in Tr, \langle s, A, s' \rangle \not\models l\} \end{aligned}$$

where $\alpha(Tr, l) = \bigwedge_{\langle s, A, s' \rangle \in Tr, \langle s, A, s' \rangle \not\models l} \neg A \vee \neg s$.

In the algorithm above, first every transition tr violating the necessity queries in Q is removed, by adding to D the causal laws $Delete(tr)$. The new action description, D' , entails Q_n . Then, for each state s violating a possibility query $q = \text{possibly } \psi \text{ after } A \text{ if } \phi$ in Q relative to D' , a set $Cands$ of transition candidates tr (triples of form $\langle s, A, s' \rangle$ where $s' \in S(D)$) that, when added to $T(D')$, would

satisfy q at s (i.e., $s' \models \psi$) but not violate any necessity queries in Q (i.e., $tr \models q', \forall q' \in Q_n$), is computed. If such transition candidates exist (i.e., $Cands \neq \emptyset$), by introducing only one of these candidates into $T(D')$, the violation of q at s is prevented; otherwise no repair of D exists for Q (i.e., $Incon$ is not empty, and it contains the possibility queries that conflict with some necessity query in Q). The set Ins denotes all the transition candidates to be introduced into $T(D')$ so that no possibility query is violated in any state. Adding Ins to $T(D')$ can be achieved by adding to D' the causal laws $Insert(Ins, D')$.

Theorem 1 For any repair Mod and set $Incon$ of queries output by RESOLVE(D, Q), the following hold:

1. $D \models Q$ iff $Mod = \emptyset$ and $Incon = \emptyset$;
2. $Incon = \emptyset$ iff $\exists D'$ such that $S(D) = S(D')$ and $D' \models Q$;
3. if $Incon = \emptyset$, then $Mod(D) \models Q$.

The selection of a transition candidate $tr \in Cands$ for repairing a possibility query constitutes a choice point of the algorithm, where further heuristics can be employed to prune the set of repairs. We could, e.g., prefer transition candidates that *respect inertia conditions* or compute *minimal modifications*, i.e., repairs such that the modifications to $T(D)$ are minimal w.r.t. addition or deletion of transitions.

Example 3 (cont'd) Stipulating preference of transition candidates that respect inertia, the basic method resolves the conflicts as follows. First, the only transition violating q_n (i.e., $\langle s_1, \{ \text{Toggle} \}, s_1 \rangle$, where $s_1 = \{ \text{Light}, \neg \text{Broken} \}$) is deleted from $T(D)$ by adding the law:

caused False if Light $\wedge \neg \text{Broken}$ after Toggle $\wedge \text{Light} \wedge \neg \text{Broken}$.

Then, to resolve conflicts with q_p , the only transition candidate respecting inertia (i.e., $tc = \langle s_2, \{ \text{Toggle} \}, s_2 \rangle$, where $s_2 = \{ \neg \text{Light}, \text{Broken} \}$) is introduced into $T(D')$ ($Insert(tc, D') = \{(add, l_i, (modify, (1), l_j)) \mid i = 1, 2, j = 3, 4\}$), replacing (1) with the laws:

$$\begin{aligned} l_1 &: \text{caused } \neg \text{Light} \text{ if } \neg \text{Light} \wedge \text{Broken} \text{ after } \\ &\quad \text{Toggle} \wedge \neg \text{Light} \wedge \text{Broken}, \\ l_2 &: \text{caused } \text{Broken} \text{ if } \neg \text{Light} \wedge \text{Broken} \text{ after } \\ &\quad \text{Toggle} \wedge \neg \text{Light} \wedge \text{Broken}, \\ l_3 &: \text{caused } \text{Light} \text{ if } \text{Light} \text{ after } \text{Toggle} \wedge \neg \text{Light} \wedge \text{Broken}, \\ l_4 &: \text{caused } \text{Light} \text{ after } \text{Toggle} \wedge \neg \text{Light} \wedge \neg \text{Broken}. \end{aligned}$$

We remark that algorithm RESOLVE can be implemented to use polynomial work space, producing its output, which is exponential in general, as a stream. After computing RESOLVE(D, Q), to get a more concise description, one may drop redundant causal laws that might have been introduced (e.g., (6) where $U \equiv \text{False}$), and apply some equivalence preserving transformations (e.g., replacing two laws **caused L after $A \wedge U$** and **caused L after $A \wedge \neg U$** with **caused L after A** .) Note also, that if there exists a repair for D , then there always also exists a repair D' of polynomial size. Informally speaking, D' can be obtained by expressing all necessity queries as dynamic laws and dispensing causality for all actions occurring in queries (**caused L if L after A** , for every literal L). Such a repair is independent of D apart from static laws and semantically it amounts to a complete transition graph w.r.t. actions occurring in queries modulo transitions violating necessity queries. Thus, it is even less appealing than solutions computed by RESOLVE(D, Q), which aim at making modifications as local as possible on single transitions (in order to retain the original semantics of D as much as possible even in case of further modifications). In most cases, however, neither of these basic repairs will be satisfactory. This motivates the utilization of additional knowledge of certain properties for repair.

5 TOWARDS USER-ASSISTED REPAIRS

With the method described above we can automatically repair an action description D with respect to a set Q of queries, under the assumption that the states of the world are described correctly by D . However, we may end up with an action description with many causal laws, some possibly redundant or implausible. To get a more appealing description most often requires respecting additional knowledge or intuitions of the *designer* about the action description.

Usually, this knowledge cannot be easily formalized, as the following example illustrates:

Example 4 The designer of D might use her knowledge about the domain, i.e., light bulbs and switches, to infer from the conflict with the observation expressed in q_n that the duality of the toggle action has not been modeled correctly, and that the conflict with q_p is due to neglecting the effects of toggling when the bulb is broken. Hence, instead of D , she might consider D' consisting of (2), (7), and:

$$\begin{aligned} \text{caused } & \text{Light after Toggle} \wedge \neg \text{Light} \wedge \neg \text{Broken} \\ \text{caused } & \neg \text{Light after Toggle} \wedge \text{Light} \wedge \neg \text{Broken}. \end{aligned} \quad (10)$$

Note that this description is more concise and plausible than the one generated by the basic method (see Example 3).

For (interactively) providing support to a designer repairing an action description, we present some questions that she may ask about Q , D , and $T(D)$. Answers to these questions are obtained from useful properties of queries, action descriptions, and transition diagrams.

Questions about queries and causal laws. To better understand the reasons for conflicts, the designer may want to check the given queries Q make sense with each other. Then the question is:

D1: If Q is contradictory relative to D , which queries in Q are contradictory?

We understand contradiction in a set Q as follows:

Definition 1 A set Q of queries is contradictory relative to an action description D , if there is no action description D' such that $S(D) = S(D')$ and $D' \models Q$.

With an answer to **D1**, the designer may drop contradictory queries from Q . Here are some sufficient conditions to find these queries.

Proposition 1 A set Q of queries is contradictory relative to D , if Q includes a possibility query of form (8) such that some $s \in S(D)$ satisfies ϕ , but no $s \in S(D)$ satisfies ψ .

Proposition 2 A set Q of queries is contradictory relative to D , if Q includes a necessity query necessarily ψ' after A if ϕ' and a possibility query (8) such that some state in $S(D)$ satisfies $\phi \wedge \phi'$, but no state in $S(D)$ satisfies $\psi \wedge \psi'$.

Example 5 In our running example (i.e., Example 1), if Q had contained the query possibly $\text{Light} \wedge \text{Broken}$ after Toggle if True then, due to Proposition 1, Q would be contradictory relative to D .

If the given set of queries is not contradictory, then she may ask:

D2: If D does not satisfy a particular necessity query q in Q , which dynamic causal laws in D violate q ?

We understand violation of a query as follows:

Definition 2 A dynamic causal law $l \in D$ violates a given necessity query q , if there is a transition $tc = \langle s, A, s' \rangle$ in $T(D)$ such that tc violates q , l is applicable to tc , and s' satisfies the head of l .

Once the designer finds out which causal laws violate which queries, she may want to repair the action description in a way that some causal laws (e.g., the inertia laws) are not modified at all:

D3: Can we resolve a conflict between D and Q , without modifying a set D_0 of causal laws in D ?

To answer **D3** the following definition and proposition are helpful.

Definition 3 A transition diagram T satisfies a set D of causal laws (denoted $T \models D$), if, for each transition $tc = \langle s, A, s' \rangle$ in T , for each causal law $l \in D$, l is not applicable to tc or s' satisfies the head of l .

Proposition 3 Let D be an action description, and Q be a set of queries. If there exists a transition diagram T such that $T \models D$ and $T \models Q$, then there exists an action description D' , such that $S(D) = S(D')$, $D \subseteq D'$ and $T = T(D')$.

With this proposition, we can answer **D3** by checking if any transition diagram, having states $S(D)$, that satisfies D_0 also entails Q .

Example 6 In our running example it is possible to repair D without modifying the inertia laws: there exists an action description containing the inertia laws and satisfying the given queries (cf. Example 4).

In another scenario, the designer may suspect that the definition of a particular fluent causes problems, so she may want to know whether some particular laws have to be modified in order to obtain a repair:

D4: Do we have to modify a set D_0 of dynamic causal laws in D to resolve a conflict between D and Q ?

For this, due to the proposition below, we can check whether none of the transition diagrams, with the same states as D (and thus as D_0), that satisfy D_0 , entails Q .

Proposition 4 Let D_0 be an action description, and Q be a set of queries. If some $D_0 \subseteq D$ satisfies $S(D_0) = S(D)$ and $D \models Q$, then there exists a transition diagram T such that $T \models D_0$ and $T \models Q$.

Questions about states and transitions. Alternatively, the designer may want to extract some information from $T(D)$. For instance, an answer to the following question gives information about states violating a query q in Q :

T1: Which states of $T(D)$ satisfying a given formula ϕ' violate q ?

Example 7 In Example 1, if we just consider states where the light is on (i.e., $\phi' = \text{Light}$), then the only state at which a query of Q is violated is $\{\text{Light}, \neg \text{Broken}\}$.

An answer to the following question gives information about transitions violating a necessity query q in Q :

T2: Given formulas ψ' and ϕ' , which transitions $\langle s, A, s' \rangle$ of $T(D)$ such that s satisfies ϕ' and s' satisfies ψ' , violate q ?

With such information extracted from the transition diagram, the designer might decide how to modify the action description D .

Suppose that D does not satisfy a possibility query (8) in Q . The designer may want to learn about possible transition candidates that, when added to $T(D)$ by modifying the definition of some literal L in D , might lead to a repair:

T3: Given a literal L , for every state s of $T(D)$ such that s satisfies ϕ , is there some under-specified transition candidate $tc = \langle s, A, s' \rangle$ for D such that s' satisfies $\psi \wedge L$ and L is under-specified relative to tc ? If there is, then what are they?

Here under-specification is understood as follows:

Definition 4 A transition candidate $tc = \langle s, A, s' \rangle$ for D is under-specified, if $\{s'\} \subset \text{sat}(H_D(tc))$. A literal L is under-specified relative to a transition candidate tc , if $\{L, \bar{L}\} \cap H_D(tc) = \emptyset$.

With a positive answer to **T3**, the designer may try to modify the description D , e.g., by adding caused L if ψ after $A \wedge \phi$.

6 COMPLEXITY RESULTS

First let us remind the following result from [2]: Given an action description D and a set Q of queries, deciding $D \models Q$ is Π_2^p -complete in general. When Q contains the single query **possibly True after A if True**, the executability of an action A at every state, this result conforms with the ones reported in [10, 6].

In the following, we formally state two central results and, informally discuss how to obtain further results. The first main result is about the existence of a conflict resolution between an action description D and Q without modifying a subset D_0 of D .

Theorem 2 *Given D, Q , and $D_0 \subseteq D$, deciding if there exists some D' , such that $S(D)=S(D')$, $D_0 \subseteq D'$, and $D' \models Q$, is Π_2^p -complete.*

We can show Π_2^p -hardness even for $D_0 = \emptyset$; for such D_0 , complexity drops only if in addition Q is restricted to queries of form (8) (to P_{\parallel}^{NP} -completeness, i.e., polynomial time with parallel queries to an NP-oracle, see, e.g., [5]).

The second main result is about the existence of a conflict resolution between an action description D and Q without modifying the transition diagram described by D .

Theorem 3 *Given D and Q , deciding if there exists some D' , such that $S(D)=S(D')$, $D' \models Q$, and $R(D) \subseteq R(D')$, is Π_2^p -complete.*

We remark that if some repair of D for Q is known to exist, then deciding the above problem is coNP-complete.

Table 1. Complexity results (completeness) for problems **D1–D4**, **T1–T3**.

Problem	D1	D2	D3	D4	T1	T2	T3
	Σ_2^p	NP	Π_2^p	Σ_2^p	Σ_2^p	NP	Π_2^p
$Q_n = \emptyset$	P_{\parallel}^{NP}	$O(1)$	Π_2^p	Σ_2^p	Σ_2^p	$O(1)$	Π_2^p
$Q_p = \emptyset$	$O(1)$	NP	$O(1)$	$O(1)$	NP	NP	Π_2^p

Table 1 shows complexity results for the decision problems resp. existence problems⁴ related to the questions above (denoted **D1–D4**, resp. **T1–T3**) for the general case, and when $Q_n = \emptyset$, or $Q_p = \emptyset$.

Deciding whether Q is contradictory w.r.t. D (**D1**) is Σ_2^p -complete in general. Intuitively, this is because deciding the violation of a possibility query q is Σ_2^p -complete. We have to guess a violating state and verify, by means of an NP-oracle, for corresponding transition candidates that they do not satisfy q . Since we can express necessity queries by dynamic causal laws, this source of complexity carries over to deciding whether a set of (mixed) queries Q is contradictory. From these observations, Σ_2^p -completeness of the existence version of **T1** (i.e., whether such a state exists) is straightforward. However, if $Q_n = \emptyset$, to show that Q is contradictory w.r.t. D , it is sufficient to test whether, for some query (8) in Q_p , some state satisfies ϕ but no state satisfies ψ . This amounts to a Boolean combination of SAT instances, whose evaluation is in P_{\parallel}^{NP} . For $Q_p = \emptyset$, note that a set Q_n of necessity queries cannot be contradictory.

On the other hand, deciding whether a necessity query q is violated is in NP: Guess and verify in polynomial time a transition violating q . Thus, e.g., deciding whether a causal law $l \in D$ violates $q \in Q_n$ (i.e., **D2**) is NP-complete, as well as the existence version of **T2**.

D3 is the problem considered in Theorem 2, **D4** is the complementary problem, and corresponding results have been discussed above. Finally, the property of **T3** fails if there exists a state s satisfying ϕ , such that no under-specified transition candidate $tc = \langle s, A, s' \rangle$ for D exists, such that $s' \models \psi \wedge L$. Since for a given s , this can be checked with an NP-oracle, failure of the property is in Σ_2^p .

⁴ Formal statements of these problems will be given in an extended version.

7 RELATED AND FUTURE WORK

In [2], the authors describe a method to minimally modify an action description, when new causal laws are added, by deleting some causal laws, so that given queries are satisfied. In the method above, we obtain an action description by adding or modifying some causal laws, motivated by some reasons for conflicts. For some problems, as discussed in the introduction, just dropping causal laws as in [2] does not lead to a solution, whereas our method above does.

Similar to [2], [8] discusses how to minimally update a logic program syntactically so that given observations are satisfied. A semantical approach to updating a logic program by changes to Kripke structures is given in [9], but no conditions are considered. [11] describes how to resolve conflicts between a logic program and a set of constraints by “forgetting” some atoms in the program; [12] describes how logic programs can be updated with that approach.

In [1], the authors extend an action description, encoded as a logic program, with “consistency restoring” rules, so that when the action description and given observations are incompatible, these rules can be “applied” to get some consistent answer set. This, however, is more geared towards handling exceptions. Lifschitz describes in [7] an action domain in language C such that every causal law is defeasible (by means of an abnormality predicate). To formulate some other variations of the domain, the agent can just add new causal laws, some of which “disable” some existing causal laws. In [1] and [7], the causal laws of the original domain description are not modified.

Ongoing work includes an implementation of the method described above for resolving conflicts, and the investigation of the use of a SAT solver or an answer set solver to answer the questions discussed above (as suggested by the computational complexity results of the corresponding decision problems, presented in Table 1). Employing a richer query language, like that of [2] or the extension of action query language \mathcal{P} as in [3], in which conditions on sequences of action occurrences can be expressed, is a future work.

Possibilistic Influence Diagrams

Laurent GARCIA¹ and Régis SABBADIN²

Abstract. In this article we present the framework of *Possibilistic Influence Diagrams* (PID), which allow to model in a compact form problems of sequential decision making under uncertainty, when only ordinal data on transitions likelihood or preferences are available. The graphical part of a PID is exactly the same as that of usual influence diagrams, however the semantics differ. Transition likelihoods are expressed as possibility distributions and rewards are here considered as satisfaction degrees. Expected utility is then replaced by anyone of two possibilistic qualitative utility criteria for evaluating strategies in a PID. We describe a decision tree-based method for evaluating PID and computing optimal strategies. We then study the computational complexity of PID-related problems (computation of the value of a policy, computation of an optimal policy).

Keywords: decision, possibility theory, causal networks, influence diagrams.

1 INTRODUCTION

For several years, there has been a growing interest in the Artificial Intelligence community towards the foundations and computational methods of decision making under uncertainty. This is especially relevant for applications to planning, where a suitable sequence of decisions is to be found, starting from a description of the initial world, of the available decisions and their effects, and of the goals to reach. Several authors have thus proposed to integrate some parts of decision theory into the planning paradigm. A classical model for decision making under uncertainty is based on *Markov decision processes* (MDP), where actions effects are stochastic and the satisfaction of agents expressed by a numerical, additive utility function. However, classical dynamic programming (DP) algorithms [9] do not scale to the size of problems that can be compactly represented by the factored representations traditionally used in AI. Therefore several methods of aggregation/decomposition for large problems have been proposed in the AI community. Aggregation methods [2], for example, use a compact representation of probability and reward functions involved in the MDP description and propose algorithms dealing explicitly with this representation. These methods are often based on the use of *Influence Diagrams* [6] which form such a factored representation framework for problems of decision under uncertainty (sequential or non sequential).

However, transition probabilities are not always available for representing the effects of actions, especially in Artificial

Intelligence applications where uncertainty is often ordinal, qualitative. The same remark applies to utilities: it is often more adequate to represent preference over states simply with an ordering relation rather than with additive utilities. Several authors have advocated this qualitative view of decision making and have proposed qualitative versions of decision theory. [4] propose a qualitative utility theory based on possibility theory, where preferences and uncertainty are both expressed qualitatively. [5, 10] have extended the use of these criteria to sequential decision, allowing the definition of (non-factored) possibilistic MDP and have proposed counterparts of the classical DP solution methods for MDP.

In this paper, after having presented possibilistic counterparts of expected utility (Section 2), we present (Section 3) the framework of *Possibilistic Influence Diagrams* (PID), which allow to model in a compact form problems of sequential decision making under uncertainty, where only ordinal data on transition likelihoods or preferences are available. The graphical part of PID is exactly the same as that of usual influence diagrams, however the semantics differ. Transition likelihoods are expressed by possibility distributions, and rewards are here considered as satisfaction degrees attached to partial goals. Expected utility is then replaced by anyone of the two possibilistic qualitative utility criteria proposed by [4] for evaluating strategies in a PID. Then (Section 4), we describe a decision tree-based method for evaluating PID and computing optimal strategies. We finally show some complexity results on solving PID-related problems (Section 5).

2 POSSIBILISTIC COUNTERPARTS OF EXPECTED UTILITY

[4] propose an ordinal counterpart of the expected utility theory based on possibility theory. The basic measure of possibility theory is the possibility distribution which describes knowledge about the unknown value taken by one or several attributes used to describe states of affairs. It can represent *uncertain knowledge* distinguishing what is plausible from what is less or it can represent *preferences* over desired or less desired states.

In the framework of decision under uncertainty, some state variables are *controlled* by a decision maker who can choose their value, depending on the observation of the values of (all or) some other state variables. The decision maker thus applies a *strategy* δ mapping the set of (observed) uncontrolled state variables values into controlled (decision) variables values. The uncertainty of the agent about the effect of strategy δ is represented by a possibility distribution π_δ mapping the set X of state variables values into a bounded, linearly ordered

² INRA-BIA Toulouse, France. Email: sabbadin@toulouse.inra.fr

(qualitative) valuation set L . Set L is assumed to be equipped with an order-reversing map n . Let 1_L and 0_L denote the top and bottom elements of L , respectively. Then $n(0_L) = 1_L$ and $n(1_L) = 0_L$. The quantity $\pi_\delta(x)$ thus represents the degree of possibility of the state x being the consequence of strategy δ . $\pi_\delta(x) = 1_L$ means that x is completely plausible, whereas $\pi_\delta(x) = 0_L$ means that it is completely impossible.

It makes sense, if information is qualitative, to represent not only the incomplete knowledge on the state by a possibility distribution π_δ on X but also the decision-maker's preferences on X by means of another possibility distribution μ_δ with values on a preference scale U . Here, we assume that uncertainty and preferences are commensurate, that is U can be identified to L . $\mu_\delta(x) = 1_L$ means that x is completely satisfactory, whereas if $\mu_\delta(x) = 0_L$, it is totally unsatisfactory. Notice that π_δ is normalised (there shall be at least one completely possible state of the world), but μ_δ may not be (it can be that no consequence is totally satisfactory).

[4] proposed the two following qualitative decision criteria for assessing the value of a strategy δ :

$$\begin{aligned} u^*(\delta) &= \max_{x \in X} \min\{\pi_\delta(x), \mu_\delta(x)\} \\ u_*(\delta) &= \min_{x \in X} \max\{n(\pi_\delta(x)), \mu_\delta(x)\} \end{aligned}$$

u^* can be seen as an extension of the *maximax* criterion which assigns to an action the utility of its best possible consequence. On the other hand, u_* is an extension of the *maximin* criterion which corresponds to the utility of the worst possible consequence. u_* measures to what extent every plausible consequence is satisfactory. u^* corresponds to an adventurous (optimistic) attitude in front of uncertainty, whereas u_* is conservative (cautious).

3 POSSIBILISTIC INFLUENCE DIAGRAMS

Possibilistic influence diagrams are the possibilistic counterpart of *influence diagrams* (ID) [6, 11] which extend Bayesian networks to handle decision under uncertainty. A *possibilistic influence diagram* (PID, see Figure 1) is a *directed acyclic graph* DAG containing three different kinds of nodes :

- **chance nodes**, drawn as circles, represent state variables $X_i \in \mathcal{X} = \{X_1, \dots, X_n\}$, as in the *Bayesian Networks* (BN) framework [8]. A combination $x = \{x_1, \dots, x_n\}$ of state variables values represents a state.
- **decision nodes**, drawn as rectangles, represent decision variables $D_i \in \mathcal{D} = \{D_1, \dots, D_p\}$. A combination $d = \{d_1, \dots, d_p\}$ of values represents a decision.
- **utility nodes** $\{V_1, \dots, V_q\}$, drawn as diamonds, represent local “satisfaction degree” functions $r_i \in \{r_1, \dots, r_q\}$.

The directed edges in the PID represent either causal influences or information influences between variables.

Before we describe the underlying semantics of possibilistic influence diagrams (PID), let us give two structural assumptions on the DAG : i) The utility nodes have no children. ii) There exists a directed path comprising all decision nodes³.

³ While the first assumption is classical in usual ID, the second one is simply a convention which simplifies the resolution of problems described as ID (possibilistic or not). The directed path induces an ordering of decision variables which will be exploited by the decision tree solution methods.

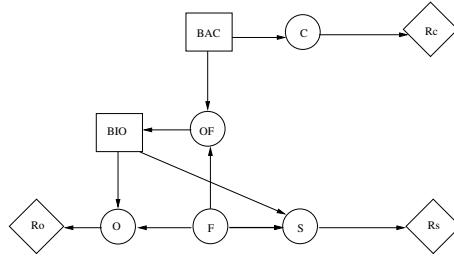

Figure 1. How to make a six-egg omelette from a five-egg one

Now, in addition to the graphical part, which is very similar to that of a classical ID, PID also comprise numerical (ordinal) specifications. Let us recall that, in our possibilistic setting, this numerical ordering is handled in a qualitative way. First, state and decision variables have a finite state space. Furthermore, utility nodes have no state space attached. Then, concerning local dependencies, each state variable X_i has a set $Par(X_i)$ of parents in the DAG. $Par(X_i)$ can comprise both state and decision variables. A conditional possibility table $\Pi(X_i|Par(X_i))$ is attached to every state variable X_i . It specifies every conditional possibility $\Pi(x_i|x_{Par(X_i)}, d_{Par(X_i)})$ where $x_i \in X_i$ ⁴, $x_{Par(X_i)} \in \mathcal{X}_{Par(X_i)} = \bigotimes_{j, X_j \in Par(X_i) \cap \mathcal{X}} X_j$ and $d_{Par(X_i)} \in \mathcal{D}_{Par(X_i)} = \bigotimes_{j, D_j \in Par(X_i) \cap \mathcal{D}} D_j$. $\mathcal{X}_{Par(X_i)}$ is the Cartesian product of the domains of the state variables belonging to $Par(X_i)$ and $\mathcal{D}_{Par(X_i)}$ is the Cartesian product of the domains of the decision variables belonging to $Par(X_i)$. If X_i is a root of the DAG ($Par(X_i) = \emptyset$) we specify the a priori possibility degrees $\Pi(x_i)$ associated with each instance x_i of X_i .

Now if D_j is a decision node, its value d_j will be fixed by the decision maker. However, incoming links will specify which information is available when the decision is taken, and how the domain of D_j is restricted by the values of the variables in $Par(D_j)$ ⁵. Furthermore, we adopt the generally accepted *no forgetting assumption*, which implies that all the values of the variables that have been instantiated before d_j is chosen are still known at the time of the choice of d_j .

Solving a PID amounts to compute a *strategy*, allowing to maximise one of the possibilistic qualitative utilities. A strategy for a PID specifies the value of every decision variables as a function of all (or part of) the known values of the variables at the time the decision is taken.

Formally, a strategy is defined as :

Definition 1 (Strategy) In a PID, a strategy is a function $\delta : \mathcal{X} \rightarrow \mathcal{D}$ which can be represented as a set of local functions $\{\delta_j\}_{j \in 1 \dots p}$, $\delta_j : \Omega_j \rightarrow D_j$.

⁴ X_i will denote both the variable name and its domain, the meaning should be clear from the context. In the same way, \mathcal{X}_A , with $A \subseteq \{1, \dots, n\}$ will represent both a set of variables and the Cartesian product of their domains. The same holds for decision variables.

⁵ For sake of simplicity of exposition, we will assume in this paper that no restriction to the domain D_j will result from any instantiation of variables in $Par(D_j)$. However, this simplifying assumption is easy to relax, despite the fact that it induces cumbersome notations.

Ω_j denotes the cross product of the domains of all the variables (state and decision) instantiated before D_j . The variables instantiated before D_j (or before any state variable X_i) are called *ancestors* of D_j (of X_i). A strategy δ assigning an instantiation d to any global instantiation x of the state variables can thus be decomposed as a set of *local strategies* $\{\delta_j\}_{j \in 1 \dots p}$, δ_j specifying the value of decision variable D_j , for any possible instantiation of the variables in Ω_j . Notice that since Ω_j can contain decision variables, it is necessary to instantiate the decision variables in a suitable order (parents must be instantiated before their children). The fact that the diagram is a DAG guarantees that this order exists, and the above-mentioned assumption on the existence of a direct path comprising every decision variables guarantees its uniqueness.

Finally, for each utility node V_k , we prescribe ordinal values $\mu_k(x_{Par(V_k)}, d_{Par(V_k)})$ to every possible instantiations $(x_{Par(V_k)}, d_{Par(V_k)})$ of the parent variables of V_k . These values represent satisfaction degrees attached to the local instantiations of the parent variables. It is assumed, analogously to *Flexible Constraint Satisfaction Problems* [3], that the global satisfaction degree $\mu(x, d)$ associated with a global instantiation (x, d) of all variables (state and decision) can be computed as the *minimum* of the local satisfaction degrees : $\mu(x, d) = \min_{k=1 \dots q} \mu_k(x_{Par(V_k)}, d_{Par(V_k)})$.

Now, we are able to compute the optimistic and pessimistic utilities of a strategy δ . Once a strategy δ is chosen, the chance nodes form a possibilistic causal network and thus determine a unique *least specific* joint possibility distribution π_δ over chance nodes interpretations $x = \{x_1, \dots, x_n\}$. This joint possibility distribution can be computed by applying the *chain rule* [1] :

$$\pi_\delta(x) = \min_{k=1 \dots n} \Pi(x_k | x_{Par(X_k)}, d_{Par(X_k)}),$$

where $d = \delta(x)$. A global satisfaction degree $\mu_\delta(x)$ on state variables instantiations induced by a strategy can also be computed :

$$\mu_\delta(x) = \min_{l=1 \dots q} \mu_l(x_{Par(V_l)}, d_{Par(V_l)}).$$

Notice that $\pi_\delta(x)$ and $\mu_\delta(x)$ depend on the value of state variables only since a strategy δ uniquely defines the value $d = \delta(x)$ from x . It is then possible to compute the possibilistic optimistic and pessimistic qualitative expected utilities of a strategy δ :

$$\begin{aligned} u^*(\delta) &= \max \min_x \{\pi_\delta(x), \mu_\delta(x)\} \\ u_*(\delta) &= \min_x \max \{n(\pi_\delta(x)), \mu_\delta(x)\} \end{aligned} \quad (1)$$

Consider the example of Figure 1. The problem is to make a six-egg omelette from a five-egg one. The new egg can be fresh or rotten. There are two binary decision variable: break the egg in the omelette BIO ($BIO = yes$ if the egg is put in the omelette and $BIO = false$ if the egg is thrown away) ; break it apart in a cup BAC .

The state variables are the following. C : whether we have a cup to wash ($C = t$) or not ($C = f$). OF : whether we observe that the egg is fresh ($OF = t$) or rotten ($OF = f$) or we do not observe the egg ($OF = u$). F : the “real” state of the egg, fresh ($F = t$) or rotten ($F = f$). O : whether we get a six-egg omelette ($O = 6O$), a five-egg omelette ($O = 5O$) or no omelette at all ($O = nO$). S : whether an egg is spoiled ($S = t$) or not ($S = f$).

Let us take $L = \{0, \dots, 5\}$. The only a priori possibilities concern F , let us stand for $\Pi(F = t) = 5$ and $\Pi(F = f) = 3$. The

conditional possibilities are defined w.r.t. the natural meaning of the problem (here each possibility value is 0 or 5 but it is not always the case) :

$\Pi(C BAC)$	t	f	$\Pi(S F, BIO)$	(t, f)	(t, t)	(f, f)
t	5	0	t	5	0	0
f	0	5	f	0	5	5
u	0	0	u	0	0	5

$\Pi(O F, BIO)$	(t, t)	(f, t)	(\cdot, f)
t	5	0	0
f	0	5	0
u	0	0	5

$\Pi(O F, BIO)$	(\cdot, f)	(t, t)	(f, t)
$6O$	0	5	0
$5O$	5	0	0
nO	0	0	5

Utility functions μ_O, μ_S and μ_C are defined as follows, and for any global instantiation (x, d) , $\mu(x, d) = \min\{\mu_O(o), \mu_S(s), \mu_C(c)\}$.

O	$\mu_O(O)$	S	$\mu_S(S)$	C	$\mu_C(C)$
$6O$	5	f	5	t	5
$5O$	3	t	2	f	4
nO	0				

4 SOLUTION METHOD: DECISION TREE

Solving a PID amounts to finding an *optimal* strategy δ^* , i.e. one which maximises the (either optimistic or pessimistic) possibilistic utility. A PID can be unfolded into a *possibilistic decision tree*, using a method very similar to that of [6] for usual ID. A decision tree represents every possible scenarios of successive actions and observations, for a given ordering of decision variables⁶. In a possibilistic decision tree, branches issuing from a decision node are labelled with possible instantiations of the decision variable. Branches issuing from a chance node X_i are labelled with an instantiation of the variable and with its possibility degree computed from local transition possibilities together with the instantiations of the ancestors of X_i in the branch.

In order to build the decision tree, an ordering of the variables, compatible with the precedence constraints expressed by the DAG in Figure 1, must be chosen. Figure 2 shows a decision tree obtained by unfolding the PID in Figure 1 with the ordering $\{BAC, F, OF, BIO, O, S, C\}$, which is obviously compatible with the order induced by the DAG.

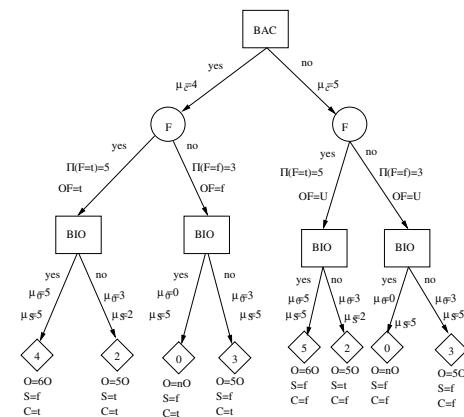

Figure 2. Decision tree associated with the example PID.

⁶ This is the reason why we choose to fix an ordering of decision variables in a PID.

The tree is then built by successively adding nodes, following the initial ordering. Branches issuing from the node are then added and labelled with the different possible values of the corresponding variable (either states or decisions). Note that in the decision tree of figure 2, after nodes *BAC* and *F* have been added, node *OF* is omitted since it has only one possible value, knowing the values of *BAC* and *F* (for example, in the leftmost branch *OF* is *true* since *F* is known to be *true* and *BAC* = *yes*). For the same reasons, nodes *C*, *O* and *S* are not displayed. Then, to each leaf of the decision tree is associated one particular interpretation of the variables. In figure 2, the leftmost branch corresponds to the instantiations $F = t, OF = t, O = 6O, S = f, C = t$ and $BAC = yes, BIO = yes$.

Then, to each leaf are attached both a possibility degree $\pi(x)$ and an aggregated satisfaction degree $\mu(x)$. Following the chain rule, $\pi(x)$ (resp. $\mu(x)$) is the minimum of the transition possibilities (resp. satisfaction degrees) involved in the branch from the root to the leaf. For example, the possibility degree of the leftmost branch of figure 2 is $\pi = \Pi(F = t) = 5$ and its utility is $\mu = \min(\mu_O(6O), \mu_C(t), \mu_S(f)) = 4$.

Now, in order to compute a possibilistic optimal strategy from the decision tree, we apply a *backwards induction* method similar to the one designed in [5]. First, note that choosing a strategy amounts to cut all branches issuing from each decision node, but one (corresponding to the action prescribed by the strategy, the values of the ancestor variables of the decision node being fixed in the branch). Figure 3 shows the pruned tree when strategy (*BAC* = *no*, *BIO* = *yes*) is chosen (note that this strategy is unconditional). In the optimistic case, the value of the leaf is $\min(\pi(x), \mu(x))$, hence the value of the leftmost leaf is 4. The utility of a strategy δ is then simply the maximum of the leaves values, corresponding to $u^*(\delta) = \max_{x \in \mathcal{X}} \min\{\pi_\delta(x), \mu_\delta(x)\}$. In Figure 3, the values of the two remaining leaves of the pruned tree are 5 and 0, thus the utility of the chosen strategy is 5. The pessimistic value of the same strategy corresponds to $u_*(\delta) = \min_{x \in \mathcal{X}} \max\{\pi_\delta(x), \mu_\delta(x)\}$. The remaining leaves take values $\max(0, 5) = 5$ and $\max(0, 3) = 3$ and the pessimistic utility is the minimum of these leaves values : $\min(5, 3) = 2$.

An optimal strategy can be computed by rolling the full decision tree backwards, keeping only one issuing branch for each decision node, and eliminating unobserved chance nodes:

- If all the children of a decision node already have an attached possibilistic utility, only its issuing branch with the highest value is kept. This highest value is attached to the decision node.
- If all the children of an unobserved chance node already have an attached possibilistic utility, it is replaced with a utility node containing its possibilistic (either optimistic or pessimistic) expected value.

These two steps are iterated until a possibilistic utility is attached to the root node. The remaining tree represents the optimal optimistic strategy, together with its utility. Figure 3 shows the optimal optimistic strategy computed with the omelette example. Note that the computed strategy (which is to break the egg directly in the omelette without using the cup) agrees with the intuition that since the a priori distribution on *F* makes *F* more likely than *noF* and since the

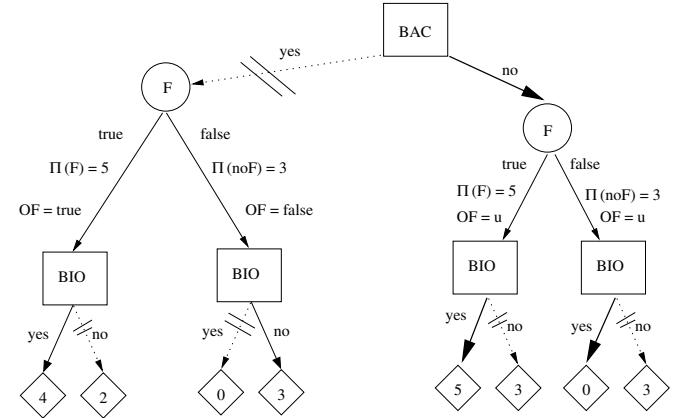

Figure 3. Optimal optimistic decision strategy computation.

decision maker is optimistic, he should not bother testing the freshness of the egg before using it.

5 COMPLEXITY RESULTS

The two basic questions which can be answered within the PID framework are :

1. Assessment of the possibilistic utility of a strategy δ .
2. Computation of an optimal strategy δ^* .

In this section we give the complexity of these problems, both for optimistic and pessimistic utilities. Proofs of Prop. 2, 3, 4 will only be sketched for sake of brevity since they are largely similar to that of Prop. 1. Note that NPO represent the class of optimisation problems “find $\alpha^* = \max_\alpha \dots$ ” for which the associated decision problem “is $\alpha^* = (\max_\alpha \dots) \geq \beta$?” is in NP.

Proposition 1 (Optimistic strategy evaluation (OSE))
A PID and a strategy δ being given, the problem of computing $u^*(\delta)$ is in NPO and is NP-hard.

Proof : OSE is a maximisation problem, since $u^*(\delta) = \max_x \min\{\pi_\delta(x), \mu_\delta(x)\}$. OSE is in NPO since it can be solved in polynomial time by the following non-deterministic algorithm, where step 2 can obviously be performed in polynomial time:

1. $\forall \alpha \in L$,
guess x ,
2. if $\min\{\pi_\delta(x), \mu_\delta(x)\} \geq \alpha$, return YES(α), else NO(α).
3. $u^*(\delta) = \max\{\alpha \text{ s.t. YES}(\alpha) \text{ holds}\}$.

Now, in order to show that OSE is NP-hard, we exhibit a polynomial transformation from 3-SAT to OSE. Let 3-SAT be defined as a set $\{v_1, \dots, v_n\}$ of variables and $\{\psi_1, \dots, \psi_m\}$ be a set of 3-clauses. Let us define the following PID, where $\mathcal{X} = \{X_1, \dots, X_n\}$ are binary variables, and the set of utility nodes is $\{r_0, r_1, \dots, r_m\}$. $\mathcal{D} = \{D_0\}$, where D_0 has domain $\{t, f\}$. Variables X_i have no parents and their unconditional possibility distributions are defined as $\Pi(X_i = t) = \Pi(X_i = f) = 1_L, \forall i$. There are arcs from X_i to r_j if and only if $v_i \in \text{Scope}(\psi_j)$. The local utility functions are the following : $\forall j > 0$, $\mu_j(x_{Par(r_j)}) = 1_L$ if $x_{Par(r_j)}$ satisfies ψ_j and 0_L else. D_0 is not connected to any other node. Then, if we fix δ

to $d_0 = t$ (δ is unconditional) and if we fix $\alpha = 1_L$, then obviously the utility of any δ is 1_L if and only if $\{\psi_1, \dots, \psi_m\}$ is satisfiable. So, this OSE solves 3-SAT for any strategy δ . Furthermore, the transformation is polynomial in time and space since utility tables have at most 2^3 elements (the ψ_j are 3-clauses). \square

Proposition 2 (Optimistic strategy optimisation (OSO))

A PID being given, the problem of computing an optimal optimistic policy δ^ and its utility $u^*(\delta)$ is in NPO and is NP-hard.*

Sketch of proof : Just notice that the OSO problem can be stated equivalently as the following maximisation problem : Find $U^* = \max_d \max_x \min\{\Pi(x|d), \mu(x, d)\}$. So, similarly to the OSE case, the problem will be here to guess interpretations (x, d) (instead of x only) for all fixed $\alpha \in L$, and to keep the “best one” : (x^*, d^*) . Thus, OSO is NPO. OSO is of course NP-hard, since OSE is. Note that δ^* is only defined in x^* ($\delta^*(x^*) = d^*$) and can take any value elsewhere. \square

Remark that it is obvious, from the proof of Prop. 2 that finding an optimal policy in an optimistic decision problem amounts to finding the branch with maximal leaf utility in the corresponding decision tree.

Proposition 3 (Pessimistic strategy evaluation (PSE))

A PID and a strategy δ being given, the problem of computing $u_(\delta)$ is in NPO and is NP-hard.*

Sketch of proof : PSE is a *minimisation* problem. $u_*(\delta) = \min_x \max\{n(\pi_\delta(x)), \mu_\delta(x)\}$. The same reasoning as for OSE can be used to show that PSE is NPO:

- 1. $\forall \alpha \in L$,
- 1. guess x ,
- 2. if $\max\{n(\pi_\delta(x)), \mu_\delta(x)\} \leq \alpha$, return YES(α), else NO(α).
- 3. $u^*(\delta) = \min\{\alpha \text{ s.t. YES}(\alpha) \text{ holds}\}$.

To show NP-hardness, we use the same transformation as for OSE, except that $\forall j > 0$, $\mu_j(x_{Par(r_j)}) = 0_L$ if $x_{Par(r_j)}$ satisfies ψ_j and 1_L else. Then the logic base will be satisfiable if and only if $u_* = 0_L$ (and not 1_L). \square

The problem, when solving a PSE, amounts to finding the branch in the pruned decision tree (a strategy being fixed) with *minimum* leaf utility.

The pessimistic strategy optimisation problem is more complex since the corresponding exploration of the (complete) decision tree alternates maximisation at decision nodes and minimisation at state nodes. The following result can be shown:

Proposition 4 (Pessimistic strategy optimisation (PSO))

A PID being given, the problem of computing an optimal pessimistic policy δ^ and its utility $u_*(\delta)$ is \sum_2^p -complete.*

Sketch of proof : We want to compute: $\max_\delta u_*(\delta) = \max_\delta \min_x \max\{n(\pi_\delta(x)), \mu_\delta(x)\}$, which we can write $\max_\delta u_*(\delta) = \max_d \min_x \max\{n(\Pi(x|d)), \mu(x, d)\}$. Let $\alpha \in L$ be given, “is $\max_\delta u_*(\delta) \leq \alpha$?” is equivalent to “is it true that $\exists x, \forall d, \max\{n(\Pi(x|d)), \mu(x, d)\} \leq \alpha$?” This question, of the form “is it true that $\exists x, \forall y, r(x, y)$?” is known to be \sum_2^p -complete. So, PSO can be solved by solving at most $|L| \sum_2^p$ -complete decision problems and is thus \sum_2^p -complete itself. \square

6 CONCLUSION

In this article we have described *Possibilistic Influence Diagrams* (PID), which allow to model in a compact form problems of sequential decision making under qualitative uncertainty in the framework of possibility theory. We have described a decision-tree based solution method for PID and we have given computational complexity results for several questions related to PID. Even though our complexity results seem negative in a sense, PID-related problems being at least NP-hard, these results have to be mitigated by comparing this complexity to that of structured stochastic MDP, shown to be EXP-hard [7], i.e. provably not in the polynomial hierarchy!

We now plan to work in the two following directions. First, even if we know that PID solving is at best NP-hard, we may look for more efficient solution methods than decision tree “brute force” exploration. We can either explore methods derived from stochastic ID [11, 12], such as *variable elimination* and to exploit specific features of PID. We can also try to exploit methods of exploration of *minimax* trees, since the decision tree obtained in the pessimistic case is a minimax tree. Another possible direction is to study more particularly structured *possibilistic Markov decision processes* [10] for which specific PID representations should be defined, representing explicitly the time-structure of the process (in the way 2-DBN are used to model structured MDP in [2]). This would lead to define structured versions of the possibilistic *value iteration* and *policy iteration* algorithms proposed in [10].

Solving Optimization Problems with DLL

Enrico Giunchiglia¹ and Marco Maratea^{1, 2}

Abstract.

Propositional satisfiability (SAT) is a success story in Computer Science and Artificial Intelligence: SAT solvers are currently used to solve problems in many different application domains, including planning and formal verification. The main reason for this success is that modern SAT solvers can successfully deal with problems having millions of variables. All these solvers are based on the Davis-Logemann-Loveland procedure (DLL). DLL is a decision procedure: Given a formula φ , it returns whether φ is satisfiable or not. Further, DLL can be easily modified in order to return an assignment satisfying φ , assuming one exists. However, in many cases it is not enough to compute a satisfying assignment: Indeed, the returned assignment has also to be “optimal” in some sense, e.g., it has to minimize/maximize a given objective function.

In this paper we show that DLL can be very easily adapted in order to solve optimization problems like MAX-SAT and MIN-ONE. In particular these problems are solved by simply imposing an ordering on a set of literals, to be followed while branching. Other popular problems, like DISTANCE-SAT and WEIGHTED-MAX-SAT, can be solved in a similar way. We implemented these ideas in ZCHAFF and the experimental analysis show that the resulting system is competitive with respect to other state-of-the-art systems.

1 Introduction

Propositional satisfiability (SAT) is a success story in Computer Science and Artificial Intelligence: SAT solvers are currently used to solve problems in many different application domains, including planning [11], formal verification [6], and many others such as RNA folding, hand-writing recognition, graph isomorphism and sudoku problems. The main reason for this success is that modern SAT solvers can successfully deal with problems having millions of variables [5]. All these solvers are based on the Davis-Logemann-Loveland procedure (DLL) [9]. DLL is a decision procedure: Given a formula φ , it returns whether φ is satisfiable or not; Further, DLL can be easily modified in order to return an assignment satisfying φ , assuming one exists. However, in many cases it is not enough to compute a satisfying assignment: Indeed, the returned assignment has also to be “optimal” in some sense, e.g., it has to minimize/maximize a given objective function. MIN-ONE and MAX-SAT are two optimization versions of SAT. In MIN-ONE (resp. MIN-ONE \subseteq), given a satisfiable instance, the goal is to find a satisfying assignment in which the set of variables assigned to true is of minimal cardinality (resp. minimal). In MAX-SAT (resp. MAX-SAT \subseteq), given an unsatisfiable instance, the goal is to find an assignment in which the set of satisfied clauses is of maximal cardinality (resp. maximal). MIN-ONE and MAX-SAT problems have been studied, e.g., in [8, 16], and are particular cases of DISTANCE-SAT [3] and Pseudo-Boolean (see

e.g., [4]) problems. Our interest for MIN-ONE, MIN-ONE \subseteq , MAX-SAT and MAX-SAT \subseteq problems are related to their applications in the area of planning and formal verification, as briefly discussed in the rest of the paper. Besides these application domains, [8] shows that many important graph problems involving combinatorial optimization (such as Max-Cut, Max-Clique, and Min Vertex Cover) have linear-time reductions to MIN-ONE and MAX-SAT problems. Considering the procedures used to solve such problems, the standard approach is to modify DLL following a branch&bound schema. In the MIN-ONE case, whenever an assignment satisfying the input formula φ and with cost c_μ is found, search continues looking for another assignment satisfying φ but with a lower cost: The drawback of such approaches is that they may generate, at least in principle, all the assignments satisfying φ . Analogously for MAX-SAT problems.

In this paper we show that DLL can be very easily adapted in order to solve optimization problems like MIN-ONE, MAX-SAT and their variants. In particular these problems are solved by simply imposing an ordering on a set of literals, to be followed while branching. With such modification —differently from what happens for branch&bound approaches— the first discovered assignment satisfying the input formula, is guaranteed to be “optimal”: This assumes we are given a MIN-ONE/MIN-ONE \subseteq problem, but analogous considerations hold for the MAX-SAT/MAX-SAT \subseteq case. Other optimization problems, like DISTANCE-SAT and WEIGHTED-MAX-SAT, can be solved in a similar way. We implemented these ideas in ZCHAFF and the experimental analysis we conducted on MIN-ONE and MAX-SAT problems shows that:

- On MIN-ONE and MAX-SAT problems, our system is competitive with respect to other dedicated solvers and state-of-the-art systems used in the last Pseudo-Boolean evaluation [12].
- Considering MIN-ONE \subseteq problems, our solver is the fastest. In particular, our solver is much faster in solving MIN-ONE \subseteq instances than the corresponding MIN-ONE instances, while this is not the case for MAX-SAT \subseteq with respect to the MAX-SAT.
- Related to the previous point, comparing the cardinality $\#C$ (resp. $\#C\subseteq$) of the set of true variables returned when solving a MIN-ONE and a MIN-ONE \subseteq problem, we see that for most instances $\#C = \#C\subseteq$. Comparing the analogous values for MAX-SAT and MAX-SAT \subseteq , these are equal on all instances but three. Thus, provided we have an efficient solver for MIN-ONE \subseteq (resp. MAX-SAT \subseteq), it makes sense to use it also for MIN-ONE (resp. MAX-SAT) problems, at least for computing a “good” upper (resp. lower) bound.

The paper is structured as follows. In Section 2, we give the basic terminology and notation. We then present OPT-DLL, i.e., DLL modified in order to solve optimization problems (Section 3). How to model and solve optimization problems with OPT-DLL is showed in Section 4. The last two sections are devoted to the experimental analysis and the conclusions.

2 Formal preliminaries

Given a set S , a relation " $\prec \subseteq S \times S$ " is a (strict or irreflexive) *partial order on S* if it has the following properties:

1. *Irreflexivity*: $a \not\prec a$, for each $a \in S$.
2. *Antisymmetry*: $a \prec b$ and $b \prec a$ implies $a = b$.
3. *Transitivity*: $a \prec b$ and $b \prec c$ implies $a \prec c$.

If for each two distinct $a, b \in S$, $a \prec b$ or $b \prec a$ then \prec is said to be a *total order*. It is common to call the pair S, \prec a *partially ordered set*.

Consider a set P of *variables*. A *literal* is a variable or the negation \bar{x} of a variable x . In the following, $\bar{\bar{x}}$ is the same as x .

A *clause* is a finite set of literals, and a *formula* is a finite set of clauses. An *assignment* is a consistent set of literals.

Consider an assignment μ and formula φ .

A literal l is *assigned by μ* if either l or \bar{l} is in μ . We say that μ

- is *total* if each variable in P is assigned by μ ;
- *satisfies* a formula φ if for each clause $C \in \varphi$, $C \cap \mu \neq \emptyset$.

A formula is *satisfiable* if there exists an assignment satisfying it.

Consider a partial order \prec on the set of total assignments. Intuitively speaking, $\mu' \prec \mu$ means that μ' is preferred to μ . Thus, for us, a *total assignment μ is optimal (with respect to \prec)* if

1. μ satisfies φ ; and
2. there is no total assignment μ' satisfying φ and with $\mu' \prec \mu$.

An *assignment μ is optimal (with respect to \prec)* if μ satisfies φ and there exists a total and optimal assignment extending μ .

3 OPT-DLL

As we anticipated in the introduction, OPT-DLL is like the standard DLL except for the heuristic. Given a formula φ , the basic idea of OPT-DLL is to first explore the search space where there can be a not yet ruled-out optimal assignment. In DLL, assuming that the current assignment is μ and that it is not the case that all the assignments extending μ are equally good, this amounts to knowing on which literal we have to branch.

To make these notions precise, consider a partially ordered set S, \prec in which S is a set of literals and \prec is such that for each literal $l \in S$, either $l \prec \bar{l}$ or $\bar{l} \prec l$: If \prec satisfies this condition, we say that \prec is *DLL-compatible (with respect to S)*. For example, the partial order on $\{\bar{x}_0, x_0, \bar{x}_1, x_1\}$ such that

$$\bar{x}_0 \prec x_0, \bar{x}_1 \prec x_1, \bar{x}_1 \prec \bar{x}_0, \quad (1)$$

is DLL-compatible with respect to $\{x_0, \bar{x}_0, x_1, \bar{x}_1\}$. Notice that the condition that for each $l \in S$, either $l \prec \bar{l}$ or $\bar{l} \prec l$ ensures that both $l \in S$ and $\bar{l} \in S$. Given this, the set S can be omitted from the specification of a DLL-compatible partially ordered set S, \prec .

The pseudo-code of OPT-DLL is represented in Figure 1, where:

- φ is a formula; μ is an assignment; \prec is a partial order DLL-compatible with respect to a set S of literals;
- $\text{assign}(l, \varphi)$ returns the formula obtained from φ by (i) deleting the clauses $C \in \varphi$ with $l \in C$, and (ii) deleting \bar{l} from the other clauses in φ ;
- $\text{ChooseLiteral}(\varphi, \mu, \prec)$ returns an unassigned literal l such that
 - if there exists a variable in S which is not assigned by μ , then each literal l' with $l' \prec l$ has to be assigned by μ , and

```

function OPT-DLL( $\varphi, \mu, \prec$ )
1 if ( $\emptyset \in \varphi$ ) return FALSE;
2 if ( $\varphi = \emptyset$ ) return  $\mu$ ;
3 if ( $\{\bar{l}\} \in \varphi$ ) return OPT-DLL( $\text{assign}(l, \varphi), \mu \cup \{l\}, \prec$ );
4  $l := \text{ChooseLiteral}(\varphi, \mu, \prec)$ ;
5  $v := \text{OPT-DLL}(\text{assign}(l, \varphi), \mu \cup \{l\}, \prec)$ ;
6 if ( $v \neq \text{FALSE}$ ) return  $v$ ;
7 return OPT-DLL( $\text{assign}(\bar{l}, \varphi), \mu \cup \{\bar{l}\}, \prec$ ).

```

Figure 1. The algorithm of OPT-DLL.

$-\$ is an arbitrary literal occurring in φ , otherwise.

OPT-DLL has to be invoked with φ and μ set to the input formula and the empty set respectively. It is easy to see that if the set S is empty, OPT-DLL is the same as DLL.

Assuming \prec is (1), OPT-DLL checks the existence of an assignment satisfying φ and extending one of $\{\bar{x}_1, \bar{x}_0\}$, $\{\bar{x}_1, x_0\}$, $\{x_1, \bar{x}_0\}$, $\{x_1, x_0\}$, following the order in which they are listed. Assuming x_1, x_0 are two variables encoding the values from 0 to 3, OPT-DLL will return

- an assignment with minimal corresponding value, if φ is satisfiable, and
- FALSE otherwise.

Assuming x_0, x_1 represent the actions of going by car and by plane respectively, (1) encodes the fact that we prefer to not perform these actions, and that not going by plane is preferred to not going by car. Consequently, OPT-DLL will first look for an assignment where both actions are false, then one in which we use only the car, then one in which we use only the plane, and only finally for assignments where we have to use both the car and the plane.

As the example makes clear, the partial order on the set S of literals induces a partial order on the set of total assignments. In the case of the example (1), if $\mu_0 = \{\bar{x}_0, \bar{x}_1\} \cup S_0$, $\mu_1 = \{\bar{x}_1, x_0\} \cup S_1$, $\mu_2 = \{x_1, \bar{x}_0\} \cup S_2$, $\mu_3 = \{x_1, x_0\} \cup S_3$ are four total assignments, we have

$$\mu_0 \prec \mu_1 \prec \mu_2 \prec \mu_3, \quad (2)$$

while, if μ and μ' are two total assignments assigning in the same way both x_0 and x_1 , $\mu \not\prec \mu'$, i.e., μ and μ' are equally good.

Assuming \prec is a given partial order on S , \prec is extended to the set of total assignments as follows: If μ and μ' are total assignments, $\mu \prec \mu'$ if and only if

1. there exists a literal $l \in S$ with $l \in \mu$ and $\bar{l} \in \mu'$; and
2. for each literal $l' \in S \cap (\mu' \setminus \mu)$, there exists a literal $l \in S \cap (\mu \setminus \mu')$ such that $l \prec l'$.

The first condition says that two total assignments are not in partial order if they assign in the same way the literals in S . The second condition says that μ is preferred to μ' if for each literal $l' \in S$ with $l' \in \mu'$ and $\bar{l}' \in \mu$, μ contains a literal $l \in S$ with $l \in \mu$ and $\bar{l} \in \mu'$, and l is preferred to l' (i.e., $l \prec l'$).

In the case of (1), the above definition leads to the partial order on the set of total assignment satisfying (2).

We can now state the formal result that OPT-DLL returns an optimal assignment, assuming the input formula is satisfiable.

Theorem 1 Let φ be a formula and \prec a DLL-compatible partial order on a set of literals. OPT-DLL($\varphi, \emptyset, \prec$) returns an optimal (with respect to \prec extended to the set of total assignments) assignment if φ is satisfiable, and returns FALSE otherwise.

4 Solving optimization problems with OPT-DLL

Considering OPT-DLL and our definition of optimality given in Section 2, it is clear that OPT-DLL can solve only those optimization problems in which the partial order on the set of total assignments can be obtained as the extension of a DLL-compatible partial order on a set of literals. Indeed, this is not always possible: Assuming we have only two variables x_0, x_1 , the total order on the set of total assignments $\{\bar{x}_1, \bar{x}_0\} \prec \{x_1, \bar{x}_0\} \prec \{x_1, x_0\} \prec \{\bar{x}_1, x_0\}$ is not obtainable as the result of the extension of a DLL-compatible partial order on a set of literals. Still, many important optimization problems can be easily modeled via a DLL-compatible partial order on a set of literals, and thus solved with OPT-DLL. Given a formula φ , we first consider MIN-ONE/MIN-ONE $_{\subseteq}$ and then MAX-SAT/MAX-SAT $_{\subseteq}$ problems: These problems are very interesting from an application perspective, as briefly described below. We also show how DISTANCE-SAT/DISTANCE-SAT $_{\subseteq}$ problems can be solved via OPT-DLL.

4.1 MIN-ONE and MIN-ONE $_{\subseteq}$

Let S be a subset of the set P of variables. Consider a satisfiable formula φ . Define $\text{MIN-ONE}^S(\varphi)$ (resp. $\text{MIN-ONE}_{\subseteq}^S(\varphi)$) to be the set of assignments μ satisfying φ and having $\mu \cap S$ of minimal cardinality (resp. minimal). It is clear that $\text{MIN-ONE}^S(\varphi) \subseteq \text{MIN-ONE}_{\subseteq}^S(\varphi)$.

In MIN-ONE (resp. MIN-ONE $_{\subseteq}$), the goal is to find an assignment μ in $\text{MIN-ONE}^P(\varphi)$ (resp. $\text{MIN-ONE}_{\subseteq}^P(\varphi)$). As pointed out in [8], MIN-ONE problems are interesting because various graph problems involving combinatorial optimization can be converted in linear time into them. In planning, if φ is a formula encoding a planning as satisfiability problem, any assignment satisfying φ corresponds to a sequence of (possibly parallel) actions achieving the goal: If S is the set of action variables in φ ,

1. if we want that as few as possible actions are executed, then we have to find an assignment in $\text{MIN-ONE}^S(\varphi)$;
2. if we want that no redundant sequence of (possibly parallel) actions is executed, then we have to find an assignment in $\text{MIN-ONE}_{\subseteq}^S(\varphi)$.

An assignment in $\text{MIN-ONE}_{\subseteq}^S(\varphi)$ can be easily computed via OPT-DLL, as stated by the following theorem, consequence of Theorem 1.

Theorem 2 Let S be a subset of P , and let φ be a formula. Let \prec be the DLL-compatible partial order such that $l \prec l'$ iff $l = \bar{x}$, $l' = x$, $x \in S$. If $\text{OPT-DLL}(\varphi, \emptyset, \prec)$ returns an assignment μ then $\mu \in \text{MIN-ONE}_{\subseteq}^S(\varphi)$. If $\text{OPT-DLL}(\varphi, \emptyset, \prec)$ returns FALSE then φ is unsatisfiable.

Intuitively speaking, DLL is forced to split first on the variables in S , assigning them to false.

An assignment in $\text{MIN-ONE}^S(\varphi)$ can be computed via OPT-DLL, assuming we have a formula encoding the objective function. This amounts to define a formula $\text{adder}(S)$ such that³

1. the only variables in common to $\text{adder}(S)$ and φ are those in S ;
2. if $n = \lceil \log_2(|S| + 1) \rceil$, $\text{adder}(S)$ contains n new variables b_{n-1}, \dots, b_0 ; and
3. for any total assignment μ to the variables in φ , there exists a unique total assignment ν to the variables in $\text{adder}(S)$ such that
 - (a) ν satisfies $\text{adder}(S)$;

³ The specification of $\text{adder}(S)$ will be used also in Section 4.3, where S is assumed to be an assignment.

- (b) μ and ν assign in the same way the variables in S , i.e., $\mu \cap S = \nu \cap S$;
- (c) $|\nu \cap S| = \sum_{i=0}^{n-1} \nu(b_i) \times 2^i$, where $\nu(b_i)$ is 1 if ν assigns b_i to true, and is 0 otherwise.

$\text{adder}(S)$ can be realized in polynomial time in many ways, see, e.g., [17]. If the above conditions are satisfied, we say that $\text{adder}(S)$ is an *adder of S with output b_{n-1}, \dots, b_0* .

Theorem 3 Let S be a subset of P . Let $\text{adder}(S)$ be an adder of S with output b_{n-1}, \dots, b_0 . Let φ be a formula. Let \prec be the DLL-compatible partial order on $\{b_{n-1}, \dots, b_0\}$ such that for each $i \in [0, n - 1]$, $\bar{b}_i \prec b_i$, and, if $i \neq 0$, $\bar{b}_i \prec \bar{b}_{i-1}$. If $\text{OPT-DLL}(\varphi \cup \text{adder}(S), \emptyset, \prec)$ returns an assignment μ then $\mu \cap P \in \text{MIN-ONE}^S(\varphi)$. If $\text{OPT-DLL}(\varphi, \emptyset, \prec)$ returns FALSE then φ is unsatisfiable.

Intuitively speaking, assuming no literal in $\{b_{n-1}, \dots, b_0\}$ is assigned as unit, OPT-DLL first explores the branches with the variables b_{n-1}, \dots, b_0 assigned to false; If all such branches fail, then OPT-DLL explores the branches in which b_{n-1}, \dots, b_1 are assigned to false while b_0 is assigned to true; If also these branches fail, then OPT-DLL explores the branches in which b_{n-1}, \dots, b_2, b_0 are assigned to false while b_1 is assigned to true; and so on and so forth.

4.2 MAX-SAT and MAX-SAT $_{\subseteq}$

Consider a formula φ . Let S be a subset of the clauses in φ . Intuitively speaking, we consider the problem of satisfying S and “as many as possible” clauses in $\varphi \setminus S$. Formally, define $\text{MAX-SAT}^S(\varphi)$ (resp. $\text{MAX-SAT}_{\subseteq}^S(\varphi)$) to be the set of assignments μ satisfying each clause in S and such that the set $\{C : C \in \varphi \setminus S, C \cap \mu \neq \emptyset\}$ is of maximal cardinality (resp. maximal). It is clear that $\text{MAX-SAT}^S(\varphi) \subseteq \text{MAX-SAT}_{\subseteq}^S(\varphi)$.

In MAX-SAT (resp. MAX-SAT $_{\subseteq}$), the goal is to find an assignment μ in $\text{MAX-SAT}^{\emptyset}(\varphi)$ (resp. $\text{MAX-SAT}_{\subseteq}^{\emptyset}(\varphi)$). The problem of determining an assignment in $\text{MAX-SAT}^S(\varphi)/\text{MAX-SAT}_{\subseteq}^S(\varphi)$ can be easily reduced to a MIN-ONE/MIN-ONE $_{\subseteq}$ problem by considering the formula $x(\varphi, S)$, obtained from φ by adding a newly created variable v_i to the i -th clause in $\varphi \setminus S$.

For example, if $\varphi = \{\{\bar{x}_0, \bar{x}_1\}, \{\bar{x}_0, x_1\}, \{x_0\}\}$ and $S = \{x_0\}$, $x(\varphi, S)$ is $\{\{v_1, \bar{x}_0, \bar{x}_1\}, \{v_2, \bar{x}_0, x_1\}, \{x_0\}\}$

Theorem 4 Let φ be a formula. Let S be a subset of φ . Let V be the set of variables in $x(\varphi, S)$ and not in φ . The following equalities hold:

$$\text{MAX-SAT}^S(\varphi) = \{\mu \cap P : \mu \in \text{MIN-ONE}^V(x(\varphi, S))\},$$

and

$$\text{MAX-SAT}_{\subseteq}^S(\varphi) = \{\mu \cap P : \mu \in \text{MIN-ONE}_{\subseteq}^V(x(\varphi, S))\}.$$

MAX-SAT is arguably the most studied problem in the SAT literature after the SAT problem itself. MAX-SAT $_{\subseteq}$ problems arise in many settings. For instance, in formal verification, if φ is a formula encoding an initial specification of a system, and if φ' encodes a refinement of the initial specification, a standard verification task is to prove that the refinement φ' is compatible with φ , i.e., that $\varphi \cup \varphi'$ is satisfiable. If $\varphi \cup \varphi'$ is unsatisfiable, one goal is to find “as large as possible” parts of the refinement which are consistent with the initial design: Such parts correspond to the assignments in $\text{MAX-SAT}_{\subseteq}^{\varphi}(\varphi \cup \varphi')$.

4.3 DISTANCE-SAT and DISTANCE-SAT \subseteq

DISTANCE-SAT [3] is another optimization problem in which, given a formula φ and an assignment μ , the goal is to find an assignment μ' satisfying φ and differing “as little as possible” from μ . Here we consider also its variant DISTANCE-SAT \subseteq . Formally: Let μ be an assignment. Define DISTANCE-SAT(φ, μ) (resp. DISTANCE-SAT \subseteq (φ, μ)) to be the set of assignments μ' satisfying φ and having the set $\{l : l \in \mu, \bar{l} \in \mu'\}$ of minimal cardinality (resp. minimal). It is clear that DISTANCE-SAT S (φ) \subseteq DISTANCE-SAT \subseteq (φ).

Theorem 5 Let φ be a formula. Let μ be an assignment. The following two facts hold:

1. Let \prec be the DLL-compatible partial order such that $l \prec \bar{l}$ if $l \in \mu$. If OPT-DLL($\varphi, \emptyset, \prec$) returns an assignment μ' then $\mu' \in$ DISTANCE-SAT \subseteq (φ, μ). If OPT-DLL($\varphi, \emptyset, \prec$) returns FALSE then φ is unsatisfiable.
2. Let adder(μ) be an adder of μ with output b_{n-1}, \dots, b_0 . Let \prec be the DLL-compatible partial order on $\{b_{n-1}, \dots, b_0\}$ such that for each $i \in [0, n-1]$, $b_i \prec \bar{b}_i$, and, if $i \neq 0$, $b_i \prec b_{i-1}$. If OPT-DLL($\varphi \cup$ adder(μ), \emptyset, \prec) returns an assignment μ' then $\mu' \cap P \in$ DISTANCE-SAT(φ, μ). If OPT-DLL($\varphi \cup$ adder(μ), \emptyset, \prec) returns FALSE then φ is unsatisfiable.

Table 1. MIN-ONE (columns 3-7) and MIN-ONE \subseteq (columns 8-9) problems.

The implementation of a solver based on our ideas requires the modification of the heuristic of a DLL based SAT solver. In our case, we selected zCHAFF [13], the 2004 version. Such choice is motivated by our interest in solving large problems coming from applications, and by the fact that we already had some experience in hacking zCHAFF code.

Table 2. MAX-SAT and MAX-SAT \subseteq problems, columns 3-8 and 9-10 resp.

For MIN-ONE \subseteq problems, the heuristics VSIDS of zCHAFF has been modified by simply selecting the unassigned literal l with highest VSIDS score, and then assigning the variable x in l to false. For MAX-SAT \subseteq , if there exists an unassigned literal l in $x(\varphi, S)$ and not in φ , the one with the highest VSIDS score is selected and the variable in it is assigned to false. Otherwise, the unassigned literal l with highest VSIDS score is selected and assigned to true. Analogous modifications have been done on VSIDS in order to solve MIN-ONE/MAX-SAT problems.

The solution of MIN-ONE/MAX-SAT problems also required the implementation of a function $adder(S)$ as specified in Section 4.1. As we already said, there are various ways to implement such function. We used the method described in [17] which takes linear time in the size of S . We call $optsat$ the resulting system.⁴ Beside the modification in the heuristic, we had also to modify zCHAFF pre-processor in order to disable the assignment of pure literals.

About the other solvers, we initially considered both dedicated solvers for MAX-SAT problems —like BF [7], MAXSATVER [18], WCSP [14]— and generic Pseudo-Boolean solvers —like OPBDP ver. 1.1.1 [4], PBS ver. 2.1 and ver. 4 [1], MSAT+ (abbreviation of MINISAT+) based on MINISAT ver. 1.13 [10]. MSAT+ was the solver able to prove unsatisfiability and optimality to a larger number of instances than all the other solvers that entered into the last Pseudo-Boolean evaluation [12]. Considering the dedicated solvers for MAX-SAT, we discarded MAXSATVER and WCSP after an initial analysis because they seem to be tailored for relatively small typically randomly generated problems, and are thus not suited to deal with problems coming from applications. About the Pseudo-Boolean solvers, we do not show the results for PBS ver 2.1 because it is almost always slower than ver 4.0.

Each solver has been run using its default settings. All the ex-

⁴ Available at <http://www.star.dist.unige.it/~marco/OPTSAT/>.

periments have been run on a Linux box equipped with a Pentium IV 2.4GHz processor and 1GB of RAM. The results for MIN-ONE/MIN-ONE \subseteq and MAX-SAT/MAX-SAT \subseteq problems are reported in Tables 1 and 2 respectively.⁵ CPU time is measured in seconds; timeout has been set to 1800 seconds. In the tables, “TIME” indicates that the solver does not solve the instance within the time limit; “MEM” indicates that the solver exceeds all the available memory; “SF” indicates that the solver exits abnormally; “–” indicates that the solver returns an incorrect result.

Considering the results for MIN-ONE problems in columns 4-7 of Table 1, we see that our solver **optsat** performs much better than all the other solvers except for MSAT+. OPBPD solves a few instances, PBS times out or outputs an incorrect result on large instances, our solver times out on four instances, while MSAT+ times out on 1 instance and on another instance it exits abnormally.

Considering MIN-ONE \subseteq problems, the results of our solver are shown in the last column of the table. Given that for any formula φ in the table $\emptyset \neq \text{MIN-ONE}(\varphi) \subseteq \text{MIN-ONE}_\subseteq(\varphi)$ and that it is not possible to codify MIN-ONE \subseteq problems in the other solvers we considered, it makes sense to compare the performances of our solver with the performances of the other solvers in columns 4-6. The first observation is that **optsat** is much faster than all the other systems: Almost all the problems are solved in less than 1s. Two other observations are in order:

1. Comparing **optsat** results in columns 7 and 9 we see that our solver is much faster in solving MIN-ONE \subseteq than MIN-ONE problems. This could have been expected given that handling MIN-ONE problems requires the encoding of adders counting the number of variables set to true, and many of the examples have more than a thousand variables (the “gal8” instance has ≥ 58000 variables).
2. comparing the cardinality $\#C_\subseteq$ in column 8 (resp. $\#C$ in column 3) of the optimal assignment returned by **optsat** when solving a MIN-ONE \subseteq (resp. MIN-ONE) problem, we see that for most instances $\#C = \#C_\subseteq$.

Considering the results for MAX-SAT problems in Table 2, we see that our solver **optsat** performs much better than all the other solvers, including the dedicated ones, except for MSAT+. In comparison to MSAT+, our solver is slower of a factor on most instances, but is also faster on some instances. As in the previous case, the performances of **optsat** on the same instances treated as MAX-SAT \subseteq problems are shown in the last column. Differently from the previous case, **optsat** is slower in solving MAX-SAT \subseteq than MAX-SAT problems except for the planning instances (rows (23-28)). We do not yet have a clear understanding of why this happens. We believe that this is related to the fact that for all the instances that we considered, $\#C/\#C_\subseteq$ (representing the cardinality of the set returned by **optsat** when solving a MAX-SAT/MAX-SAT \subseteq problem) are very close to number of clauses in the original SAT instance, but this is still subject of investigation.

6 Conclusions and future work

In this paper we showed that DLL can be used to solve optimization problems by simply imposing an ordering on the

⁵ In Table 1 (1-5) are Formal Verification instances ((1-2) from the Beijing’96 competition, (3-5) by Ofer Shtrichman); (6-14) are planning problems from SATPLAN; (15-20) are Data Encryption Standard problems; (21-26) are quasi group. literals to be used while branching. We specifically considered MIN-ONE/MIN-ONE \subseteq /MAX-SAT/MAX-SAT \subseteq /DISTANCE-SAT/DISTANCE-SAT \subseteq problems, but it is clear that any optimization problem where the ordering on the set of total assignments can be obtained by extending a partial order on a set of literals can be handled by OPT-DLL. In particular, all the problems where the optimality condition is expressed via an objective function f , can be handled by OPT-DLL, provided we have a formula encoding the value of f . This is indeed the case, e.g., for WEIGHTED-MAX-SAT where the encoding is illustrated, e.g., in [17].

We implemented our ideas using zCHAFF as engine, and the encoding of [17] to solve MIN-ONE/MAX-SAT problems. The results are positive and encouraging. We believe that even better performances will be obtained by using MINISAT and, for MIN-ONE/MAX-SAT problems, using the encoding presented in [2, 15] of the objective function. Some of these encoding produce formulas of a bigger size, but they should lead to better performances of the back-end solver: See [2, 15] for more details.

Discovering Missing Background Knowledge in Ontology Matching

Fausto Giunchiglia and Pavel Shvaiko and Mikalai Yatskevich¹

Abstract. *Semantic matching* determines the mappings between the nodes of two graphs (e.g., ontologies) by computing *logical relations* (e.g., subsumption) holding among the nodes that correspond semantically to each other. We present an approach to deal with the lack of background knowledge in matching tasks by using semantic matching *iteratively*. Unlike previous approaches, where the missing axioms are manually declared before the matching starts, we propose a fully automated solution. The benefits of our approach are: (i) saving some of the pre-match efforts, (ii) improving the quality of match via iterations, and (iii) enabling the future reuse of the newly discovered knowledge. We evaluate the implemented system on large real-world test cases, thus, proving empirically the benefits of our approach.

1 INTRODUCTION

Match is a critical operator in many applications, e.g., AI, Semantic Web, WWW, e-commerce. It takes two graph-like structures, e.g., lightweight ontologies, such as Google and Looksmart², or business catalogs, such as UNSPSC and eCl@ss³, and produces a mapping between the nodes that correspond semantically to each other.

Many various solutions of match have been proposed so far, see for recent surveys [17, 3, 13, 9, 16]⁴. We focus on a schema-based solution, namely a matching system exploiting only the schema information, thus not considering instances. We follow the so-called *semantic matching* approach [6]. This approach is based on two key ideas. The first is that mappings are calculated between ontology entities by computing *logical relations* (e.g., equivalence, subsumption), instead of computing coefficients rating match quality in the $[0,1]$ range, as it is the case in the other approaches, e.g., [14, 5, 15]. The second idea is that the relations are determined by analyzing the *meaning* which is codified in the elements and the structures of ontologies. In particular, labels at nodes, written in natural language, are translated into propositional formulas which explicitly codify the labels' intended meaning. This allows the translation of the matching problem into a propositional unsatisfiability problem, which can then be efficiently resolved using (sound and complete) state of the art propositional satisfiability (SAT) deciders, e.g., [2].

Recent industrial-strength evaluations of matching systems, see, e.g., [4, 1], show that lack of background knowledge, most often domain specific knowledge, is one of the key problems of matching systems these days. In fact, most state of the art systems, for the tasks of matching thousands of nodes show low values of *recall* ($\sim 30\%$), while with *toy* examples, the recall they demonstrated was most often around 90%. This paper addresses the problem of the missing background knowledge by using semantic matching iteratively. The contributions of the paper are: (i) the new automatic *iterative* semantic

matching algorithm, which provides such benefits as a better quality of match (recall), saving some of the pre-match efforts, enabling the future reuse of the newly discovered knowledge; (ii) the *quality evaluation* of the implemented system on large real-world test cases.

The rest of the paper is organized as follows. The semantic matching algorithm is briefly summarized in Section 2. Section 3 introduces the problem of the lack of background knowledge in matching and its possible solutions. Section 4 presents the iterative semantic matching algorithm and its details. Section 5 discusses experiments with matching lightweight ontologies. Section 6 reports some conclusions and outlines the future work.

2 SEMANTIC MATCHING

We focus on tree-like structures (e.g., Google, Looksmart, Yahoo!). *Concept of a label* is the propositional formula which stands for the set of documents that one would classify under a label it encodes. *Concept at a node* is the propositional formula which represents the set of documents which one would classify under a node, given that it has a certain label and that it is in a certain position in a tree.

The following relations can be discovered among the concepts at nodes of two ontologies: *equivalence* (=); *more/less general* (\sqsubseteq , \sqsupseteq); *disjointness* (\perp). When none of the relations holds, the special *idk* (I don't know) relation is returned. The relations are ordered according to decreasing binding strength, i.e., from the strongest (=) to the weakest (*idk*). *Semantic matching* is defined as follows: given two trees T1, T2 compute the $N_1 \times N_2$ *mapping elements*, $\langle ID_{i,j}, C_{1,i}, C_{2,j}, R' \rangle$, where $ID_{i,j}$ is a unique identifier of the given mapping element; $C_{1,i} \in T_1$; $i=1,\dots,N_1$; $C_{2,j} \in T_2$; $j=1,\dots,N_2$; R' is the strongest relation holding between the concepts at nodes $C_{1,i}, C_{2,j}$.

Let us summarize the semantic matching algorithm via a running example. We consider ontologies O1 and O2 shown in Figure 1, which are small parts of Google and Looksmart. The algorithm inputs two ontologies and outputs a set of mapping elements in four macro steps. The first two steps represent the pre-processing phase, while the third and the fourth steps are the element level and structure level matching respectively.

Step 1. For all labels L in two trees, compute concepts of labels.

Labels at nodes are viewed as concise descriptions of the documents that are stored under the nodes. The meaning of a label at a node is computed by inputting a label, by analyzing its real-world semantics, and by outputting a concept of the label, C_L . For example, by writing $C_{Hobbies_and_Interests}$ we move from the natural language ambiguous label *Hobbies_and_Interests* to the concept $C_{Hobbies_and_Interests}$, which codifies explicitly its intended meaning, namely the documents which are about hobbies and interests. Technically, based on WordNet (WN) [12] *senses*, concepts of labels are codified as propositional logical formulas, see [10] for details.

From now on, it is assumed that the propositional formula encoding the concept of label is the label itself. Numbers "1" and "2" are used as subscripts to distinguish between trees in which the given concept of label occurs, e.g., TOP_1 (belongs to O1) and TOP_2 (belongs to O2).

⁴ See, www.OntologyMatching.org for a complete information on the topic.

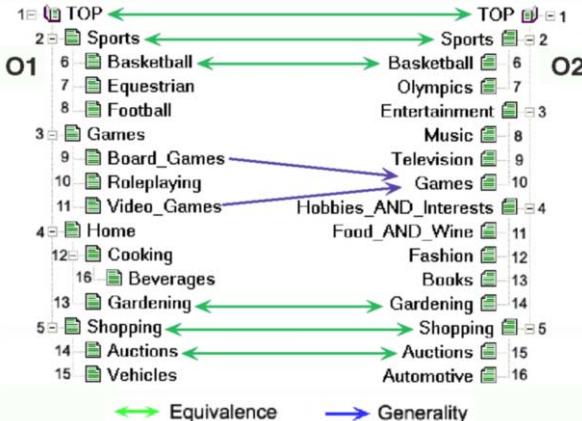

Figure 1. Parts of Google and Looksmart and some of the mappings

Step 2. For all nodes N in two trees, compute concepts at nodes.

We analyze the meaning of the *positions* of labels at nodes in a tree. By doing this concepts of labels are extended to concepts at nodes, C_N . This is required to capture the knowledge residing in the structure of a tree, namely the context in which the given concept at label occurs. Technically, concepts at nodes are written in the same propositional logical language as concepts of labels. For example, $C_{2_8} = TOP_2 \sqcap Entertainment_2 \sqcap Music_2$ stands for the concept describing all the documents about a particular kind of entertainment which is music.

Step 3. For all pairs of labels in two trees, compute relations among concepts of labels.

Relations between concepts of labels are computed by using a library of element level matchers, see Table 1. The first column contains the names of the matchers. The second col-

Table 1. Element level semantic matchers (Part 1)

Matcher name	Execution order	Approximation level	Matcher type	Schema info
WordNet	1	1	Sense-based	WordNet senses
Prefix	2	2	String-based	Labels
Suffix	3	2	String-based	Labels
Edit distance	4	2	String-based	Labels
Ngram	5	2	String-based	Labels

umn lists the order in which they are executed. The third column introduces the matchers' approximation level. The relations produced by a matcher with the first approximation level are always correct. For example, $Beverages_1$ can be found less general than $Food_2$. In fact, according to WordNet, *beverages* is hyponym (subordinate word) to *food*. Notice, in WordNet *beverages* has 1 sense, while *food* has 3 senses. Some sense filtering techniques are used to discard the irrelevant senses for the given context, see [10] for details. The relations produced by a matcher with the second approximation level are likely to be correct (e.g., *net* = *network*, but *hot* = *hotel* by *Prefix*). The WordNet matcher has two WordNet senses in input and computes equivalence, generality, and disjointness relations. String-based matchers have two labels as input. These compute only equivalence relations (e.g., equivalence holds if the weighted *distance* between the input strings is lower than a threshold), see [7]. String-based matchers are used iff WordNet fails to find a relation. The result of step 3 is a matrix of relations holding between atomic concepts of labels. A part of it, for the example of Figure 1, is shown in Table 2.

Table 2. cLabsMatrix: relations holding among atomic concepts of labels

	$Games_1$	$Board.Games_1$	$Beverages_1$
$Games_2$	=	\sqsupseteq	idk
$Food_2$	idk	idk	\sqsubseteq
$Wine_2$	idk	idk	\sqsubseteq

Step 4. For all pairs of nodes in two trees, compute relations among concepts at nodes. The tree matching problem is reformulated into a set of node matching problems, see Algorithm 1.

Algorithm 1 The tree matching algorithm

```

1: Node: struct of
2:   int nodeId;
3:   String label;
4:   String cLabel;
5:   String cNode;
6:   Node parent;
7:   AtomicConceptOfLabel[] ACOL;
8: AtomicConceptOfLabel: struct of
9:   int id;
10:  String token;
11:  String[] wnSenses;
12:  String[][] cLabsMatrix, cNodesMatrix;
30: String[] [] treeMatch(Tree of Nodes source, target)
31: Node sourceNode, targetNode;
32: int i, j;
33: String[] [] relMatrix;
34: String axioms, context1, context2;
35: cLabsMatrix = fillCLabMatrix(source, target);
50: for each sourceNode ∈ source do
51:   i = getNodeID(sourceNode);
52:   context1 = getCnodeFormula(sourceNode);
53:   for each targetNode ∈ target do
54:     j = getNodeID(targetNode);
55:     context2 = getCnodeFormula(targetNode);
80:     relMatrix = extractRelMatrix(cLabsMatrix, sourceNode, targetNode);
81:     axioms = mkAxioms(relMatrix);
82:     cNodesMatrix[i][j] = nodeMatch(axioms, context1, context2);
110: end for
111: end for
150: return cNodesMatrix;

```

In line 30, the *treeMatch* function inputs two trees of *Nodes* (*source* and *target*). Two loops are run over all the nodes of *source* and *target* trees in lines 50-111 and 53-110 in order to formulate all the node matching problems. Then, for each node matching problem, a pair of propositional formulas encoding concepts at nodes and relevant relations holding between concepts of labels are taken by using the *getCnodeFormula* and *extractRelMatrix* functions respectively. The former are memorized as *context₁* and *context₂* in lines 52 and 55. The latter are memorized in *relMatrix* in line 80. In order to reason about relations between concepts at nodes, the premises (*axioms*) are built in line 81. These are a conjunction of atomic concepts of labels which are related in *relMatrix*. Finally, in line 82, the relations holding between the concepts at nodes are calculated by *nodeMatch* and are reported in line 150 (*cNodesMatrix*). A part of this matrix for the example of Figure 1 is shown in Table 3.

Table 3. cNodesMatrix: relations holding among concepts at nodes⁴

	$C1_3$	$C1_4$	$C1_5$	$C1_9$	$C1_{10}$	$C1_{11}$
$C2_{10}$	=	idk	idk	\sqsupseteq	=	\sqsubseteq

nodeMatch translates each node matching problem into a propositional validity problem. Thus, we have to prove that $axioms \rightarrow rel(context_1, context_2)$ is valid. *axioms*, *context₁*, and *context₂* are as defined in the tree matching algorithm. *rel* is the logical relation that we want to prove holding between *context₁* and *context₂*. *nodeMatch* checks for sentence validity by proving that its negation is unsatisfiable. Thus, the algorithm uses, depending on a matching task, either ad hoc reasoning techniques, see [8], or standard DPLL-based SAT solvers, e.g., [2]. From the example in Figure 1, trying to prove that $C1_9$ is less general than $C2_{10}$, requires constructing the following formula: $((TOP_1 \leftrightarrow TOP_2) \wedge (Games_1 \leftrightarrow Games_2) \wedge (Games_1 \leftrightarrow Entertainment_2)^5 \wedge (Board.Games_1 \rightarrow Games_2)) \rightarrow ((TOP_1 \wedge Games_1 \wedge Board.Games_1) \rightarrow (TOP_2 \wedge Entertainment_2 \wedge Games_2))$. As it turns out, this formula is unsatisfiable, hence, the less generality holds.

⁵Notice, by applying element level matchers of Table 1 we can only determine the *idk* relation between *games* and *entertainment*. For example, in WordNet there is no direct lexical relation between *games* and *entertainment*. However, to simplify the presentation, we assume that it has been already determined that $Games_1 = Entertainment_2$. See Section 4 for the details of how the equivalence between the given concepts can be discovered.

3 LACK OF KNOWLEDGE

Recent industrial-strength evaluations of matching systems, see, e.g., [4, 1], show that lack of background knowledge, most often domain specific knowledge, is one of the key problems of matching systems these days. In fact, for example, should **PO** match **Post Office**, **Purchase Order**, or **Project Officer**? At present, most state of the art systems, for the tasks of matching thousands of nodes, perform not with such high values of *recall* ($\sim 30\%$) as in cases of toy examples, where the recall was most often around 90%. Also, contributing to this problem, [11] shows that complex matching solutions (requiring months of algorithms design and development) on big tasks may perform as badly as a baseline matcher (requiring one hour burden).

In order to understand better the above observations, let us consider a preliminary analytical comparative evaluation of some state of the art matching systems together with a baseline solution⁶ on three large real-world test cases. Table 4 provides some indicators of the test cases complexity.

Table 4. Some indicators of the complexity of the test cases

	#nodes	max depth	#labels per tree
Google vs. Looksmart	706/1081	11/16	1048/1715
Google vs. Yahoo	561/665	11/11	722/945
Yahoo vs. Looksmart	74/140	8/10	101/222

These test cases were taken from the OAEI-2005 ontology matching contest⁷. As match quality measures we focus here on recall which is a completeness measure. It varies in the $[0,1]$ range; the higher the value, the smaller is the set of correct mappings (true positives) which have not been found. The summarized evaluation results for all the three matching tasks are shown in Figure 2. Notice, the results for such matching systems as **OMAP**, **CMS**, **Dublin20**, **Falcon**, **FOAM**, **OLA**, and **ctxMatch2**, were taken from OAEI-2005, see [4], while evaluation results for the **baseline** matcher and **S-Match** were taken from [1]. As Figure 2 shows, none of the considered matching systems performs with a value of recall which is higher than 32%.

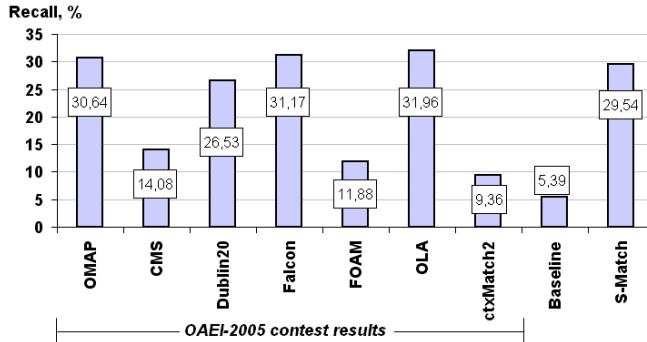

Figure 2. Analytical comparative evaluation

There are multiple strategies to attack the problem of the lack of background knowledge. One of the most often used methods so far is to declare the missing axioms manually as a pre-match effort. Some other plausible strategies include (i) extending stop word lists, (ii) expanding acronyms, (iii) reusing the previous match results, (iv) querying the web, (v) using (if available) domain specific sources of knowledge, and so on.

In this paper, we propose a fully automated solution to address the problem of the lack of knowledge by using semantic matching iteratively. The idea is to repeat *Step 3* and *Step 4* of the matching algorithm for some critical (hard) matching tasks. In particular, the result of SAT is analyzed. We identify critical points in the matching process, namely mapping elements with the *idk* relation where a stronger

⁶ This matcher does simple string comparison among sets of labels on the paths from nodes under consideration to the roots of the input trees, see [1].

⁷ See for details, <http://oaei.ontologymatching.org/2005>

relation (e.g., generality) should have taken place. We attack critical points by exploiting sophisticated element level matchers which use the *deep* information encoded in WordNet, e.g., its internal structure. Then, taking into account the newly discovered information as additional axioms, we re-run SAT solver on a critical task. Finally, if SAT returns *false*, we save the newly discovered knowledge, thereby enabling its future reuse.

4 ITERATIVE SEMANTIC MATCHING

We first discuss how the tree matching algorithm should be modified in order to suitably enable iterations. Then, we present the main building blocks of the iterative tree matching algorithm, namely, algorithms for critical points discovery and critical points resolution.

4.1 Iterative Tree Matching Algorithm

The iterative tree matching algorithm is shown as Algorithm 2. The numbers on the left indicate where the new code must be positioned in Algorithm 1.

Algorithm 2 A vanilla iterative tree matching algorithm

```

13: Boolean[ ][ ] cPointsMatrix;
100:   if (cPointsDiscovery(sourceNode, targetNode) == true) then
101:     cPointsMatrix[i][j] = true;
102:     ResolveCpoint(sourceNode, targetNode, context1, context2);
103:   end if

```

In line 13, we introduce **cPointsMatrix** which memorizes critical points. Semantic matching algorithm works in a top-down manner, and hence, mismatches among the top level classes of ontologies imply further mismatches between their descendants. Thus, the descendants should be processed only after the critical point at those top level nodes has been resolved. This is ensured by suitably positioning the new functions (enabling iterations) in a double loop of Algorithm 1. Hence, in line 100, we check with the help of **cPointsDiscovery** function if the nodes under consideration are the critical point. If they indeed represent the critical point, they are (memorized and) resolved by using the **ResolveCpoint** function (line 102). In the example of Figure 1, critical points which are determined are, for example, $\langle C_{12}, C_{23} \rangle$, $\langle C_{13}, C_{23} \rangle$, $\langle C_{14}, C_{24} \rangle$.

An updated **cNodesMatrix**, after running the iterative tree matching algorithm, is presented in Table 5. Comparing it with the non-iterative matching algorithm result, which is further reported in Table 7, we can see that having identified and resolved the $\langle C_{13}, C_{23} \rangle$ critical point, we also managed to discover the new correspondences, namely between C_{23} and C_{19} , C_{110} , C_{111} .

Table 5. Recomputed **cNodesMatrix**: relations among concepts at nodes

	C_{11}	C_{12}	C_{13}	C_{14}	C_{15}	C_{19}	C_{110}	C_{111}
C_{21}	=	\sqsubseteq						
C_{23}	\sqsubseteq	=	=	idk	idk	\sqsubseteq	\sqsubseteq	\sqsubseteq

Having computed all the mapping elements for a given pair of ontologies, the identified critical relations are validated by a human user. In particular, user decides if the type of relation determined automatically is appropriate for the given pair of ontologies (e.g., is it appropriate that $Games_1 \leftrightarrow Entertainment_2$ or a weaker relation, namely $Games_1 \rightarrow Entertainment_2$, should have taken place ?), (s)he decides either to use this relation once (only for this pair of ontologies) or to save it in a domain specific oracle in order to enable its future reuse.

Finally, it is worth noting that iterative semantic matching algorithm amounts to *robustness* of the semantic matching. In fact, even if non-iterative semantic matching determines a (false) top level mismatch, this can be discovered and resolved by applying Algorithm 2. Thus, avoiding a further propagation of possible mismatches between the descendants of the initially mismatched top level nodes.

4.2 The Critical Points Discovery Algorithm

The algorithm for discovering critical points is based on the following intuitions:

- each *idk* relation in *cNodesMatrix* is potentially a critical point, but it is not always the case;
- since critical points arise due to lack of background knowledge, the clue is to check whether some other nodes located below the critical nodes (those representing a critical point) are related somehow. In case of a positive result the actual nodes are indeed the critical point; they represent a false alarm otherwise.

Algorithm 3 Critical points discovery algorithm

```

1: Boolean cPointsDiscovery(Node sourceNode, targetNode)
2: Node[ ] sDescendant, tDescendant;
3: ACOL sACOL, tACOL;
4: if (cNodesMatrix[sourceNode.nodeID][targetNode.nodeID]==“idk”)
then
5:   sDescendant = getSubTree(sourceNode);
6:   tDescendant = getSubTree(targetNode);
7:   for each sACOL ∈ sDescendant.ACOL do
8:     for each tACOL ∈ tDescendant.ACOL do
9:       if cLabsMatrix[sACOL.id][tACOL.id] != “idk” then
10:         return true;
11:       end if
12:     end for
13:   end for
14: else
15:   return false;
16: end if

```

Algorithm 3 formalizes these intuitions. In particular, the first condition mentioned above is checked in line 4. Verifying the second condition is more complicated. We call a relation holding between descendants of the potentially critical nodes a *support relation*. The support relation holds if there exists atomic concept of label (*sACOL*) in the descendants of *sourceNode* which is related in *cLabsMatrix* (by any semantic relation, except *idk*) to any atomic concept of label (*tACOL*) in the descendants of *targetNode*. This condition is checked in a double loop in lines 7-13. Finally, if both conditions are satisfied, the *cPointsDiscovery* function concludes that the nodes under consideration are the critical point (line 10). Under the given critical points discovery strategy, performing such a look up over the *cLabsMatrix* makes sense, obviously, only when *sourceNode* and *targetNode* are non-leaf nodes.

For example, suppose we want to match $C1_3$ and $C2_3$. Parts of *cLabsMatrix* (notice, the relations in this matrix were computed by applying element level matchers of Table 1) and *cNodesMatrix* with respect to the given matching task are shown in Table 6 and Table 7.

Table 6. *cLabsMatrix*: relations holding among atomic concepts of labels

	<i>TOP</i> ₁	<i>Games</i> ₁	<i>Board_Games</i> ₁
<i>TOP</i> ₂	=	<i>idk</i>	<i>idk</i>
<i>Entertainment</i> ₂	<i>idk</i>	<i>idk</i>	<i>idk</i>
<i>Games</i> ₂	<i>idk</i>	=	⊓

Table 7. *cNodesMatrix*: relations holding among concepts of nodes

	<i>C1</i> ₁	<i>C1</i> ₂	<i>C1</i> ₃	<i>C1</i> ₄	<i>C1</i> ₅	<i>C1</i> ₉	<i>C1</i> ₁₀	<i>C1</i> ₁₁
<i>C2</i> ₁	=	⊓	⊓	⊓	⊓	⊓	⊓	⊓
<i>C2</i> ₃	⊓	<i>idk</i>	<i>idk</i>	<i>idk</i>	<i>idk</i>	<i>idk</i>	<i>idk</i>	<i>idk</i>

In *cNodesMatrix* (Table 7) the relation between $C1_3$ and $C2_3$ is *idk*. In *cLabsMatrix* (Table 6) there is a support relation for the given matching problem, e.g., $Board_Games_1 \sqsubseteq Games_2$. Therefore, relation between $C1_3$ and $C2_3$ represents the critical point and we should reconsider the relation holding between $Games_1$ and $Entertainment_2$ in *cLabsMatrix*.

Finally, it is worth noting that this algorithm also properly handles nodes, which are indeed dissimilar, e.g., $C1_5$ and $C2_2$ are determined not to be the critical point.

4.3 The Critical Points Resolution Algorithm

Let us discuss how the critical points are resolved, see Algorithm 4.

Algorithm 4 Critical points resolution algorithm

```

1: ResolveCpoint(Node sourceNode, targetNode, String context1, context2)
2: String cRel;
3: String[ ] ExecutionList;
4: ACOL sACOL, tACOL;
5: for each sACOL ∈ sourceNode.ACOL do
6:   for each tACOL ∈ targetNode.ACOL do
7:     cRel = GetMLibRel(ExecutionList, sACOL.wnSenses, tACOL.wnSenses);
8:     cLabsMatrix[sACOL.id][tACOL.id] = cRel;
9:   end for
10: end for
11: cNodesMatrixUpdate(sourceNode, targetNode, context1, context2);

```

The *ResolveCpoint* function determines relations (*cRel*) for the critical points. Also, by exploiting the *cNodesMatrixUpdate* procedure, it updates accordingly *cNodesMatrix*. In particular, *ResolveCpoint* executes sophisticated element level matchers, see Table 8, over the atomic concepts of labels by using the *GetMLibRel* function (line 7). Matchers are applied following the order (*ExecutionList*) given in the second column of Table 8. These matchers have the third approximation level, which means that the relations they produce depend heavily on the context of the matching task. Also, execution times of them are much longer than of those of Table 1. Thus, they can not be applied in all the cases.

Table 8. Element level semantic matchers (Part 2)

Matcher name	Exec. order	Approx. level	Matcher type	Schema info
<i>Hierarchy Distance</i>	1	3	Sense-based	WN senses
<i>WN Gloss</i>	2	3	Gloss-based	WN senses
<i>Extended WN Gloss</i>	3	3	Gloss-based	WN senses
<i>Gloss Comparison</i>	4	3	Gloss-based	WN senses
<i>Extended Gloss Comparison</i>	5	3	Gloss-based	WN senses

For example, a *Hierarchy Distance* (*HD*) matcher computes the equivalence relation if the distance between two input senses in the WordNet hierarchy is less than a given threshold value (e.g., 3) and returns *idk* otherwise. According to WordNet, *games* and *entertainment* have a common ancestor, which is *diversion*. The distance between these concepts is 2 (1 more general link and 1 less general). Therefore, the *HD* matcher concludes that *Games*₁ is equivalent to *Entertainment*₂. If the *HD* matcher fails, which is not the case in our example, we apply a set of *gloss-based* matchers. These also have two WordNet senses in input and exploit techniques based on comparison of textual definitions (*glosses*) of the words whose senses are taken in input. They compute, depending on a particular matcher, the equivalence, more/less general relations. Due to lack of space, we give here only hints on how some gloss-based matchers work. For example, *WN Gloss* (*WNG*) counts the number of occurrences of the label of the source input sense in the gloss of the target input sense. If this number is lower than (equal to) a threshold, the less generality (due to a common pattern of defining terms in glosses through a more general term) is returned. *Gloss Comparison* (*GC*) counts the number of the same words in the glosses of the source and target input senses. If this number (of shared words) exceeds a threshold, the equivalence is returned. *Extended* gloss matchers are build in a straightforward way, by also considering glosses of the parent (children) nodes of the input senses in the WordNet *is-a* (*part-of*) hierarchy, see for details [7].

In line 8, we update *cLabsMatrix* with the critical relation, *cRel*, such that in all the further computations and for the current pair of nodes this relation is available. Finally, given the new axiom ($Games_1 \leftrightarrow Entertainment_2$) we recompute (line 11)⁸, by re-running SAT, the relation holding between the pair of critical nodes, thus determining that $C1_3 = C2_3$.

⁸ *cNodesMatrixUpdate* performs functionalities identical to those of lines 80-82 in Algorithm 1.

5 EVALUATION

In this section we present the quality evaluation of the iterative semantic matching algorithm. Due to lack of space we report here only what we have realized to be the most important findings.

Evaluation set-up. In our evaluation we have used three large real-world test cases, which were introduced in Table 4. As expert mappings for these test cases we used 2265 mappings acquired in [1]. By construction those expert mappings represent only true positives, thereby allowing us to estimate only the recall with them. To the best of our knowledge, at the moment, there are no large datasets as, for example, that one of Table 4, where available expert mappings allow measuring both precision⁹ and recall. Thus, in the following we focus mostly on analyzing the recall.

Two further observations. First is that higher values of recall can be obtained at the expense (lower values) of precision. Thus, in order to ensure a *fair* recall evaluation, before running tests on the matching tasks of Table 4, we have analyzed behavior of the iterative semantic matching on a number of test cases, e.g., course university catalogs¹⁰, where expert mappings allowed measuring both precision and recall. Matchers decreasing precision substantially in these tests were discarded from the further evaluation. In fact, for this reason we exclude from the further considerations the *Extended Gloss Comparison* matcher. The second observation is that using matchers of Table 8 exhaustively for all the tasks, hence, omitting the critical points discovery algorithm, also leads to a significant precision decrease, thus justifying usefulness of the cPointsDiscovery algorithm.

Evaluation results. The summarized evaluation results for all the three matching tasks of Table 4 are shown in Figure 3. In particular, it demonstrates contributions to the recall of matchers of Table 8 as well as of their combinations. The *Extended WN Gloss* matcher performed very poorly, i.e., contributing less than 1% to the recall, hence, we do not report its results in Figure 3. By using a combination of the *HD*, *WNG*, *GC* matchers we have improved S-Match recall results (29,5%) up to 46,1% within the iterative S-Match¹¹.

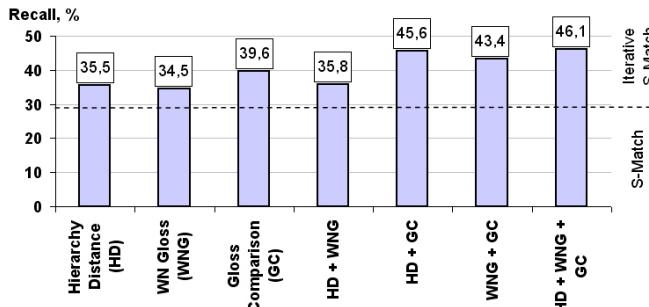

Figure 3. Evaluation results (absolute values)

Let us now consider *relative* characteristics of the iterative S-Match with respect to the non-iterative version, see the first row of Table 9 for a summary. The highest recall increase by using only a single matcher of Table 8 within the iterative S-Match was achieved by the *GC* matcher, namely 34% over the non-iterative S-Match. The best, in this sense, combination of two matchers is being that of the *HD* and *GC* matchers: recall increased by 54%. Finally, a combination of the *HD*, *WNG* and *GC* matchers resulted in the 56% recall increase with respect to the non-iterative S-Match.

Table 9 also reports values of thresholds used within the evaluation. These values were obtained based on the rationale behind designing matchers of Table 8 and their evaluation results.

⁹ Precision is a correctness measure; the higher the value, the smaller is the set of false positives which has been computed, see for details, e.g., [4].

¹⁰ See, <http://dit.unitn.it/~accord/Experimentaldesign.html> for a repository of test cases, expert mappings we have used.

¹¹ Note, this result should be considered as a complimentary one to the results of S-Match++ reported in [1], since they address separate problem spaces.

Table 9. Some element level matchers and their evaluation results

	HD	GC	HD + GC	HD + WNG + GC
Recall increase (relative), %	20	34	54	56
Threshold value	4	2	4 \ 2	4 \ 1 \ 2

Evaluation summary. The evaluation we have conducted shows that the problem of the lack of background knowledge is a hard one. In fact, as it turns out, not all the designed element level matchers can perform always well in real-world applications, as it might (mistakenly) seem from the toy evaluations. Also, new matchers are still needed, since, for example, we could discover that $\langle C_{14}, C_{24} \rangle$ is the critical point, however, we were unable to resolve it with the matchers of Table 8, namely to match *Home1* and *Hobbies AND Interests2*.

6 CONCLUSIONS

We have presented an automated approach to attack the problem of the lack of background knowledge by applying semantic matching iteratively. We implemented the proposed approach and evaluated it on large real-world (lightweight) ontology matching tasks with encouraging results. Future work proceeds at least in the following directions: (i) adapting the iterative semantic matching algorithm for handling leaf-node critical points, (ii) design and development of the new element level matchers, (iii) involving user within the matching process, where his/her input is maximally useful, (iv) conducting further large and extensive real-world evaluations.

Extracting MUSes

Éric GRÉGOIRE and Bertrand MAZURE and Cédric PIETTE ¹

Abstract. Minimally unsatisfiable subformulas (in short, MUSes) represent the smallest explanations for the inconsistency of SAT instances in terms of the number of involved clauses. Extracting MUSes can thus prove valuable because it circumscribes the sources of contradiction in an instance. In this paper, a new heuristic-based approach to approximate or compute MUSes is presented. It is shown that it often outperforms current competing ones.

1 INTRODUCTION

SAT is the NP-complete decision problem that consists in checking whether a set of Boolean clauses admits at least one truth assignment that satisfies all clauses. These last years, many researchers have focused on the more difficult task of extracting minimally unsatisfiable subformulas (in short, MUSes) of unsatisfiable SAT instances. Although this problem exhibits a high worst case complexity since e.g. checking whether a formula belongs to the set of MUSes of an inconsistent instance or not is in Σ_2^P [9], extracting MUSes can prove valuable because it circumscribes what is *wrong* with an instance. Indeed, many application domains like model-based diagnosis, knowledge-base validation or VLSI correctness checking, require such explanations to be delivered. When e.g. a knowledge-base is checked for consistency, we often prefer to know which clauses are actually contradicting one another, rather than just being told that the whole base is inconsistent.

Recently, several approaches have been proposed to approximate or compute MUSes. Unfortunately, they concern specific classes of clauses or they remain tractable for small instances only. Among them, let us mention Bruni's work [4], who has shown how a MUS can be extracted in polynomial time through linear programming techniques for clauses exhibiting a so-called integral point property. However, only restrictive classes of clauses obey such a property (mainly Horn, renamable Horn, extended Horn, balanced and matched ones). Let us also mention [5, 7, 10] as they are other important studies in the complexity and the algorithmic aspects of extracting MUSes for specific classes of clauses. In [3], Bruni has also proposed an approach that approximates MUSes by means of an adaptative search guided by clauses hardness. Zhang and Malik have described in [23] a way to extract MUSes by learning nogoods involved in the derivation of the empty clause by resolution. In [17], Lynce and Marques-Silva have proposed a complete and exhaustive technique to extract smallest MUSes. Oh and his co-authors have presented in [20] a Davis, Putnam, Logemann and Loveland DPLL-oriented approach that is based on a marked clause concept to allow one to approximate MUSes. Liffiton and Sakallah have shown how

MUSes can be computed through the dual concept of maximally satisfiable subsets [16].

In [19], a heuristic was also proposed to approximate MUSes, based on the experimental finding that clauses that are most often falsified during a failed local search often belong to MUSes. It has also been used to improve the performance of DPLL-like complete algorithms [6]. In this paper, a new variant and original extensions of this heuristic are studied. During the local search run, relevant parts of the neighborhood of the current truth assignment are explored in order to decide whether an unsatisfied clause during this local search should be actually counted or not. It is then extended in order to compute sets of MUSes. This new approach is shown to often outperform the current competing ones from an experimental point of view.

The paper is organized as follows. In the next section, the concept of MUS is presented formally. In section 3, a crucial notion of critical clause is introduced and analyzed. In section 4, the new approach to approximate or compute one MUS is presented. Extensive experimental results are given in section 5. Before we conclude, section 6 shows how the approach can be extended to compute sets of MUSes.

2 MINIMALLY UNSATISFIABLE SUBFORMULA (MUS)

Let \mathcal{L} be a standard Boolean logical language built on a finite set of Boolean variables, denoted a, b , etc. Formulas will be denoted using upper-case letters such as C . Sets of formulas will be represented using Greek letters like Γ or Σ . An interpretation is a truth assignment function that assigns values from $\{\text{true}, \text{false}\}$ to every Boolean variable. A formula is consistent or satisfiable when there is at least one interpretation that satisfies it, i.e. that makes it become *true*. An interpretation will be denoted by upper-case letters like I and will be represented by the set of literals that it satisfies. Actually, any formula in \mathcal{L} can be represented (while preserving satisfiability) using a set (interpreted as a conjunction) of clauses, where a clause is a finite disjunction of literals, where a literal is a Boolean variable that can be negated. SAT is the well-known NP-complete problem that consists in checking whether a set of Boolean clauses is satisfiable or not, i.e. whether there exists an interpretation that satisfies all clauses in the set or not.

When a SAT instance is unsatisfiable, it exhibits at least one minimally unsatisfiable subformula, in short one *MUS*.

Definition 1 A MUS Γ of a SAT instance Σ is a set of clauses s.t.

1. $\Gamma \subseteq \Sigma$
2. Γ is unsatisfiable
3. Every proper subset of Γ is satisfiable

Computing MUSes is a heavy computational task in the worst case. Indeed, checking whether a set of clauses is a MUS is DP-complete [21], and checking whether a formula belongs to the set of

¹ CRIL-CNRS & IRCICA,
 Université d'Artois, rue Jean Souvraz SP18, F-62307 Lens Cedex France
 E-mail: {gregoire,mazure,piette}@cril.univ-artois.fr

MUSes of an inconsistent instance or not, is in Σ_2^p [9]. Let us note that although the set of MUSes of an n -clauses instance is $C_n^{n/2}$ in the worst case, this number is often tractable in real-life situations. For example, in model-based diagnosis [13], based on experimental studies, it is often assumed that single faults occur most often, which is translated by a limited number of MUSes.

3 A NEW HEURISTIC TO DETECT MUSes

In [19], it is shown how local search can be helpful for approximating MUSes. The basic idea is that clauses that are often falsified during a failed local search for satisfiability belong most probably to MUSes, when the instance is actually unsatisfiable. When the score of a clause is the number of times it has been falsified during a failed local search (in short, failed LS), discriminating the clauses with a high score can deliver a good approximation of the set of MUSes. Such a heuristic has been studied in an extensive manner in [18, 19]. It has also been extended in several ways to address decision and optimisation problems that belong to higher levels of the polynomial hierarchy [11, 2, 12, 1].

In the following, we assume that the SAT instance is unsatisfiable. The above heuristic can require us to increment the score of clauses even when they do not actually belong to any MUS. Unless we solve the problem of finding MUSes itself, we can only rely on some heuristic indications about the extent to which a currently falsified clause could or could not belong to a MUS. In this respect, we claim that some relevant parts of the neighborhood of the current interpretation can be checked and provide more information about whether a currently falsified clause C should be counted or not. The idea is to take the structure of C into account and to increment the score of C only when it cannot be satisfied without conducting other clauses to be falsified in their turn. We shall see that this technique implements definitions that approximate a property that is intrinsic to clauses belonging to MUSes.

To illustrate this concept, let us use the following example. Let $\Delta = \{a \vee b \vee c, \neg a \vee b, \neg b \vee c, \neg c \vee a, \neg a \vee \neg b \vee \neg c\}$. Δ is unsatisfiable and is its own MUS. Let $I = \{a, b, c\}$ be an interpretation. Under this interpretation, only the clause $\neg a \vee \neg b \vee \neg c$ is falsified. In the following, the *once-satisfied* clause concept will prove useful.

Definition 2 A clause C is once-satisfied by an interpretation I iff only one literal of C is satisfied by I .

In the above example, the clauses $\neg a \vee b$, $\neg b \vee c$ and $\neg c \vee a$ are once-satisfied by $I = \{a, b, c\}$.

Definition 3 A clause C falsified by the interpretation I is critical w.r.t. I iff the opposite of every literal of C belongs to a clause that is once-satisfied by I . These once-satisfied clauses that are not tautological ones are called linked to C .

In the example, $\neg a \vee \neg b \vee \neg c$ is falsified by I and is critical w.r.t. I . Its related linked clauses are the once-satisfied ones $\neg a \vee b$, $\neg b \vee c$ and $\neg c \vee a$.

The role of these definitions is easily understood thanks to the following property.

Property 1 Let C be a critical clause w.r.t. the interpretation I , then any flip from I to I' that is such that C is satisfied under I' will conduct I' to falsify at least one clause that was satisfied by I .

In order to discriminate clauses belonging to MUSes, the idea is to increment the scores of critical clauses during the search, together with their linked (satisfied) clauses, rather than increment the scores of all falsified clauses. Indeed, this strategy exploits a property that is obeyed by clauses belonging to MUSes.

Property 2 Let I be an interpretation giving an optimal result for max-SAT on an inconsistent instance Σ . Then, any clause C of Σ falsified by I belongs to at least one MUS of Σ and is critical w.r.t. I . Moreover, at least one clause linked to C that is once-falsified by I also belongs to a MUS of Σ .

In this respect, a direct implementation of this technique would thus yield an approximation one in the sense that clauses and their linked ones are considered during the whole search, and not only at the best step of a max-SAT procedure. Such a technique can be easily grafted to a LS algorithm.

However, being a critical clause is neither a necessary nor a sufficient condition to belong to a MUS. As the following example illustrates, a critical clause w.r.t. an interpretation that is not an optimal one w.r.t. max-SAT for an unsatisfiable formula might not belong to a MUS. Let $\Delta = \{a \vee d, \neg a \vee \neg b, \neg d \vee e, f, \neg e \vee \neg f\}$. Clearly, Δ is consistent. $\neg e \vee \neg f$ is falsified by $I = \{a, b, d, e, f\}$ and is critical w.r.t. I . Moreover, a clause from a MUS that is falsified by a given interpretation I is not necessarily critical w.r.t. I , as the following example shows. Let $\Delta = \{a \vee d, b, \neg a \vee \neg b, \neg d \vee e, f, \neg e \vee \neg f\}$. Clearly, Δ is a minimal inconsistent set of clauses. $\neg a \vee \neg b$ is falsified by $I = \{a, b, d, e, f\}$. However, it is not critical w.r.t. I . Fortunately, the following property ensures that all clauses from a MUS can be scored by the heuristic.

Property 3 Let Γ be a MUS of Σ . For all clause $C \in \Gamma$, there exists an interpretation I s.t. C is critical w.r.t. I .

This property ensures that any clause that takes part in a MUS can be critical w.r.t. at least one interpretation. As such, this property does not guarantee that our scoring heuristic will allow us to exhibit all clauses belonging to MUSes. Indeed, it does not indicate that a LS run will necessarily increment the score of all such clauses at least once since LS does not necessarily visit all interpretations. However, the following property and its corollary provide us with a good indication that LS will probably visit interpretations where clauses belonging to MUSes are critical. Indeed, it is well-known that LS is in general attracted by local minima. Property 4 ensures that all falsified clauses are critical in local or global minima.

Definition 4 A local minimum is an interpretation s.t. no flip can increase the number of satisfied clauses. A global minimum (or max-SAT solution) is an interpretation delivering the maximal number of satisfied clauses.

Property 4 In (local or global) minima, all falsified clauses are critical.

A corollary even ensures that at least one clause per MUS is critical in such minima.

Corollary 1 In (local or global) minima, at least one clause per MUS is critical.

4 APPROXIMATING AND COMPUTING ONE MUS

In the following, it is shown that a meta-heuristic based on scoring critical clauses can be the cornerstone of a novel complete method to approximate or compute MUSes. Actually, due to implementation efficiency constraints, we update the scores of critical clauses only. Updating the scores of their linked clauses does not lead to dramatic performance improvements, at least w.r.t. our selected LS algorithm and tested benchmarks.

The main idea is as follows. Let Σ be an UNSAT instance. While LS fails to find a model of Σ (each time within a preset amount of computing resources), Σ is recorded on a stack and clauses that exhibit the lowest scores are removed from Σ . Then, the inconsistency of the last version of Σ for which LS has failed to find a model is checked using a complete search algorithm. If it is indeed inconsistent, then it is an upper-approximation of a MUS of the initial instance. Else, this inconsistency test is repeated on the next version of Σ from the stack until unsatisfiability is proved. Roughly, this algorithm is described in the following AOMUS procedure.

```
Procedure AOMUS ( $\Sigma$ ) // Approximate One MUS
begin
  stack :=  $\emptyset$  ;
  while (LS+Score ( $\Sigma$ ) fails to find a model)
    do
      push ( $\Sigma$ ) ;
       $\Sigma := \Sigma \setminus \text{LowestScore} (\Sigma)$  ;
    done
  repeat
     $\Sigma := \text{pop} ()$  ;
  until ( $\Sigma$  is UNSAT)
end
```

Then an exact MUS can be obtained by a step-by-step minimization of the upper-approximation until the remaining clauses are proved to form a MUS (see [14] for an alternative method). This process is called *fine-tune*. The order of tested clauses can be guided by the score of each clause.

```
Procedure fine-tune ( $\Sigma$ )
begin
  foreach clauses  $c \in \Sigma$  // sorted by scores
    If ( $\Sigma \setminus c$  is inconsistent) then  $\Sigma := \Sigma \setminus c$  ;
  done
end
```

The efficiency of this procedure directly depends on the quality of the upper-approximation. In the next section, experimental results show that the approximation delivered by AOMUS is often of a good quality, because a very small set of clauses is removed by the *fine-tune* step and in consequence a very small number of inconsistency tests are performed (when a clause belongs to the MUS, the test amounts to a consistency check).

Actually, we have refined this basic procedure in the following manner. Whenever a unique clause remains falsified during any of the LS runs, then we are sure that this clause belongs to all MUSes. We mark it as protected and it cannot be removed from Σ thereafter. When the remaining falsified clauses contain protected clauses only, they form one MUS: indeed, removing any one of these clauses will restore consistency. Moreover, when all clauses are protected and Σ is unsatisfiable, we are sure that Σ is a MUS and the *fine-tune* step

can be omitted. It appears that this refinement proves valuable for many instances, and allows a dramatic gain in the efficiency of the procedure. The OMUS algorithm includes the AOMUS procedure together with the *fine-tune* one with this refinement.

The parameters for these methods that were selected are as follows. Wsat [15] with the *Rnovelty+* option was chosen as the LS procedure. The following parameters were fine-tuned based on extensive tests on various benchmarks. After each flip of the LS, the score of critical clauses is increased by the number of their linked clauses. This technique allows us to take the length of critical clauses into account, since the number of linked clauses depends on the length of the critical clause in terms of the number of involved literals. Now, clauses whose score is lower than $(\text{min-score} + \frac{\#Flips}{\#Clauses})$ are dropped, where *min-score* is the lowest score for a clause of Σ ; *#Flips* and *#Clauses* are the number of performed flips and the number of clauses in Σ , respectively.

This procedure was tested extensively on various UNSAT instances from several difficult benchmarks from DIMACS [8] and from the annual SAT competitions [22], and compared with other published approaches to compute MUSes, as described in the next section.

5 EXPERIMENTAL RESULTS

All experiments have been conducted on Pentium IV, 3Ghz under linux Fedora Core 4. As our results show, this approximation delivers an exact result most of the time. Moreover, the *fine-tune* procedure ensures that a MUS is actually obtained. As most current approaches do not guarantee that the delivered inconsistent sets of clauses are actually MUSes, we provide both the results of applying our algorithm with and without the *fine-tune* routine. Without the *fine-tune* routine, the approach delivers upper-approximations of MUSes, and is called AOMUS (Approximate One MUS). However, on many instances, these approximations are actual MUSes. Moreover, it appeared very often that the last subformula for which LS failed to find a model was in fact unsatisfiable. Thus, in practice the last loop of the AOMUS algorithm often reduces to a unique inconsistency test. Let us stress that our approach is complete in the sense that it always delivers an approximate MUS for any UNSAT instance and a MUS when the *fine-tune* routine is run.

We compared our approach with an adaptation of AOMUS where *Scoring* is the basic heuristic of [19], which simply counts the number of times a clause is falsified. We also compared our approach with *zCore*, the core extractor of *zChaff* [23]. *zChaff* is currently one of the most efficient SAT solvers. We also ran Lynce and Marques-Silva's procedure [17], and took Bruni's [3] experimental results into account. For Bruni's technique, we only mention the experimental results obtained by the author, since this system is not available. Although a comparison with Bruni's technique is thus difficult to achieve from an experimental side, it appears that Bruni's technique has been experimented on small instances only. *zCore* proved competitive for single-MUS instances but failed to deliver good results when several MUSes are present. Indeed, *zCore* does not concentrate on finding one MUS, but on finding proofs of inconsistency. Not surprisingly, our approach proved more efficient than the similar one where *Scoring* is based on the heuristic from [19]. Most often, it proved to be more competitive than all the other considered techniques when very large and difficult multi-MUSes instances were considered. Noticeably, it was also the only technique to perform in a competitive way on all benchmarks. Let us stress that the Lynce-Silva's procedure computes the smallest MUS, that *zCore* delivers

an approximation of a MUS, whereas our OMUS and AOMUS procedures deliver one exact and one approximate MUS, respectively. Moreover, it should be emphasized that MUSes that are discovered by the various approaches are not necessarily the same ones.

In Table 1, some typical experimental results are given. Except for Bruni's results which are just size results that we have extracted from [3], we provide both the experimental size of the discovered smallest inconsistent subsets, together with the CPU time in seconds to get them. Time-out indicates that no result has been obtained within 1 hour CPU time. For example, for the `homer14` instance, AOMUS delivered an approximate MUS made of 561 clauses within 28.03 s. Actually, this was an exact MUS, as it was found by OMUS in 30.64 s. Note that an AOMUS version based on [19] delivered the same result in 347.19 s. zCore delivered an approximate MUS made of 1065 clauses within 714 s. Actually, this approximate MUS was a superset of the MUS discovered by both AOMUS and OMUS. Also, it can be seen e.g. on the `fpga` benchmarks that AOMUS (i.e. our approach without the `fine-tune` procedure) delivered smaller inconsistent subsets than any other considered method, most often. Let us also emphasize that even on small instances like the `aim` ones, OMUS proved very competitive, as well.

6 APPROXIMATING THE SET OF MUSes

Based on the OMUS procedure, we now address the problem of computing the set of MUSes of unsatisfiable instances, also called *clutter* by Bruni [4]. Since a MUS can be “broken” by removing one of its clauses, a naive approach consists in removing one clause of a MUS after this latter one has been discovered by the OMUS procedure, and then in iterating the process. Such an approach would deliver the right result when any pair of MUSes exhibits an empty intersection. However, MUSes can have non-empty intersections. Ac-

cordingly, when we remove a clause from a MUS, we actually break all MUSes containing it. To prevent this drawback from occurring as much as possible, we should prefer dropping clauses that belong to a minimal number of MUSes. Accordingly, we have investigated the following heuristic.

As max-SAT is intended to deliver a minimal number of unsatisfied clauses, the remaining unsatisfied clauses in a max-SAT solution must belong to intersections of MUSes as much as possible. Accordingly, for each clause, we record the minimum number of clauses that have been falsified at the same time during a failed LS. After a MUS is detected, the clause in the MUS with the lowest score is removed from the instance.

Clearly, such an approach (that we note ASMUS (Approximate Set of MUS)) is incomplete. However, it delivers very good results with respect to current existing approaches, as illustrated by our experimental investigations summarized in Table 2. For these experiments, the time-out was set to 20000 s. Aleat X_Y_Z instances are standard generated (unsatisfiable) random ones, with X variables and Y clauses. XAIM $\alpha\beta$ _ Z instances are the mere concatenations of X AIM $\alpha\beta$ instances, where $\alpha = \frac{Y}{X}$ and $\beta = \frac{Z}{Y}$.

We have compared the ASMUS method with the complete algorithm proposed in [16] from an experimental point of view. Table 2 shows that both approaches appear to deliver the *exact* sets of MUSes on the simple “aim” benchmarks, using similar run-times. On more difficult instances like Aleat30_75_*, ASMUS almost extracts all MUSes and its computation time is in general better than the complete method one.

Moreover, Liffiton and Sakallah's algorithm can get into trouble for larger instances, since a CNF formula can exhibit an exponential number of MUSes and since their approach aims at computing all MUSes individually, only after having computed all maximally sat-

Table 2. Finding as many MUSes as possible.

isifiable subformulas, which can be intractable. On the opposite, our approximation technique does not suffer from such a drawback and exhibits an anytime property since MUSes are directly computed one after the other. For example, let us consider the Aleat20_70_2 random instance. It exhibits 70 clauses and these constraints form more than 114 000 MUSes. Due to the very small size of this formula, [16] has been able to compute all MUSes. For larger instances involving many MUSes, like dp02u01 (213 atoms, 376 clauses), the set of MUSes could not be computed within 20000 s., while our approach extracted 14 MUSes in 26 s.

7 CONCLUSION

In this paper, thanks to an original concept of critical clauses, a novel meta-heuristic-based approach to compute MUSes in SAT instances has been introduced. As our experimental results on difficult benchmarks illustrate it, the approach proves to be viable and often more competitive than previously published ones. The meta-heuristic is based on the intuitive idea that the most often falsified constraints during a failed local search are often the actual unsatisfiable ones. This idea has been refined to take the falsification propagation effect of these constraints. We believe that such a meta-heuristic could be applied to various difficult decision and optimisation problems. We plan to explore this in the near future.

ANNEX: PROOFS

Proof of Property 1 If C is critical w.r.t. I then for each literal l of C , $\exists C'$ s.t. C' is once-satisfied by I and \bar{l} belongs to C' . C is falsified by I , thus l is false w.r.t. I and \bar{l} is true w.r.t. I . \bar{l} is the only literal of C' satisfied by I . Accordingly if the value of l is reversed then C' becomes falsified. \square

Proof of Property 2 Any clause falsified by I belongs to a MUS of Σ because I is optimal w.r.t. the number of satisfied clauses and at least one clause of each MUS cannot be satisfied by I . The fact that any clause falsified by I is critical is proved thanks to property 4 since I is a global minimum. I is optimal w.r.t. the number of satisfied clauses, thus at most one clause per MUS is falsified. Also, if one flip allows us to satisfy one of these clauses, another clause of the MUS becomes falsified. Accordingly, at least one once-satisfied clause linked to a clause falsified by I belongs to a MUS of Σ . \square

Proof of Property 3 Let Γ be a MUS of Σ and C be a clause of Γ . By definition of a MUS, $\Gamma \setminus \{C\}$ is satisfiable. Let M be a model of $\Gamma \setminus \{C\}$. Let us prove that C is critical w.r.t. M . First, C is falsified. Indeed, if C were not falsified then Γ would exhibit a model M , which is impossible because Γ is a MUS. Second, C is critical. Indeed, if any variable occurring in C is flipped w.r.t. M , then at least one clause of Γ becomes unsatisfied since Γ is unsatisfiable. That means that this new unsatisfied clause was once-satisfied and linked to C . Accordingly, C is critical w.r.t. M . \square

Proof of Property 4 If a variable occurring in a falsified clause w.r.t. a minimum is flipped, then this clause is satisfied and at least one previously satisfied clause becomes unsatisfied. That means that this new unsatisfied clause was once-satisfied. Accordingly, the initial falsified clause was critical. \square

On Probing and Multi-Threading in PLATYPUS

J. Gressmann¹ and T. Janhunen² and R. Mercer³ and T. Schaub^{1,4} and S. Thiele¹ and R. Tichy¹

Abstract. The PLATYPUS approach offers a generic platform for distributed answer set solving, accommodating a variety of different architectures for distributing the search for answer sets across different processes and different search modes for modifying search behaviour. We describe two major extensions of PLATYPUS. First, we present its *probing* mode which provides a controlled non-linear traversal of the search space. Second, we present its new *multi-threading* architecture allowing for intra-process distribution. Both contributions are underpinned by experimental results illustrating their computational impact.

1 INTRODUCTION

The success of Answer Set Programming (ASP) has been greatly enhanced by the availability of highly efficient ASP-solvers [8, 11]. But, more complex applications are requiring computationally more powerful devices. Distributing parts of the search space among cooperating sequential solvers performing independent searches can provide increased computational power. We have proposed a generic approach to distributed answer set solving, called PLATYPUS [5].

The PLATYPUS approach differs from other pioneering work in distributed answer set solving [3, 10], by accommodating in a single design a variety of different architectures for distributing the search for answer sets over different processes. The resulting platform, *platypus*, allows one to exploit the increased computational power of clustered and/or multi-processor machines via different types of inter- and intra-process distribution techniques like MPI [7], Unix' fork mechanism, and (as discussed in the sequel) multi-threading. In addition, the generic approach permits a flexible instantiation of all parts of the design.

More precisely, the PLATYPUS design incorporates two distinguishing features: First, it modularises (and is thus independent of) the propagation engine (currently exemplified by *smodels*' and *nomore++*' expansion procedures). Second, the search space is represented explicitly. This representation allows a flexible distribution scheme to be incorporated, thereby accommodating different distribution policies and architectures. The two particular contributions discussed in this paper take advantage of these two aspects of the generic design philosophy. The first extension to PLATYPUS, *probing*, refines the encapsulated module for propagation. Probing is akin to restart in the SAT solving framework [4]. The introduction of probing demonstrates one aspect of the flexibility in our PLATYPUS design: by having a modularised generic design, we can easily specify parts of the generic design to give different computational properties to the *platypus* system. Our second improvement to

platypus is the integration of multi-threading into our software package [9]. Multi-threading expands the implemented architectural options for delegating the search space and adds several new features to *platypus*: (1) the single- and multi-threaded versions can take advantage of new hardware innovations such as multi-core processors, as well as primitives to implement lock-free data structures, (2) a hybrid architecture which allows the mixing of inter- and intra-process distribution, and (3) the intra-process distribution provides a lighter parallelisation mechanism than forking.

We highlight our two contributions, *probing* and *multi-threading*, by focusing on the appropriate aspects of the abstract PLATYPUS algorithm reproduced from [5] below. As well, their computational impact is exposed in data provided by a series of experiments.

2 THE PLATYPUS APPROACH

In ASP, a logic program Π is associated with a set of *answer sets*, $AS(\Pi)$, which are distinguished models of the rules in Π . We do not elaborate, but refer the reader to [2] for a formal introduction to ASP. For computing answer sets, we rely on *partial assignments*, mapping atoms in an alphabet \mathcal{A} onto true, false, or undefined. We represent such assignments as pairs (X, Y) of sets of atoms, in which X contains all true atoms and Y all false ones. In general, a partial assignment (X, Y) aims at capturing a subset of the answer sets of Π , viz. $AS_{(X,Y)}(\Pi) = \{Z \in AS(\Pi) \mid X \subseteq Z, Z \cap Y = \emptyset\}$.

To begin, we recapitulate the major features of the PLATYPUS approach [5]. To enable a distributed search for answer sets, the search space is decomposed by means of partial assignments. This method works because partial assignments that differ with respect to defined atoms represent different parts of the search space. To this end, Al-

Algorithm 1: PLATYPUS

Global : A logic program Π over alphabet \mathcal{A} .
Input : A nonempty set S of partial assignments.
Output : Print a subset of the answer sets of Π .

```

repeat
1    $(X, Y) \leftarrow \text{CHOOSE}(S)$ 
2    $S \leftarrow S \setminus \{(X, Y)\}$ 
3    $(X', Y') \leftarrow \text{EXPAND}((X, Y))$ 
4   if  $X' \cap Y' = \emptyset$  then
5     if  $X' \cup Y' = \mathcal{A}$  then print  $X'$  else
6        $A \leftarrow \text{CHOOSE}(\mathcal{A} \setminus (X' \cup Y'))$ 
7        $S \leftarrow S \cup \{ (X' \cup \{A\}, Y'), (X', Y' \cup \{A\}) \}$ 
8        $S \leftarrow \text{DELEGATE}(S)$ 
until  $S = \emptyset$ 

```

gorithm 1 is based on an explicit representation of the search space in terms of a set S of partial assignments, on which it iterates until S becomes empty. The algorithm relies on the omnipresence of a

logic program Π and its alphabet \mathcal{A} as global parameters. Communication between PLATYPUS instances is limited to delegating partial assignments as representatives of parts of the search space. The set of partial assignments provided in the input variable S delineates the search space given to a specific instance of PLATYPUS. Although this explicit representation offers an extremely flexible access to the search space, it must be handled with care since it grows exponentially in the worst case. Without Line 8, Algorithm 1 computes all answer sets in $\bigcup_{(X,Y) \in S} AS_{(X,Y)}(\Pi)$. With Line 8 each PLATYPUS instance generates a subset of the answer sets. CHOOSE and DELEGATE are in principle non-deterministic selection functions: CHOOSE yields a single element, DELEGATE communicates a subset of S to a PLATYPUS instance and returns a subset of S . Clearly, depending on what these subsets are, this algorithm is subject to incomplete and redundant search behaviours. The EXPAND function hosts the deterministic part of Algorithm 1. This function is meant to be implemented with an off-the-shelf ASP-expander that is used as a black-box providing both sufficiently strong as well as efficient propagation operations. See [5] for details.

We now turn to specific design issues beyond the generic description of Algorithm 1. To reduce the size of partial assignments and thus that of passed messages, we follow [10] in representing partial assignments only by atoms⁵ whose truth values were assigned by choice operations (cf. atom A in Lines 6 and 7). Given assignment (X, Y) with its subsets $X_c \subseteq X$ and $Y_c \subseteq Y$ of atoms assigned by a choice operation, we have $(X, Y) = \text{EXPAND}((X_c, Y_c))$. Consequently, the expansion of assignment (X, Y) to (X', Y') in Line 3 does not affect the representation of the search space in S .⁶ Furthermore, the design includes the option of using a choice proposed by the EXPAND component for implementing Line 6. Additionally, the currently used expanders, smodels and nomore++, also supply a *polarity*, indicating a preference for assigning true or false.

Each `platypus` process has an explicit representation of its (part of the) search space in its variable S . This set of partial assignments is implemented as a tree. Whenever more convenient, we describe S in terms of a set of assignments or a search tree and its branches. In contrast to stack-based ASP-solvers, like smodels or nomore++, whose search space contains a single branch at a time, this tree normally contains several independent branches. The *active* partial assignment (or branch) selected in Line 1, is the one being currently treated by the expander. The state of the expander is characterised by the contents of its stack, which corresponds to the active branch in the search tree. While the stack contains the full assignment (X, Y) , the search tree's active branch only contains the pair of subsets (X_c, Y_c) .

3 PROBING

The explicit representation of the (partial) search space, although originally devised to enable the use of a variety of strategies for delegating parts of the search space in the distributed setting, appears to be beneficial in some sequential contexts, as well. Of particular interest, when looking for a single answer set, is limiting fruitless searches in parts of the search tree that are sparsely populated with answer sets. In such cases, it seems advantageous to leave a putatively sparsely populated part and continue at another location in the search space. In `platypus`, this decision is governed by two command line options, $\#c$ and $\#j$. A part of the search is regarded as fruitless, whenever the number of *conflicts* (as encountered in Line 4)

⁵ Assignments are not restricted to atoms, as used when using nomore++.

⁶ Accordingly, the tests in Lines 4 and 5 must be handled with care; see [5].

exceeds the value of $\#c$. The corresponding conflict counter⁷ c is incremented each time a conflict is detected in Line 4. The counter c is reset to zero whenever an answer set is found in Line 5 or the active branch in S is switched (and thus the expander is reinitialised; see Algorithm 2). The number of *jumps* in the search space is limited by $\#j$; each jump changes the active branch in the search space. We use a *binary exponential back-off* (cf. [12]) scheme to heed unsuccessful jumps. The idea is as follows. At first, probing initiates a jump in the search space whenever the initial conflict limit $\#c$ is reached. If no solution is found after $\#j$ jumps, then the problem appears to be harder than expected. In this case, the permissible number of conflicts $\#c$ is doubled and the allowed number of jumps $\#j$ is halved. The former is done to prolong systematic search, the latter to reduce gradually to zero the number of jumps in the search space. We refer to this treatment of the search space as *probing*. Probing is made precise in Algorithm 2, which is a refinement of the CHOOSE operation in Line 1 of Algorithm 1. Note that probing continues until the pa-

Algorithm 2: CHOOSE (in Line 1 of Algo. 1) in *probing mode*.

Global : Positive integers $\#c, \#j$, supplied via command line.
 Integers c, j , initially $c = 0$ and $j = \#j$.
 Selection policy \mathcal{P} , supplied via command line.
Input : A set S of assignments with active assignment $b \in S$.
Output: A partial assignment.
// Counter c is incremented by one in Line 4 of Algorithm 1.
if ($c \leq \#c$) or ($\#j = 0$) **then return** b ; // no jumping
else // jumping
 $c \leftarrow 0$
 $j \leftarrow j - 1$
 if ($j = 0$) **then**
 $\#c \leftarrow (\#c \times 2)$
 $\#j \leftarrow (\#j \text{ div } 2)$
 $j \leftarrow \#j$
 let $b' \leftarrow \text{SELECT}(\mathcal{P}, S)$ **in**
 ⟨make b' the active partial assignment in S ⟩
 return b'

rameter $\#j$ becomes zero. When probing stops, search proceeds in the usual depth-first manner by considering only one branch at a time by means of the expander's stack. Clearly, this is also the case during the phases when the conflict limit has not been reached ($c \leq \#c$).

At the level of implementation, the expander must be reinitialised whenever the active branch of the search space changes. Reinitialisation is unnecessary when extending the active branch by the choice (obtained in Line 6) in Line 7 of Algorithm 1 or when backtracking is possible in case a conflict occurs or an answer set is obtained. In the first case, the expander's choice (that is, an atom with a truth value) is simply pushed on top of the expander's stack (and marked as a possible backtracking point). At the same time, the active branch in S is extended by the choice and a copy of the active branch, extended by the complementary choice, is added to S . See [6] for details.

In the case that a conflict occurs or an answer set is obtained, the active branch in S is replaced by the branch corresponding to the expander's stack after backtracking. If it exists, this is the largest branch in S that equals a subbranch of the active branch after switching the truth value of its leaf element. If backtracking is impossible, the active branch is chosen by means of the given policy \mathcal{P} (at present, a largest, a smallest, or a random assignment). If this, too, is impossi-

⁷ Each thread has its own conflict and jump counters.

ble, S must be empty and the PLATYPUS instance terminates.

The policy-driven selection of a branch, expressed in Algorithm 2 by $\text{SELECT}(\mathcal{P}, S)$, is governed by another command line option⁸ $\#n$ and works in two steps. First, among all branches in S , the $\#n$ best ones, $b_1, \dots, b_{\#n}$, are identified according to policy \mathcal{P} . To be precise, let p be a mapping of branches to ordinal values, used by \mathcal{P} for evaluating branches. For every $b \in \{b_1, \dots, b_{\#n}\}$ and $b' \in S \setminus \{b_1, \dots, b_{\#n}\}$, we then have that $p(b) \leq p(b')$. Then, a branch b is randomly selected from $\{b_1, \dots, b_{\#n}\}$. This random selection from the best $\#n$ branches counteracts the effect of a rigid policy by arbitrarily choosing some close alternatives.

To see that probing guarantees completeness, it is sufficient to see that no partial assignment is ever eliminated from the search space. Also, when probing, the number of different branches in the search space S cannot exceed twice the number of initially permitted jumps, viz. $2 \times \#j$. For instance, if the command line option sets $\#j$ to 13, we may develop at most $13 + 6 + 3 + 1$ different branches in S , which is bound by 2×13 . Thereby, a branch is considered as different if it is not obtainable from another's subbranch by switching the assigned truth value of a single atom (i.e. if it is not a backtracking point).

4 THREAD ARCHITECTURE

This section details the multi-threaded architecture extension to the *platypus* platform which adds the capacity to do intra-process distribution delegation to the existing inter-process capabilities, which are optionally realised via Unix' forking mechanism or MPI [7] (described in [5]). This richer architecture now permits hybrid delegation methods, for instance, delegating *platypus* via MPI on a cluster of multi-processor machines, with delegation among the multi-processors of each machine accomplished with multi-threading.

The architecture is split into more or less two parts: the *core* and the *distribution* components. A core encapsulates the search for answer sets, and the *DELEGATE* function is encapsulated in a distribution component. The core and distribution components have well-defined interfaces that localise the communication between the components. This design allows us to incorporate, for instance, single- and multi-threaded cores, as well as inter-process distribution schemes, like MPI and forking, with ease.

Each *platypus* process hosts an instance of the core, the core object, which cooperates with one instance of the distribution component, the distribution object. Communication is directed from core to distribution objects and is initiated by the core object. During execution the major flow of control lies with the core objects.

The multi-threaded core works according to the master/slave principle. The master coordinates a number of slave threads. Each slave thread executes the PLATYPUS algorithm on its thread-local search space. The master thread handles communication (through the distribution object) with other *platypus* processes on behalf of the slave threads. Communication between the master thread and its slave threads is based on counters and queues: Events of interest (e.g. statistics, answer sets, etc.) are communicated by the slaves to the master by incrementing the appropriate counter or adding to the respective queue. The master thread periodically polls the counters and queues for any change. The search ends (followed by termination of the *platypus* program) if there is agreement among the distribution objects that either all participating processes are in need of work (indicating all the work is done) or the requested number of answer sets is computed. In the core, the *idle thread counter* of the master thread serves two purposes: It indicates the number of idle slave

threads in the core object, and it shows the number of partial assignments in the *thread delegation queue* of the master thread. Slave threads share their search space automatically among themselves as long as one thread has some work left. A slave thread running out of work (reaching an empty search space S) checks the availability of work via the idle thread counter and if possible removes a partial assignment from the thread delegation queue. Otherwise, it waits until new work is assigned to it. Another slave thread can become aware of the existence of an idle thread by noting that the idle thread counter exceeds zero during one of its periodic checks. If this is the case, it splits off a part of its local search space according to a distribution policy, puts the partial assignment that represents the subspace into the thread delegation queue, and decrements the idle thread counter. As this may happen simultaneously in several working slave threads, more partial assignments can end up in the thread delegation queue than there exist idle slaves. These extras are used subsequently by idle threads.

When all slave threads are idle (i.e. the idle thread counter equals the number of slave threads) the master thread initiates communication via the distribution object to acquire more work from other PLATYPUS processes. To this end, the master thread periodically queries the associated distribution object for work until it either gets some work or is requested to terminate. Once work is available, the master thread adds it to the thread delegation queue, decrements the idle thread counter,⁹ and wakes up a slave thread. The awoken slave thread will find the branch there, take it out, and start working again. From there on, the core enters its normal thread-to-thread mode of work sharing. Conversely, when a *platypus* process receives notification that another process has run out of work, it attempts to delegate a piece of its search space. To this end, it sets the *other-process-needs-work* flag of the master thread in its core object. All slave threads noticing this flag clear the flag and delegate a piece of their search space according to the delegation policy by adding it to the *remote delegation queue*. The master thread takes one branch out of the queue and forwards it to the requesting *platypus* process (via the distribution object). Because of the multi-threaded nature any number of threads can end up delegating. Items left in the remote delegation queue are used by the master thread to fulfil subsequent requests for work by other *platypus* processes or work requests by its slave threads. The conceptual difference between the thread delegation and the remote delegation queues is that the former handle intra-core delegations, while the latter deal with extra-core delegation, although non-delegated work can return to the core. This is reflected by the fact that master and slave threads are allowed to insert partial assignments into the thread delegation queue, whereas only slave threads remove items from this queue. In contrast, only the master thread is allowed to eliminate items from the remote delegation queue, while insertions are performed only by slave threads.

An important aspect of the multi-threaded core implementation is the use of *lock-free data structures* for synchronising communication among master and slave threads. This is detailed in [6].

5 EXPERIMENTAL RESULTS

The following experiments aim to provide some indication of the computational value of probing and multi-threading. All experiments were conducted with some fixed parameters: (i) smodels (2.28) was used as propagation engine and for delivering the (signed) choice in Line 6 of Algorithm 1, (ii) the choice in Line 1 of Algorithm 1 was

⁸ Option $\#n$ can be zero, indicating the use of all branches.

⁹ The inserting thread is responsible for decrementing the idle thread counter.

Table 1. Experimental results for *probing* (with the single-threaded core).

fixed to the policy selecting assignments with the largest number of unassigned atoms, (iii) all such selections were done in a deterministic way by setting command-line option $\#n$ to 1 (cf. Section 2). All tests were done with *platypus* version 0.2.2 [9]. They reflect average times of 5 runs for finding the first or all answer sets, resp., of the considered instance. Timing excludes parsing and printing. The data was obtained on a quad processor (4 Opteron 2.2GHz processors, 8 GB shared RAM) under Linux.

For illustrating the advantage of probing, we have chosen the search for one Hamiltonian cycle in *clumpy graphs*, proposed in [13] as a problem set being problematic for systematic backtracking. These benchmarks are available at [9]. Table 1 contrasts different settings for numbers of conflicts $\#c$ (10, 50, 100, 200) and jumps $\#j$ (32, 64, 128, 256, 512), resp., running the single-threaded core. For comparison, we also provide the corresponding *smodels* times¹⁰ and the ones for single-threaded *platypus* without probing in the columns labelled *sm* and *st*. The remaining columns are labelled with the command line options used, viz. $\#c, \#j$. A blank entry represents a timeout after 240 seconds. First of all, we notice that the systems using standard depth first-search are unable to solve 12 instances within the given time limit, whereas when using probing, apart for a few exceptions, all instances are solved. We see that *platypus* without probing does best 8 times, as indicated in bold-face, and worst 24 times, whereas *smodels* does best 2 times¹¹ and worst 24 times. Compared to each specific probing configuration, *platypus* without probing performs better among 9 to 15 (*smodels*, 6 to 8) times out of 38. In fact, there seems to be no clear pattern indicating a best probing configuration. However, looking at the lower part of Table 1, we observe that *platypus* without probing (*smodels*) times out 12 times, while probing still gives a

¹⁰ These times are only indicative since they include printing one answer set.
¹¹ The six cases differ by only 0.01sec which is due to slightly different timing methods (see Footnote 10).

solution under all but three configurations. In all, we see that probing allows for a significant speed-up for finding the first answer set. This is particularly valuable whenever answer sets are hard to find with a systematic backtracking procedure, as witnessed by the entries in the lower part of Table 1. However, probing has generally no positive effect when computing all answer sets. Also, on more common benchmarks (cf. [1]) probing rarely kicks in since the conflict counter is earlier reset to zero whenever an answer set is found.

The computational impact of probing is even more significant when using multi-threading,¹² where further speed-ups are observed on 20 benchmarks, most of which are among the more substantial ones in the lower part of Table 1. The most substantial one is observed on clumpy graph 09,09,04 which is solved in 4.66 and 4.26 seconds, resp., when setting $\#c, \#j$ to 10,512 and using 3 and 4 slave threads, resp. Interestingly, even the multi-threaded variant *without* probing cannot solve the last seven benchmarks within the time limit, except for clumpy 09,09,07, which *platypus* with 4 slave threads is able to solve in 13.8 seconds. This illustrates that probing and multi-threading are two complementary techniques that can be used for accelerating the performance of standard ASP-solvers. A way to tackle benchmarks that are even beyond the reach of probing with multi-threading is to use randomisation via command-line option $\#n$.

Table 2 displays the effect of multi-threading, when computing all answer sets. For consistency, we have taken a subset of the asparagus benchmarks [1] in [5], used when evaluating the speed-ups obtained with the (initial) forking and MPI variant of *platypus*. Comparing the sum of the average times, the current *platypus* variant running multi-threading is 2.64 times faster than its predecessor using forking, as reported in [5].¹³ In more detail, the columns reflect the times of *platypus* run with the multi-threaded core restricted

¹² All tests on multi-threading with and without probing are provided at [9].

¹³ The forking tests in [5] were also run on the same machine.

to 1, 2, 3, and 4 slave threads (probing disabled). When looking at each benchmark, the experiments show a qualitatively consistent 2-, 3-, and 4-times speed-up when doubling, tripling, and quadrupling the number of processors, with only minor exceptions. For instance, the smallest speed-up is observed on *schur-11-5* (1.52, 1.73, 1.75); among the highest speed-ups, we find *schur-19-4* (2.17, 3.43, 4.75) and *pigeon-7-11* (2.24, 3.43, 4.6). The average speed-ups observed on this set of benchmarks is 1.96, 2.89, and 3.75. If we weight the average speed-ups with the respective average running times, we obtain even a slightly super-linear speed-up: 2.07, 3.18, 4.24. Such super-linear speed-ups are observed primarily on time-demanding benchmarks and, although less significant, have also been observed in [5] when forking (which makes us ascribe them to caching effects and/or shared memory). In all, we observe that the more substantial the benchmark, the more clear-cut the speed-up.

Given that the experiments were run on a quad processor, it is worth noting that we observe no drop in performance when increasing the number of slave threads from 3 to 4, despite having a fifth (master) thread. Finally, we note that the multi-threaded core, when restricted to a single slave thread, loses on average only 2% performance compared to the single-threaded version.

6 DISCUSSION

At the heart of the PLATYPUS design is its generality and modularity. These two features allow a great deal of flexibility in any instantiation of the algorithm, making it unique among related approaches. Up to now, this flexibility was witnessed by the possibility to use different off-the-shelf solvers, different process-oriented distribution mechanisms, and a variety of choice policies. In this paper we have presented two significant configurable enhancements to platypus.

First, we have described its probing mode, relying on an explicit yet restricted representation of the search space. This provides us with a global view of the search space and allows us to have different threads working on different subspaces. Although probing does not primarily aim at a sequential setting, we have experimentally demon-

strated its computational value on a specific class of benchmarks, which is problematic for standard ASP-solvers. Unlike restart strategies in SAT, which usually draw on learnt information [4], probing keeps previously abandoned parts of the search space, so that they can be revisited subsequently. Probing offers a non-linear¹⁴ exploration of the search space that can be randomised while remaining complete, a search strategy that no other native ASP-solver offers.

Second, we have presented *platypus*' multi-threaded architecture. Multi-threading complements the previous process-oriented distribution schemes of *platypus* by providing further intra-process distribution capacities. This is of great practical value since it allows us to take advantage of recent hardware developments, offering multi-core processors. In a hybrid setting, consisting of clusters of such machines, we may use multi-threading for distribution on the multi-core processors, while distribution among different workstations is done with previously established distribution techniques in *platypus*, like MPI. Furthermore, the modular implementation of the *core* and *distribution* component allow for easy modifications in view of new distribution concepts, like grid computing, for instance. The *platypus* platform is freely available on the web [9].

Elaborating domain descriptions

Andreas Herzig and Laurent Perrussel and Ivan Varzinczak¹

Abstract. In this work we address the problem of *elaborating* domain descriptions (alias action theories), in particular those that are expressed in dynamic logic. We define a general method based on contraction of formulas in a version of propositional dynamic logic with a solution to the frame problem. We present the semantics of our theory change and define syntactical operators for contracting a domain description. We establish soundness and completeness of the operators w.r.t. the semantics for descriptions that satisfy a principle of modularity that we have defined in previous work.

1 INTRODUCTION

Suppose a situation where an agent has always believed that if the light switch is up, then the room is light. Suppose now that someday, she observes that even if the switch is up, the light is off. In such a case, the agent must change her beliefs about the relation between the propositions “the switch is up” and “the light is on”. This is an example of changing propositional belief bases and is largely addressed in the literature about belief change [10] and update [24].

Next, let our agent believe that whenever the switch is down, after toggling it, the room is light. This means that if the light is off, in every state of the world that follows the execution of toggling the switch, the room is lit up. Then, during a blackout, the agent toggles the switch and surprisingly the room is still dark.

Imagine now that the agent never worried about the relation between toggling the switch and the material it is made of, in the sense that she ever believed that just toggling the switch does not break it. Nevertheless, in a stressful day, she toggles the switch and then observes that she had broken it.

Completing the wayside cross our agent experiments in discovering the world’s behavior, suppose she believed that it is always possible to toggle the switch, given some conditions e.g. being close enough to it, having a free hand, the switch is not broken, etc. However, in an April fool’s day, she discovers that someone has glued the switch and, consequently, it is no longer possible to toggle it.

The last three examples illustrate situations where changing the beliefs about the behavior of the action of toggling the switch is mandatory. In the first one, toggling the switch, once believed to be deterministic, has now to be seen as nondeterministic, or alternatively to have a different outcome in a specific context (e.g. if the power station is overloaded). In the second example, toggling the switch is known to have side-effects (ramifications) one was not aware of. In the last example, the executability of the action under concern is questioned in the light of new information showing a context that was not known to preclude its execution. Carrying out such modifications is what we here call *elaborating* a domain description, which has to do with the principle of *elaboration tolerance* [28].

¹ The authors are with the Institut de Recherche en Informatique de Toulouse (IRIT), Toulouse, France. e-mail: {herzig, perrusse, ivan}@irit.fr

Such cases of theory change are very important when one deals with logical descriptions of dynamic domains: it may always happen that one discovers that an action actually has a behavior that is different from that one has always believed it had.

Up to now, theory change has been studied mainly for knowledge bases in classical logics, both in terms of revision and update. Only in a few recent works it has been considered in the realm of modal logics, viz. in epistemic logic [12] and in action languages [7]. Recently, several works [31, 21] have investigated revision of beliefs about facts of the world. In our examples, this would concern e.g. the current status of the switch: the agent believes it is up, but is wrong about this and might subsequently be forced to revise her beliefs about the current state of affairs. Such revision operations do not modify the agent’s beliefs about the action laws. In opposition to that, here we are interested exactly in such modifications. The aim of this paper is to make a step toward that issue and propose a framework that deals with the contraction of action theories.

Propositional dynamic logic (PDL [13]), has been extensively used in reasoning about actions in the last years [2, 36, 8]. It has shown to be a viable alternative to situation calculus approaches because of its simplicity and existence of proof procedures for it. In this work we investigate the elaboration of domain descriptions encoded in a simplified version of such a logical formalism, viz. the multimodal logic K_n . We show how a theory expressed in terms of static laws, effect laws and executability laws is elaborated: usually, a law has to be changed due to its generality, i.e., the law is too strong and has to be weakened. It follows that elaborating an action theory means contracting it by static, effect or executability laws, before expanding the theory with more specific laws.

2 BACKGROUND

Following the tradition in the reasoning about actions community, action theories are collections of statements of the form: “if *context*, then *effect* after every execution of *action*” (effect laws); and “if *pre-condition*, then *action executable*” (executability laws). Statements mentioning no action at all represent laws about the world (static laws). Besides that, statements of the form “if *context*, then *effect* after some execution of *action*” will be used as a causal notion to solve the frame and the ramification problems.

2.1 Logical preliminaries

Let $\mathcal{Act} = \{a_1, a_2, \dots\}$ be the set of all *atomic actions* of a given domain, an example of which is *toggle*. To each atomic action a there is associated a modal operator $[a]$. $\mathcal{Prop} = \{p_1, p_2, \dots\}$ denotes all the *propositional constants* (alias *fluents* or *atoms*). Examples of those are *light* (“the light is on”) and *up* (“the switch is up”). The set of all literals is $\mathcal{Lit} = \mathcal{Prop} \cup \{\neg p : p \in \mathcal{Prop}\}$.

\mathfrak{Fml} is the set of all classical formulas. They are denoted by small Greek letters φ, ψ, \dots . An example is $up \rightarrow light$. By $val(\varphi)$ we denote the set of valuations making φ true. We view a valuation as a maximally-consistent set of literals. For $\mathfrak{Prop} = \{light, up\}$, there are four valuations: $\{light, up\}$, $\{light, \neg up\}$, $\{\neg light, up\}$ and $\{\neg light, \neg up\}$. Given a set of formulas Σ , by $lit(\Sigma)$ we denote the set of all literals appearing in formulas of Σ .

We denote complex formulas (with modal operators) by Φ, Ψ, \dots . $\langle a \rangle$ is the dual operator of $[a]$, defined as $\langle a \rangle \Phi =_{\text{def}} \neg [a] \neg \Phi$. An example of a complex formula is $\neg up \rightarrow [toggle]up$. The semantics is that of multimodal logic K [29].

A K_n -model is a tuple $\mathcal{M} = \langle W, R \rangle$ where W is a set of valuations, and R a function mapping action constants a to accessibility relations $R_a \subseteq W \times W$. Given a K_n -model $\mathcal{M} = \langle W, R \rangle$, $\models_w^{\mathcal{M}} p$ (p is true at world w of model \mathcal{M}) if $p \in w$; $\models_w^{\mathcal{M}} [a]\Phi$ if for every w' such that wR_aw' , $\models_{w'}^{\mathcal{M}} \Phi$. Truth conditions for other connectives are as usual.

\mathcal{M} is a model of Φ (noted $\models^{\mathcal{M}} \Phi$) if for all $w \in W$, $\models_w^{\mathcal{M}} \Phi$. \mathcal{M} is a model of a set of formulas Σ (noted $\models^{\mathcal{M}} \Sigma$) if $\models^{\mathcal{M}} \Phi$ for every $\Phi \in \Sigma$. Φ is a consequence of the set of global axioms Γ in the class of all K_n -models (noted $\Gamma \vdash_{K_n} \Phi$) if for every K_n -model \mathcal{M} , $\models^{\mathcal{M}} \Gamma$ implies $\models^{\mathcal{M}} \Phi$.

2.2 Describing the behavior of actions in K_n

K_n allows for the representation of statements describing the behavior of actions. They are called *action laws*. Here we distinguish several types of them. The first kind of statement represents the *static laws*, formulas that must hold in every possible state of the world.

Definition 1 A static law is a formula $\varphi \in \mathfrak{Fml}$.

An example of a static law is $up \rightarrow light$: if the switch is up, then the light is on. $\mathcal{S} \subseteq \mathfrak{Fml}$ denotes all the static laws of a domain.

The second kind of law we consider are the *effect laws*. They are formulas relating an action to its effects, which can be conditional.

Definition 2 An effect law for action a has the form $\varphi \rightarrow [a]\psi$, where $\varphi, \psi \in \mathfrak{Fml}$.

The consequent ψ is the effect always obtained when a is executed in a state where the antecedent φ holds. \mathcal{E} denotes the set of all effect laws of a domain, an example of which is $\neg up \rightarrow [toggle]light$: whenever the switch is down, after toggling it, the room is lit up. If ψ is inconsistent, we have a special kind of effect law that we call an *inexecutability law*. For example, $broken \rightarrow [toggle]\perp$ says that *toggle* cannot be executed if the switch is broken.

Finally, we also define *executability laws*, which stipulate the context for an action to be executable. In K_n , we use $\langle a \rangle$ to express executability. $\langle a \rangle \top$ thus reads “the execution of a is possible”.

Definition 3 An executability law for action a is of the form $\varphi \rightarrow \langle a \rangle \top$, where $\varphi \in \mathfrak{Fml}$.

For instance, $\neg broken \rightarrow \langle toggle \rangle \top$ says that toggling can be executed whenever the switch is not broken. The set of all executability laws of a given domain is denoted by \mathcal{X} .

3 MODELS OF CONTRACTION

When an action theory has to be changed, the basic operation is that of *contraction*. (In belief-base update [33, 24] it has also been called *erasure*.) In this section we define its semantics.

In general we might contract by any formula Φ . Here we focus on contraction by one of the three kinds of laws. We therefore suppose that Φ is either φ , where φ is classical, or $\varphi \rightarrow [a]\psi$, or $\varphi \rightarrow \langle a \rangle \top$.

For the case of contracting static laws we resort to existing approaches to change the set of static laws. In the following, we consider any belief change operator like Forbus’ update method [9], the possible models approach [33, 34], WSS [14] or MPMA [6].

Contraction by φ corresponds to adding new possible worlds to W . Let \ominus be a given contraction operator for classical logic.

Definition 4 Let $\langle W, R \rangle$ be a K_n -model and φ a classical formula. The model resulting from contracting by φ is $\langle W, R \rangle_{\varphi}^- = \{\langle W', R' \rangle\}$ such that $W' = W \ominus val(\varphi)$.

Observe that R should, a priori, change as well, otherwise contracting a classical formula may conflict with \mathcal{X} .² For instance, if $\neg \varphi \rightarrow \langle a \rangle \top \in \mathcal{X}$ and we contract by φ , the result may make \mathcal{X} untrue. However, given the amount of information we have at hand, we think that whatever we do with R (adding or removing edges), we will always be able to find a counter-example to the intuitiveness of the operation, since it is domain dependent. For instance, adding edges for a deterministic action may render it nondeterministic. Deciding on what changes to carry out on R when contracting static laws depends on the user’s intuition, and unfortunately this information cannot be generalized and established once for all. We here opt for a priori doing nothing with R and postponing correction of executability laws.

Action theories being defined in terms of effect and executability laws, elaborating an action theory will mainly involve changes in these two sets of laws. Let us consider now both these cases.

Suppose the knowledge engineer acquires new information regarding the effect of action a . Then it means that the law under consideration is probably too strong, i.e., the expected effect may not occur and thus the law has to be weakened. Consider e.g. $\neg up \rightarrow [toggle]light$, and suppose it has to be weakened to the more specific $(\neg up \wedge \neg blackout) \rightarrow [toggle]light$.³ In order to carry out such a weakening, first the designer has to contract the set of effect laws and second to expand the resulting set with the weakened law.

Contraction by $\varphi \rightarrow [a]\psi$ amounts to adding some ‘counterexample’ arrows from φ -worlds to $\neg \psi$ -worlds. To ease such a task, we need a definition. Let $PI(\varphi)$ denote the set of prime implicants of φ . If $\varphi_1, \varphi_2 \in \mathfrak{Fml}$, $NewCons_{\varphi_1}(\varphi_2) = PI(\varphi_1 \wedge \varphi_2) \setminus PI(\varphi_1)$ computes the new consequences of φ_2 w.r.t. φ_1 : the set of strongest clauses that follow from $\varphi_1 \wedge \varphi_2$, but do not follow from φ_1 alone (cf. e.g. [20]). For example, the set of prime implicants of p_1 is just $\{p_1\}$, that of $p_1 \wedge (\neg p_1 \vee p_2) \wedge (\neg p_1 \vee p_3 \vee p_4)$ is $\{p_1, p_2, p_3 \vee p_4\}$, hence $NewCons_{p_1}((\neg p_1 \vee p_2) \wedge (\neg p_1 \vee p_3 \vee p_4)) = \{p_2, p_3 \vee p_4\}$.

Definition 5 Let $\langle W, R \rangle$ be a K_n -model and $\varphi \rightarrow [a]\psi$ an effect law. The set of models that result from contracting by $\varphi \rightarrow [a]\psi$ is $\langle W, R \rangle_{\varphi \rightarrow [a]\psi}^- = \{\langle W, R \cup R'_a \rangle : R'_a \subseteq \{(w, w') : \models_w^{(W, R)} \varphi, \models_{w'}^{(W, R)} \neg \psi \text{ and } w' \setminus w \subseteq lit(NewCons_{\varphi}(\neg \psi))\}\}$.

In our context, $w' \setminus w \subseteq lit(NewCons_{\varphi}(\neg \psi))$ means that for all the added arrows, the new/extraneous effects of action a are limited to

² We are indebted to the anonymous referees for pointing this out to us.

³ Replacing the law by $\neg up \rightarrow [toggle](light \vee \neg light)$ looks silly.

the consequences of the static laws combined with $\neg\psi$, i.e., all the ramifications that action a can produce.

Suppose now the knowledge engineer learns new information about the executability of a . This usually occurs when some executabilities are too strong, i.e., the condition in the theory guaranteeing the executability of a is too weak and should be made more restrictive. Let e.g. $\langle \text{toggle} \rangle \top$ be the law to be contracted, and suppose it has to be weakened to the more specific $\neg\text{broken} \rightarrow \langle \text{toggle} \rangle \top$. To do that, the designer first contracts the executability laws and then expands the resulting set with the weakened law.

Contraction by $\varphi \rightarrow \langle a \rangle \top$ corresponds to removing some arrows leaving worlds where φ holds. Removing such arrows has as consequence that a is no longer always executable in context φ .

Definition 6 Let $\langle W, R \rangle$ be a K_n -model and $\varphi \rightarrow \langle a \rangle \top$ an executability law. The set of models that result from the contraction by $\varphi \rightarrow \langle a \rangle \top$ is $\langle W, R \rangle_{\varphi \rightarrow \langle a \rangle \top}^- = \{ \langle W, R' \rangle : R' = R \setminus R_a'', R_a'' \subseteq \{(w, w') : wR_a w' \text{ and } \models_w^{\langle W, R \rangle} \varphi\} \}$.

4 CONTRACTING AN ACTION THEORY

Having established the semantics of action theory contraction, we can turn to its syntactical counterpart. Nevertheless, before doing that we have to consider an important issue. As the reader might have expected, K_n alone does not solve the frame problem. For instance,

$$\left\{ \begin{array}{l} up \rightarrow light, \neg up \rightarrow [\text{toggle}]up, \\ up \rightarrow [\text{toggle}] \neg up, \langle \text{toggle} \rangle \top \end{array} \right\} \not\models_{K_n} \text{broken} \rightarrow [\text{toggle}] \text{broken}.$$

We need thus a consequence relation powerful enough to deal with the frame and ramification problems. Hence the deductive power of K_n has to be augmented to ensure that all the relevant frame axioms apply. Following the framework developed in [2], we consider metalogical information given in the form of dependence:

Definition 7 (Dependence relation [2]) A dependence relation is a binary relation $\rightsquigarrow \subseteq \mathfrak{Act} \times \mathfrak{Lit}$.

The expression $a \rightsquigarrow l$ denotes that the execution of action a may change the truth value of the literal l . On the other hand, $\langle a, l \rangle \notin \rightsquigarrow$ (written $a \not\rightsquigarrow l$) means that l can never be caused by a . In our example we have $\text{toggle} \rightsquigarrow light$ and $\text{toggle} \rightsquigarrow \neg light$, which means that action toggle may cause a change in literals $light$ and $\neg light$. We do not have $\text{toggle} \rightsquigarrow \neg broken$, for toggling the switch never repairs it.

Definition 8 A model of a dependence relation \rightsquigarrow is a K_n -model \mathcal{M} such that $\models^{\mathcal{M}} \{ \neg l \rightarrow [a] \neg l : a \not\rightsquigarrow l \}$.

We assume \rightsquigarrow is finite. Given a dependence relation \rightsquigarrow , the associated consequence relation in the set of models for \rightsquigarrow is noted $\models_{\rightsquigarrow}$. For our example we obtain

$$\left\{ \begin{array}{l} up \rightarrow light, \neg up \rightarrow [\text{toggle}]up, \\ up \rightarrow [\text{toggle}] \neg up, \langle \text{toggle} \rangle \top \end{array} \right\} \models_{\rightsquigarrow} \text{broken} \rightarrow [\text{toggle}] \text{broken}.$$

We have $\text{toggle} \not\rightsquigarrow \neg broken$, i.e., $\neg broken$ is never caused by toggle . Hence in all contexts where $broken$ is true, after every execution of toggle , $broken$ still remains true. This independence means that the frame axiom $\text{broken} \rightarrow [\text{toggle}] \text{broken}$ is valid in the models of \rightsquigarrow .

Such a dependence-based approach has been shown [5] to subsume Reiter's solution to the frame problem [30] and moreover treats the ramification problem, even when actions with both indeterminate and indirect effects are involved [3, 16].

Definition 9 An action theory is a tuple of the form $\langle \mathcal{S}, \mathcal{E}, \mathcal{X}, \rightsquigarrow \rangle$.

In our running example, the corresponding action theory is

$$\mathcal{S} = \{ up \rightarrow light \}, \mathcal{E} = \{ \neg up \rightarrow [\text{toggle}]up, up \rightarrow [\text{toggle}] \neg up \}$$

$$\mathcal{X} = \{ \langle \text{toggle} \rangle \top \}, \rightsquigarrow = \left\{ \begin{array}{l} \langle \text{toggle}, light \rangle, \langle \text{toggle}, \neg light \rangle, \\ \langle \text{toggle}, up \rangle, \langle \text{toggle}, \neg up \rangle \end{array} \right\}$$

And we have $\mathcal{S}, \mathcal{E}, \mathcal{X} \models_{\rightsquigarrow} \neg up \rightarrow [\text{toggle}] light$. (For parsimony's sake, we write $\mathcal{S}, \mathcal{E}, \mathcal{X} \models_{\rightsquigarrow} \Phi$ instead of $\mathcal{S} \cup \mathcal{E} \cup \mathcal{X} \models_{\rightsquigarrow} \Phi$.)

Let $\langle \mathcal{S}, \mathcal{E}, \mathcal{X}, \rightsquigarrow \rangle$ be an action theory and Φ a K_n -formula. $\langle \mathcal{S}, \mathcal{E}, \mathcal{X}, \rightsquigarrow \rangle_{\Phi}^-$ denotes the action theory resulting from the contraction of $\langle \mathcal{S}, \mathcal{E}, \mathcal{X}, \rightsquigarrow \rangle$ by Φ .

Contracting a theory by a static law φ amounts to using any existing contraction operator for classical logic. Let \ominus be such an operator. Moreover, based on [19], we also need to guarantee that φ does not follow from \mathcal{E} , \mathcal{X} and \rightsquigarrow . We define contraction of a domain description by a static law as follows:

Definition 10 $\langle \mathcal{S}, \mathcal{E}, \mathcal{X}, \rightsquigarrow \rangle_{\varphi}^- = \langle \mathcal{S}^-, \mathcal{E}^-, \mathcal{X}^-, \rightsquigarrow \rangle$, where $\mathcal{S}^- = \mathcal{S} \ominus \varphi$ and $\mathcal{X}^- = \{ (\varphi_i \wedge \varphi) \rightarrow \langle a \rangle \top : \varphi_i \rightarrow \langle a \rangle \top \in \mathcal{X} \}$.

We now consider contraction by an executability law $\varphi \rightarrow \langle a \rangle \top$. For every executability in \mathcal{X} , we ensure that a is executable only in contexts where $\neg\varphi$ is true. The following operator does the job.

Definition 11 $\langle \mathcal{S}, \mathcal{E}, \mathcal{X}, \rightsquigarrow \rangle_{\varphi \rightarrow \langle a \rangle \top}^- = \langle \mathcal{S}, \mathcal{E}^-, \mathcal{X}^-, \rightsquigarrow \rangle$, where $\mathcal{X}^- = \{ (\varphi_i \wedge \neg\varphi) \rightarrow \langle a \rangle \top : \varphi_i \rightarrow \langle a \rangle \top \in \mathcal{X} \}$.

For instance, contracting $glued \rightarrow \langle \text{toggle} \rangle \top$ in our example would give us $\mathcal{X}^- = \{ \neg glued \rightarrow \langle \text{toggle} \rangle \top \}$.

Finally, to contract a theory by $\varphi \rightarrow [a]\psi$, for every effect law in \mathcal{E} , we first ensure that a still has effect ψ whenever φ does not hold, second we enforce that a has no effect in context $\neg\varphi$ except on those literals that are consequences of $\neg\psi$. Combining this with the new dependence relation also linking a to literals involved by $\neg\psi$, we have that a may now produce $\neg\psi$ as outcome. In other words, the effect law has been contracted. The operator below formalizes this:

Definition 12 $\langle \mathcal{S}, \mathcal{E}, \mathcal{X}, \rightsquigarrow \rangle_{\varphi \rightarrow [a]\psi}^- = \langle \mathcal{S}, \mathcal{E}^-, \mathcal{X}^-, \rightsquigarrow^- \rangle$, where $\rightsquigarrow^- = \rightsquigarrow \cup \{ \langle a, l \rangle : l \in \text{lit}(\text{NewCons}_{\mathcal{S}}(\neg\psi)) \}$ and $\mathcal{E}^- = \{ (\varphi_i \wedge \neg\varphi) \rightarrow [a]\psi : \varphi_i \rightarrow [a]\psi \in \mathcal{E} \} \cup \{ (\neg\varphi \wedge \neg l) \rightarrow [a]\neg l : \langle a, l \rangle \in (\rightsquigarrow^- \setminus \rightsquigarrow) \}$.

For instance, contracting the law $blackout \rightarrow [\text{toggle}] light$ from our theory would give us $\mathcal{E}^- = \{ (\neg up \wedge \neg blackout) \rightarrow [\text{toggle}]up, (up \wedge \neg blackout) \rightarrow [\text{toggle}] \neg up \}$.

5 RESULTS

We here present the main results that follow from our framework. These require the action theory under analysis to be modular [19]. An action theory is modular if a formula of a given type entailed by the whole theory can also be derived solely from its respective module (the set of formulas of the same type) with the static laws \mathcal{S} . As shown in [19], to make a domain description satisfy such a property it is enough to guarantee that there is no classical formula entailed by the theory that is not entailed by the static laws alone.

Definition 13 (Implicit static law [17]) $\varphi \in \mathfrak{Fml}$ is an implicit static law of $\langle \mathcal{S}, \mathcal{E}, \mathcal{X}, \rightsquigarrow \rangle$ if and only if $\mathcal{S}, \mathcal{E}, \mathcal{X} \models_{\rightsquigarrow} \varphi$ and $\mathcal{S} \not\models \varphi$.

A theory is *modular* if it has no implicit static laws. Modularity of theories was originally defined in [19], but similar notions have also been addressed in the literature [4, 1, 35, 25]. A modularity-based approach for narrative reasoning about actions is given in [22].

To witness how implicit static laws can show up, consider the simple theory below, depicting the walking turkey scenario [32]:

$$\begin{aligned} \mathcal{S} &= \{\text{walking} \rightarrow \text{alive}\}, \quad \mathcal{E} = \left\{ \begin{array}{l} [\text{tease}]\text{walking}, \\ \text{loaded} \rightarrow [\text{shoot}] \neg \text{alive} \end{array} \right\} \\ \mathcal{X} &= \left\{ \begin{array}{l} \langle \text{tease} \rangle \top, \\ \langle \text{shoot} \rangle \top \end{array} \right\}, \quad \rightsquigarrow = \left\{ \begin{array}{l} \langle \text{shoot}, \neg \text{loaded} \rangle, \langle \text{shoot}, \neg \text{alive} \rangle, \\ \langle \text{shoot}, \neg \text{walking} \rangle, \langle \text{tease}, \text{walking} \rangle \end{array} \right\} \end{aligned}$$

With this description we have $\mathcal{S}, \mathcal{E}, \mathcal{X} \models_{\rightsquigarrow} \text{alive}$.⁴ As $\mathcal{S} \not\models \text{alive}$, the formula *alive* is an implicit static law of $\langle \mathcal{S}, \mathcal{E}, \mathcal{X}, \rightsquigarrow \rangle$.

Modular theories have several advantages [17, 15]. For example, consistency of a modular action theory can be checked by just checking consistency of \mathcal{S} : if $\langle \mathcal{S}, \mathcal{E}, \mathcal{X}, \rightsquigarrow \rangle$ is modular, then $\mathcal{S}, \mathcal{E}, \mathcal{X} \models_{\rightsquigarrow} \perp$ if and only if $\mathcal{S} \models \perp$. Deduction of an effect of a sequence of actions $a_1; \dots; a_n$ (prediction) needs not to take into account the effect laws for actions other than a_1, \dots, a_n . This applies in particular to plan validation when deciding whether $\langle a_1; \dots; a_n \rangle \varphi$ is the case.

Throughout this work we use multimodal logic K_n . For an assessment of the modularity principle in the Situation Calculus, see [18].

Here we show that our operators are correct w.r.t. the semantics. The first theorem establishes that the semantical contraction of models of $\langle \mathcal{S}, \mathcal{E}, \mathcal{X}, \rightsquigarrow \rangle$ by Φ produces models of $\langle \mathcal{S}, \mathcal{E}, \mathcal{X}, \rightsquigarrow \rangle_{\Phi}^-$.

Theorem 1 Let $\langle W, R \rangle$ be a model of $\langle \mathcal{S}, \mathcal{E}, \mathcal{X}, \rightsquigarrow \rangle$, and let Φ be a formula that has the form of one of the three laws. For all models \mathcal{M} , if $\mathcal{M} \in \langle W, R \rangle_{\Phi}^-$, then \mathcal{M} is a model of $\langle \mathcal{S}, \mathcal{E}, \mathcal{X}, \rightsquigarrow \rangle_{\Phi}^-$.

It remains to prove that the other way round, the models of $\langle \mathcal{S}, \mathcal{E}, \mathcal{X}, \rightsquigarrow \rangle_{\Phi}^-$ result from the semantical contraction of models of $\langle \mathcal{S}, \mathcal{E}, \mathcal{X}, \rightsquigarrow \rangle$ by Φ . This does not hold in general, as shown by the following example: suppose there is only one atom p and one action a , and consider the theory $\langle \mathcal{S}, \mathcal{E}, \mathcal{X}, \rightsquigarrow \rangle$ such that $\mathcal{S} = \emptyset$, $\mathcal{E} = \{p \rightarrow [a] \perp\}$, $\mathcal{X} = \{\langle a \rangle \top\}$, and $\rightsquigarrow = \emptyset$. The only model of that action theory is $\mathcal{M} = \langle \{\{\neg p\}\}, \{\{\neg p\}, \{\neg p\}\} \rangle$. By definition, $\mathcal{M}_{p \rightarrow \langle a \rangle \top}^- = \{\mathcal{M}\}$. On the other hand, $\langle \mathcal{S}, \mathcal{E}, \mathcal{X}, \rightsquigarrow \rangle_{p \rightarrow \langle a \rangle \top}^- = \langle \emptyset, \{p \rightarrow [a] \perp\}, \{\neg p \rightarrow \langle a \rangle \top\}, \emptyset \rangle$. The contracted theory has two models: \mathcal{M} and $\mathcal{M}' = \langle \{\{p\}\}, \{\neg p\}, \{\{\neg p\}, \{\neg p\}\} \rangle$. While $\neg p$ is valid in the contraction of the models of $\langle \mathcal{S}, \mathcal{E}, \mathcal{X}, \rightsquigarrow \rangle$, it is invalid in the models of $\langle \mathcal{S}, \mathcal{E}, \mathcal{X}, \rightsquigarrow \rangle_{p \rightarrow \langle a \rangle \top}^-$.

Fortunately, we can establish a result for those action theories that are modular. The proof requires three lemmas. The first one says that for a modular theory we can restrict our attention to its ‘big’ models.

Lemma 1 Let $\langle \mathcal{S}, \mathcal{E}, \mathcal{X}, \rightsquigarrow \rangle$ be modular. Then $\mathcal{S}, \mathcal{E}, \mathcal{X} \models_{\rightsquigarrow} \Phi$ if and only if $\models_{\langle W, R \rangle}^{\langle \mathcal{S}, \mathcal{E}, \mathcal{X}, \rightsquigarrow \rangle} \Phi$ for every model $\langle W, R \rangle$ of $\langle \mathcal{S}, \mathcal{E}, \mathcal{X}, \rightsquigarrow \rangle$ such that $W = \text{val}(\mathcal{S})$.

Note that the lemma does not hold for non-modular theories (the set $\{\langle W, R \rangle : \langle W, R \rangle$ is a model of $\langle \mathcal{S}, \mathcal{E}, \mathcal{X}, \rightsquigarrow \rangle$ and $W = \text{val}(\mathcal{S})\}$ is empty then).

The second lemma says that contraction preserves modularity.

⁴ Because first $\{\text{walking} \rightarrow \text{alive}, [\text{tease}]\text{walking}\} \models_{\rightsquigarrow} [\text{tease}]\text{alive}$, second $\models_{\rightsquigarrow} \neg \text{alive} \rightarrow [\text{tease}] \neg \text{alive}$ (from the independence $\text{tease} \not\rightsquigarrow \text{alive}$), and then $\mathcal{S}, \mathcal{E} \models_{\rightsquigarrow} \neg \text{alive} \rightarrow [\text{tease}] \perp$. As long as $\mathcal{S}, \mathcal{E}, \mathcal{X} \models_{\rightsquigarrow} \langle \text{tease} \rangle \top$, we must have $\mathcal{S}, \mathcal{E}, \mathcal{X} \models_{\rightsquigarrow} \text{alive}$.

Lemma 2 Let $\langle \mathcal{S}, \mathcal{E}, \mathcal{X}, \rightsquigarrow \rangle$ be modular, and let Φ be a formula of the form of one of the three laws. Then $\langle \mathcal{S}, \mathcal{E}, \mathcal{X}, \rightsquigarrow \rangle_{\Phi}^-$ is modular.

The third one establishes the required link between the contraction operators and contraction of ‘big’ models.

Lemma 3 Let $\langle \mathcal{S}, \mathcal{E}, \mathcal{X}, \rightsquigarrow \rangle$ be modular, and let Φ be a formula of the form of one of the three laws. If $\mathcal{M}' = \langle \text{val}(\mathcal{S}), R' \rangle$ is a model of $\langle \mathcal{S}, \mathcal{E}, \mathcal{X}, \rightsquigarrow \rangle_{\Phi}^-$, then there is a model \mathcal{M} of $\langle \mathcal{S}, \mathcal{E}, \mathcal{X}, \rightsquigarrow \rangle$ such that $\mathcal{M}' \in \mathcal{M}_{\Phi}^-$.

Putting the three above lemmas together we get:

Theorem 2 Let $\langle \mathcal{S}, \mathcal{E}, \mathcal{X}, \rightsquigarrow \rangle$ be modular, Φ be a formula of the form of one of the three laws, and $\langle \mathcal{S}^-, \mathcal{E}^-, \mathcal{X}^-, \rightsquigarrow^- \rangle$ be $\langle \mathcal{S}, \mathcal{E}, \mathcal{X}, \rightsquigarrow \rangle_{\Phi}^-$. If $\mathcal{S}^-, \mathcal{E}^-, \mathcal{X}^- \models_{\rightsquigarrow^-} \Psi$, then for every model \mathcal{M} of $\langle \mathcal{S}, \mathcal{E}, \mathcal{X}, \rightsquigarrow \rangle$ and every $\mathcal{M}' \in \mathcal{M}_{\Phi}^-$ it holds that $\models^{\mathcal{M}'} \Psi$.

Our two theorems together establish correctness of the operators:

Corollary 1 Let $\langle \mathcal{S}, \mathcal{E}, \mathcal{X}, \rightsquigarrow \rangle$ be modular, Φ be a formula of the form of one of the three laws, and $\langle \mathcal{S}^-, \mathcal{E}^-, \mathcal{X}^-, \rightsquigarrow^- \rangle$ be $\langle \mathcal{S}, \mathcal{E}, \mathcal{X}, \rightsquigarrow \rangle_{\Phi}^-$. Then $\mathcal{S}^-, \mathcal{E}^-, \mathcal{X}^- \models_{\rightsquigarrow^-} \Psi$ if and only if for every model \mathcal{M} of $\langle \mathcal{S}, \mathcal{E}, \mathcal{X}, \rightsquigarrow \rangle$ and every $\mathcal{M}' \in \mathcal{M}_{\Phi}^-$, $\models^{\mathcal{M}'} \Psi$.

We give a sufficient condition for contraction to be successful.

Theorem 3 Let Φ be an effect or an executability law such that $\mathcal{S} \not\models_{K_n} \Phi$, and let $\langle \mathcal{S}^-, \mathcal{E}^-, \mathcal{X}^-, \rightsquigarrow^- \rangle$ be $\langle \mathcal{S}, \mathcal{E}, \mathcal{X}, \rightsquigarrow \rangle_{\Phi}^-$. If $\langle \mathcal{S}, \mathcal{E}, \mathcal{X}, \rightsquigarrow \rangle$ is modular, then $\mathcal{S}^-, \mathcal{E}^-, \mathcal{X}^- \not\models_{\rightsquigarrow^-} \Phi$.

6 DISCUSSION AND CONCLUSION

In this work we have presented a general method for changing a domain description (alias action theory) given any formula we want to contract. We have defined a semantics for theory contraction and also presented its syntactical counterpart through contraction operators. Soundness and completeness of such operators with respect to the semantics have been established (Corollary 1).

We have also shown that modularity is a sufficient condition for a contraction to be successful (Theorem 3). This gives further evidence that the notion of modularity is fruitful.

What is the status of the AGM-postulates for contraction in our framework? First, contraction of static laws satisfies all the postulates, as soon as the underlying classical contraction operation \ominus satisfies all of them.

In the general case, however, our constructions do not satisfy the central postulate of preservation $\langle \mathcal{S}, \mathcal{E}, \mathcal{X}, \rightsquigarrow \rangle_{\Phi}^- = \langle \mathcal{S}, \mathcal{E}, \mathcal{X}, \rightsquigarrow \rangle$ if $\mathcal{S}, \mathcal{E}, \mathcal{X} \not\models_{\rightsquigarrow} \Phi$. Indeed, suppose we have only one atom p , and a model \mathcal{M} with two worlds $w = \{p\}$ and $w' = \{\neg p\}$ such that $wR_a w'$, $w'R_a w$, and $w'R_a w'$. Then $\models^{\mathcal{M}} p \rightarrow [a] \neg p$ and $\not\models^{\mathcal{M}} [a] \neg p$, i.e., \mathcal{M} is a model of the effect law $p \rightarrow [a] \neg p$, but not of $[a] \neg p$. Now the contraction $\mathcal{M}_{[a] \neg p}^-$ yields the model \mathcal{M}' such that $R_a = W \times W$. Then $\not\models^{\mathcal{M}'} p \rightarrow [a] \neg p$, i.e., the effect law $p \rightarrow [a] \neg p$ is not preserved. Our contraction operation thus behaves rather like an update operation.

Now let us focus on the other postulates. Since our operator has a behavior which is close to the update postulate, we focus on the following basic erasure postulates introduced in [23]. Let $Cn(\mathcal{T})$ be the set of all logical consequences of a theory \mathcal{T} .

$$\mathbf{KM1} \ Cn(\langle S, E, X, \sim \rangle_{\Phi}^-) \subseteq Cn(\langle S, E, X, \sim \rangle)$$

Postulate **KM1** does not always hold because it is possible to make the formula $\varphi \rightarrow [a]\perp$ valid in the resulting theory by removing elements of R_a (cf. Definition 6).

$$\mathbf{KM2} \ \Phi \notin Cn(\langle S, E, X, \sim \rangle_{\Phi}^-)$$

Under the condition that $\langle S, E, X, \sim \rangle$ is modular, Postulate **KM2** is satisfied (cf. Theorem 3).

$$\mathbf{KM3} \text{ If } Cn(\langle S_1, E_1, X_1, \sim_1 \rangle) = Cn(\langle S_2, E_2, X_2, \sim_2 \rangle) \text{ and } \vdash_{\mathcal{R}_n} \Phi_1 \leftrightarrow \Phi_2, \text{ then } Cn(\langle S_1, E_1, X_1, \sim_1 \rangle_{\Phi_2}^-) = Cn(\langle S_2, E_2, X_2, \sim_2 \rangle_{\Phi_1}^-).$$

Theorem 4 If $\langle S_1, E_1, X_1, \sim_1 \rangle$ and $\langle S_2, E_2, X_2, \sim_2 \rangle$ are modular and the propositional contraction operator \ominus satisfies Postulate **KM3**, then Postulate **KM3** is satisfied for every $\Phi_1, \Phi_2 \in \mathfrak{Fml}$.

Following [26, 27], Eiter *et al.* [7] have investigated update of action theories in a fragment of the action description language \mathcal{C} [11] and given complexity results showing how hard such a task can be.

Update of action descriptions in their sense is always relative to some conditions (interpreted as knowledge possibly obtained from earlier observations and that should be kept). This characterizes a constraint-based update, like ours.

Even though they do not explicitly state postulates for their kind of theory update, they establish conditions for the update operator to be successful. Basically, they claim for consistency of the resulting theory; maintenance of the new knowledge and the invariable part of the description; satisfaction of the constraints; and minimal change.

With their method we can also contract by a static and an effect law. Contraction of executabilities are not explicitly addressed.

A main difference between the approach in [7] and ours is that we do not need to add new fluents at every elaboration stage: we still work on the same set of fluents, refining their behavior w.r.t. an action a . In Eiter *et al.*'s proposal an update forces changing all the variable rules appearing in the action theory by adding to each one a new update fluent. This is a constraint when elaborating action theories.

Here we have presented the case for contraction, but our definitions can be extended to revision, too. Our results can also be generalized to the case where learning new actions or fluents is involved. This means in general that more than one simple formula should be added to the belief base and must fit together with the rest of the theory with as little side-effects as possible. We are currently defining algorithms based on our operators to achieve that.

On the Logic of Theory Change: Relations between Incision and Selection Functions

Marcelo A. Falappa¹ and Eduardo L. Fermé² and Gabriele Kern-Isbner³

Abstract. This work elaborates on the connection between partial meet contractions and kernel contractions in belief change theory. We present a way to define incision functions (used in kernel contractions) from selection functions (used in partial meet contractions) and vice versa. Then we make precise under which conditions there are exact correspondences between selection and incision functions so that the same contraction operations can be obtained by using either of them.

Key Words: Belief Revision, AGM Theory, Partial Meet Contractions, Kernel Contractions.

1 Introduction

Belief revision systems are logical frameworks for modelling the dynamics of knowledge, that is, how agents modify their beliefs when they receive new information. The main problem arises when that information is inconsistent with the beliefs that the agent holds in its epistemic state. In order to accept the new information, the agent will have to give up some information while preserving as much of the old information as possible.

The AGM-framework [1] is the most popular framework to guide the change of belief. It distinguishes between three kinds of changes, namely expansion, contraction and revision. Since expansion deals with a simple case of revision, and revision can be based on contraction, the contraction operators are considered to be particularly interesting. Basically, AGM contractions can be realized by *partial meet contractions*, which are based on a selection among subsets of the original set that do not imply the information to be retracted via so-called *selection functions*. On the other hand, *kernel contractions* [8] are based on a selection among the sentences that are relevant to derive the sentence to be retracted. In order to perform a contraction, kernel contractions use *incision functions* which cut into the minimal subsets that imply the information to be given up.

There are other change operators, which also can be defined in similar ways by making use of selection or incision functions, respectively: For instance, a *consolidation* [9] that makes a contraction of a set of sentences by a contradiction; a *semi-revision* [9] that allows a non-prioritized revision of a set of sentences by a single sentence, and a *revision by sets of sentences* [6, 7] that makes a non-prioritized revision of a set of sentences by a set of sentences. In all these cases, every partial meet operator is a kernel operator, but not vice versa.

In this paper, we elaborate the relation between partial meet and kernel contraction in more depth. Since every partial meet operator is defined in terms of a selection function and every kernel operator is defined in terms of an incision function, we investigate in particular, how these functions can be related to one another more clearly. We show how incision functions can be obtained from selection functions and vice versa. In this way, bidirectional mappings between these two kinds of functions are given by which partial meet and kernel contractions can be directly related. As the main results of this paper, we make precise under which conditions applying one mapping after the other yields the identical contraction operator (more exactly, the identical selection or incision function, respectively).

The main focus of this paper is on changing *belief bases*, for several reasons. First, since handling belief sets (*i.e.*, deductively closed sets of sentences) is computationally not feasible, taking finite or countable belief bases as convenient representations of beliefs is much more natural for practical implementations of belief revision. Second, making use of belief bases allows for distinguishing between explicitly represented beliefs and implicitly derived beliefs; so, we do not insist on the *principle of irrelevance of syntax*. Considering belief bases can even help distinguishing between different inconsistent belief sets. And finally, for belief bases, kernel contractions and partial meet contractions are more loosely connected than for belief sets, so studying the links between both types of revision operations is more rewarding. On the other hand, kernel contractions on belief bases can be, in a sense, related to truth maintenance systems and to argumentation systems [3, 4, 5, 11].

The organization of this paper is as follows: In section 2, we briefly recall the basic definitions of partial meet and kernel contraction the relations between which we start to investigate in section 3. Sections 4 and 5 show how to define incision functions from selection functions and vice versa. After that, the grounds are laid to tighten these bands by revealing exact correspondences between partial meet and kernel contractions in section 6. We summarize our results in 7.

2 Different kinds of contraction

In the following, let K be a set of sentences of a propositional language \mathcal{L} which represents the knowledge base of an intelligent agent. We will recall some facts about the two kinds of contraction which are in the focus of this paper.

2.1 Partial meet contractions

Partial meet contractions are exactly the basic AGM-contractions. They are based on the concept of a remainder set.

³ Department of Computer Science, University of Dortmund, Dortmund, Germany, email: gabriele.kern-isbner@cs.uni-dortmund.de

Definition 1 ([2]) Let K be a set of sentences and α a sentence. Then $K^\perp\alpha$ is the set of all H such that $H \subseteq K$, $H \not\models \alpha$ and if $H \subset K' \subseteq K$, $H \neq K'$, then $K' \vdash \alpha$. The set $K^\perp\alpha$ is called the remainder set of K with respect to α , and its elements are called the α -remainders of K .

In order to define a partial meet contraction operator, we need a selection function. This function makes a selection among the α -remainders, choosing those candidate sets for contraction which are preferred in some sense.

Definition 2 Let K be a set of sentences. A selection function for K is a function “ γ ” ($\gamma : 2^{\mathcal{L}} \Rightarrow 2^{\mathcal{L}}$) such that for any sentence $\alpha \in \mathcal{L}$, it holds that:

- 1) If $K^\perp\alpha \neq \emptyset$, then $\gamma(K^\perp\alpha)$ is a non-empty subset of $K^\perp\alpha$.
- 2) If $K^\perp\alpha = \emptyset$, then $\gamma(K^\perp\alpha) = K$.

Definition 3 Given a set of sentences K , a sentence α and a selection function γ for K , the partial meet contraction of K by α , denoted by $K \dot{\div}_\gamma \alpha$, is defined as:

$$K \dot{\div}_\gamma \alpha = \cap \gamma(K^\perp\alpha)$$

If γ selects a single element, then the induced contraction is called a maxichoice contraction.

That is, $K \dot{\div}_\gamma \alpha$ is equal to the intersection of the α -remainders of K selected by γ .

Obviously, for each $H \in \gamma(K^\perp\alpha)$, we have $\cap \gamma(K^\perp\alpha) \subseteq H$. Selection functions which cover all of these remainder sets are called complete.

Definition 4 ([1]) A partial meet selection function γ on K is complete iff whenever $\cap \gamma(K^\perp\alpha) \subseteq H$ for $H \in K^\perp\alpha$, then $H \in \gamma(K^\perp\alpha)$.

Important examples for belief bases that give rise to complete selection functions, are belief sets (i.e., $K = Cn(K)$).

Proposition 1 ([1]) If the language \mathcal{L} is finite and K is a belief set, then any selection function γ on K is complete.

2.2 Kernel contractions

Kernel sets are those subsets of the knowledge base which are relevant for the information to be contracted.

Definition 5 ([8]) Let K be a set of sentences and α a sentence. Then $K^\perp\alpha$ is the set of all X such that $X \subseteq K$, $X \vdash \alpha$, and if $K' \subset X$, then $K' \not\models \alpha$. The set $K^\perp\alpha$ is called the kernel set, and its elements are called the α -kernels of K .

In order to retract some information α from K , we have to give up sentences in each α -kernel. This is done by incision functions.

Definition 6 Let K be a set of sentences. An incision function for K is a function “ σ ” ($\sigma : 2^{\mathcal{L}} \Rightarrow 2^{\mathcal{L}}$) such that for any sentence $\alpha \in \mathcal{L}$, the following hold:

- 1) $\sigma(K^\perp\alpha) \subseteq \cup(K^\perp\alpha)$.
 - 2) If $X \in K^\perp\alpha$ and $X \neq \emptyset$ then $(X \cap \sigma(K^\perp\alpha)) \neq \emptyset$.
- In the limit case when $K^\perp\alpha = \emptyset$ then $\sigma(K^\perp\alpha) = \emptyset$.

So, incision functions cut into each α -kernel, removing at least one sentence. Since all α -kernels are minimal subsets implying α , from the resulting sets it is no longer possible to derive α . Hence, incision functions may be used to derive contraction operations.

Definition 7 Given a set of sentences K , a sentence α and an incision function σ for K , the kernel contraction of K by α , denoted by $K \dot{\div}_\sigma \alpha$, is defined as:

$$K \dot{\div}_\sigma \alpha = K \setminus \sigma(K^\perp\alpha)$$

That is, $K \dot{\div}_\sigma \alpha$ can be obtained by erasing from K the sentences cut out by σ .

As Hansson observed [10], kernel operators are a very general class of contraction operators, and it is easy to find examples in which the behavior of kernel operations are not at all intuitively plausible. For instance, let p and q be two logically independent sentences, and let:

$$K = \{p, p \vee q, p \leftrightarrow q\}.$$

Then we have that:

$$K^\perp(p \wedge q) = \{\{p, p \leftrightarrow q\}, \{p \vee q, p \leftrightarrow q\}\}.$$

Suppose that $\sigma(K^\perp(p \wedge q)) = \{p \vee q, p \leftrightarrow q\}$. This gives rise to an operator of contraction such that:

$$K \dot{\div}_\sigma(p \wedge q) = K \setminus \sigma(K^\perp(p \wedge q)) = \{p\}.$$

It does not seem sensible for $p \vee q$ to be given up here. Since p was not given up, $p \vee q$ is implied by the contracted set $K \dot{\div}_\sigma(p \wedge q)$. The exclusion of $p \vee q$ was unnecessary, and it violates the basic principle of minimality: nothing should be given up without reason [10].

Therefore, further properties are necessary to improve the well-behavedness of kernel contractions.

Definition 8 ([8, 10]) An incision function σ for a set K is smooth if and only if it holds for all subsets K' of K that: if $K' \vdash \beta$ and $\beta \in \sigma(K^\perp\alpha)$ then $K' \cap \sigma(K^\perp\alpha) \neq \emptyset$.

This property is needed to ensure that a kernel contraction operator $\dot{\div}_\sigma$ satisfies the postulate of relative closure [10]: $K \cap Cn(K \dot{\div}_\sigma \alpha) \subseteq K \dot{\div}_\sigma \alpha$.

3 Relating partial meet and kernel contractions

All partial meet contractions are kernel contractions, but in general, these two types of contractions are different – not every kernel contraction can be realized as a partial meet contraction. Not even smoothness (cf. Definition 8) can guarantee kernel contractions to be the same as partial meet contractions [10]. However, it is well-known that for belief sets, smooth kernel contractions and partial meet contractions coincide (cf. [8]).

A direct link from incision functions to remainder sets can be established by considering minimal incision functions.

Definition 9 An incision function σ for a set K is minimal if no proper subset of $\sigma(K^\perp\alpha)$ defines an incision function.

As the following proposition shows, the cut-ins of minimal incision functions are minimal with respect to at least one α -kernel.

Proposition 2 Let σ be a minimal incision function, and $x \in \sigma(K^\perp\alpha)$. Then there is an $X \in K^\perp\alpha$ such that $X \cap \sigma(K^\perp\alpha) = \{x\}$.

Proof. Assume the contrary: For all $X \in K^{\perp\perp}\alpha$ such that $x \in X$, it holds that $|X \cap \sigma(K^{\perp\perp}\alpha)| > 1$. Then define $\sigma'(K^{\perp\perp}\alpha) = \sigma(K^{\perp\perp}\alpha) \setminus \{x\}$. For $X \in K^{\perp\perp}\alpha$ with $x \notin X$, we have $X \cap \sigma'(K^{\perp\perp}\alpha) = X \cap \sigma(K^{\perp\perp}\alpha) \neq \emptyset$. For $X \in K^{\perp\perp}\alpha$ with $x \in X$, we have $|X \cap \sigma'(K^{\perp\perp}\alpha)| \geq 1$, hence $X \cap \sigma'(K^{\perp\perp}\alpha) \neq \emptyset$. Therefore, σ' is an incision function, which contradicts the presupposition that σ is minimal. \square

It turns out that minimality of incision corresponds to maximality of contraction. First, the following proposition shows that each kernel contraction defined by a minimal incision function satisfies *fullness*:

Fullness: If $\beta \in K$ and $\beta \notin K \div \alpha$ then $((K \div \alpha) \cup \{\beta\}) \vdash \alpha$.

Proposition 3 Let \div_σ be a kernel contraction for K based on an incision function σ . If σ satisfies minimality then \div_σ satisfies fullness.

Proof. Let σ be “minimal”. Let $\beta \in K$ and $\beta \notin K \div \alpha$. It follows by definition of kernel contraction that $\beta \in \sigma(K^{\perp\perp}\alpha)$. Assume by *reductio* that $((K \div \alpha) \cup \{\beta\}) \not\vdash \alpha$. Then $K \setminus (\sigma(K^{\perp\perp}\alpha) \setminus \{\beta\}) \not\vdash \alpha$. Let $\sigma'(K^{\perp\perp}\alpha) = \sigma(K^{\perp\perp}\alpha) \setminus \{\beta\}$. It is easy to prove that σ' is an incision function. Hence, σ is not minimal (absurd). \square

Any operator of kernel contraction satisfies the properties *success*, *inclusion* and *uniformity* (cf. e.g. [10]). Together with *fullness*, these properties characterize *maxichoice contractions* (cf. [10]). So we have the following corollary:

Corollary 1 Let \div_σ be a kernel contraction for K based on an incision function σ . If σ satisfies minimality then \div_σ is a maxichoice contraction for K .

Proposition 4 For all $H \subseteq K$, $H \in K^\perp\alpha$ iff there is a minimal incision function σ such that $H = K \setminus \sigma(K^{\perp\perp}\alpha)$.

Proof. Let $H \in K^\perp\alpha$. Define σ via $\sigma(K^{\perp\perp}\alpha) = K \setminus H$; to be shown: σ is a minimal incision function.

Let $x \in \sigma(K^{\perp\perp}\alpha) = K \setminus H$. Then $H \cup \{x\} \vdash \alpha$, so there is $X \in K^{\perp\perp}\alpha$ such that $X \subseteq H \cup \{x\}$. Then it must be that $x \in X$ (otherwise, we would have $X \subseteq H$), hence $\sigma(K^{\perp\perp}\alpha) \subseteq \bigcup K^{\perp\perp}\alpha$. Now choose $X \in K^{\perp\perp}\alpha$ arbitrarily. Then there must be $x \in X$ with $x \notin H$ (otherwise $X \subseteq H$, a contradiction). Thus $X \cap K \setminus H \neq \emptyset$. So, σ is an incision function. To see that it is minimal, assume there is an incision function σ_1 with $\sigma_1(K^{\perp\perp}\alpha) \subsetneq \sigma(K^{\perp\perp}\alpha) = K \setminus H$. Then $H \subsetneq K \setminus \sigma_1(K^{\perp\perp}\alpha)$, and $K \setminus \sigma_1(K^{\perp\perp}\alpha) \not\vdash \alpha$. This contradicts the maximality of H .

Conversely, let σ be a minimal incision function, and set $H = K \setminus \sigma(K^{\perp\perp}\alpha)$. Then certainly, $H \not\vdash \alpha$. Choose $x \in K$, $x \notin H$ arbitrarily. Then $x \in \sigma(K^{\perp\perp}\alpha)$, and by Proposition 2, there is $X \in K^{\perp\perp}\alpha$ such that $X \cap \sigma(K^{\perp\perp}\alpha) = \{x\}$. Then $X \setminus \{x\} \subseteq K \setminus \sigma(K^{\perp\perp}\alpha) = H$, hence $X \subseteq H \cup \{x\}$, and therefore $H \cup \{x\} \vdash \alpha$. This proves that $H \in K^\perp\alpha$. \square

So, minimal incision functions “generate” the remainder sets of K .

In the rest of this paper, we will study the relationships between these two kinds of contraction operators by investigating how incision functions can be obtained from selection functions and vice versa. The following proposition will prove useful for that purpose.

Proposition 5 ([10]) The following conditions are equivalent:

1. $K^\perp\alpha = K^\perp\beta$.
2. $K^{\perp\perp}\alpha = K^{\perp\perp}\beta$.
3. For all subset H of K : $H \vdash \alpha$ if and only if $H \vdash \beta$.

4 Incision functions from selection functions

We will present a formal definition of an incision function from a selection function.

Definition 10 Let γ be a selection function for a set K . We define an associated incision function σ_γ as:

$$\sigma_\gamma(K^{\perp\perp}\alpha) =_{\text{def}} K \setminus \gamma(K^\perp\alpha)$$

The intuition behind this definition is the following: β is selected by an incision function σ (over the set of α -kernels of K) if and only if β does not belong to some α -remainder of K selected by γ .

Example. Let $K = \{p, r, s, p \rightarrow q, r \rightarrow q, \neg t \rightarrow \neg q\}$. Then $K^\perp q = \{\{p, r, s, \neg t \rightarrow \neg q\}, \{p, s, r \rightarrow q, \neg t \rightarrow \neg q\}, \{s, p \rightarrow q, r \rightarrow q, \neg t \rightarrow \neg q\}, \{r, s, p \rightarrow q, \neg t \rightarrow \neg q\}, \{r, s, p \rightarrow q, \neg t \rightarrow \neg q\}\}$. Suppose that $\gamma(K^\perp q) = \{\{p, r, s, \neg t \rightarrow \neg q\}, \{r, s, p \rightarrow q, \neg t \rightarrow \neg q\}\}$. Then the associated incision function is $\sigma_\gamma(K^{\perp\perp} q) = \sigma_\gamma(\{p, p \rightarrow q\}, \{r, r \rightarrow q\}) = \{p, p \rightarrow q, r \rightarrow q\}$.

We have to prove that indeed, the function σ_γ satisfies the properties of an incision function.

Proposition 6 The function σ_γ presented in Definition 10 is an incision function.

Proof.

1. σ_γ is a well defined function due to Proposition 5.
2. Next, we have to show that $\sigma_\gamma(K^{\perp\perp}\alpha) \subseteq \bigcup(K^{\perp\perp}\alpha)$.
If $\vdash \alpha$, then $K^\perp\alpha = \emptyset$ and it follows by definition of γ that $\gamma(K^\perp\alpha) = \{K\}$. If $K \not\vdash \alpha$ it follows by definition of γ that $\gamma(K^\perp\alpha) = \{K\}$. In both cases $\sigma_\gamma(K^{\perp\perp}\alpha) = \emptyset$ and we are done.
Let $\not\vdash \alpha$ and $K \vdash \alpha$. Then $K \setminus \gamma(K^\perp\alpha) \neq \emptyset$. Let $\delta \in K$ and $\delta \notin \bigcup \gamma(K^\perp\alpha)$ (i.e., $\delta \in \sigma_\gamma(K^{\perp\perp}\alpha)$). Then there exists a $H \in \gamma(K^\perp\alpha)$ such that $\delta \notin H$ and $H \not\vdash \alpha$. Let $H' = H \cup \{\delta\}$. It follows by definition of $K^\perp\alpha$ that $H' \vdash \alpha$. By compactness there exists a minimal subset H'' of H' such that $H'' \vdash \alpha$ and $\delta \in H''$. Hence $H'' \in K^{\perp\perp}\alpha$ and $\delta \in \bigcup(K^{\perp\perp}\alpha)$.
3. Finally, it must be shown that if $X \in K^{\perp\perp}\alpha$ and $X \neq \emptyset$ then $(X \cap \sigma_\gamma(K^{\perp\perp}\alpha)) \neq \emptyset$.
Let $X \in K^{\perp\perp}\alpha$ and $X \neq \emptyset$. Let $\delta \in X$ and assume by *reductio* that $(X \cap \sigma_\gamma(K^{\perp\perp}\alpha)) = \emptyset$. Then by definition of σ_γ , $(X \cap (K \setminus \gamma(K^\perp\alpha))) = \emptyset$. Due to $X \subseteq K$ it follows that $X \subseteq \bigcup \gamma(K^\perp\alpha)$. Let $H \in \gamma(K^\perp\alpha)$. Then $X \subseteq H$ and hence $H \vdash \alpha$ (absurd). \square

5 Selection functions from incision functions

Also, we may define selection functions from incision functions.

Definition 11 Let σ a incision function for a set K . We may define an associated selection function γ_σ on $K^\perp\alpha$ by:

$$\gamma_\sigma(K^\perp\alpha) = \begin{cases} \{H \in K^\perp\alpha : (K \setminus \sigma(K^{\perp\perp}\alpha)) \subseteq H\}, & \text{if } K^\perp\alpha \neq \emptyset \\ \{K\}, & \text{otherwise} \end{cases}$$

Again, we have to show that this definition makes sense, i.e., that indeed, γ_σ fulfills the required properties.

Proposition 7 The function γ_σ presented in Definition 11 is a selection function.

Proof.

1. γ_σ is a well defined function: Suppose that $K^\perp\alpha = K^\perp\beta$. We must show that $\gamma_\sigma(K^\perp\alpha) = \gamma_\sigma(K^\perp\beta)$. By Proposition 5 $K^\perp\alpha = K^\perp\beta$ and the rest follows trivially.
2. By definition, it holds that if $K^\perp\alpha = \emptyset$ then $\gamma_\sigma(K^\perp\alpha) = K$.
3. Again by definition, $\gamma_\sigma(K^\perp\alpha) \subseteq K^\perp\alpha$. Let $K^\perp\alpha \neq \emptyset$; we have to show that $\gamma_\sigma(K^\perp\alpha) \neq \emptyset$, too.. From $K^\perp\alpha \neq \emptyset$, it follows that $\nexists \alpha$. We have two cases:
 - (a) $K \not\nvdash \alpha$. Then $K \in K^\perp\alpha$, and due to $(K \setminus \sigma(K^\perp\alpha)) \subseteq K$ it follows that $K \in \gamma_\sigma(K^\perp\alpha)$.
 - (b) $K \vdash \alpha$. By $(K \setminus \sigma(K^\perp\alpha)) \not\nvdash \alpha$ then there exists $H' \in K^\perp\alpha$ such that $(K \setminus \sigma(K^\perp\alpha)) \subseteq H'$. Hence $H' \in \gamma_\sigma(K^\perp\alpha)$. \square

Please note that this same construction of a selection function from an incision function, as we put it in Definition 11, is used by Hansson in [8] to prove that for belief sets, smooth kernel contractions are the same as partial meet contractions.

6 Bidirectional mappings

Having defined selection functions from incision functions and incision functions from selection functions, we will now investigate when these circles close, *i.e.*, under which conditions we obtain the same function that we started with after going forth and back. We will first consider selection functions.

Proposition 8 *Let γ be a selection function of a set K , σ_γ the incision function defined from γ using the Definition 10, and γ' the selection function defined from σ_γ using the Definition 11, *i.e.*, $\gamma' = \gamma_{\sigma_\gamma}$. Then:*

1. $\gamma(K^\perp\alpha) \subseteq \gamma'(K^\perp\alpha)$.
2. $\cap\gamma'(K^\perp\alpha) = \cap\gamma(K^\perp\alpha)$.

Proof. By definition, we have

$$\begin{aligned} \gamma'(K^\perp\alpha) &= \{H \in K^\perp\alpha : K \setminus \sigma_\gamma(K^\perp\alpha) \subseteq H\} \\ &= \{H \in K^\perp\alpha : K \setminus (K \setminus \cap\gamma(K^\perp\alpha)) \subseteq H\} \\ &= \{H \in K^\perp\alpha : \cap\gamma(K^\perp\alpha) \subseteq H\} \end{aligned} \quad (1)$$

1. Let $H' \in \gamma(K^\perp\alpha)$. Then $\cap\gamma(K^\perp\alpha) \subseteq H'$. Hence $\gamma(K^\perp\alpha) \subseteq \gamma'(K^\perp\alpha)$.
2. It follows immediately from 1., that $\cap\gamma'(K^\perp\alpha) \subseteq \cap\gamma(K^\perp\alpha)$. The other inclusion is straightforward, too: For each $H \in \gamma'(K^\perp\alpha)$, we have $\cap\gamma(K^\perp\alpha) \subseteq H$, due to equation (1), so $\cap\gamma(K^\perp\alpha) \subseteq \cap\gamma'(K^\perp\alpha)$. \square

In the following, we will focus on conditions when $\gamma'(K^\perp\alpha) = \gamma(K^\perp\alpha)$ holds.

Proposition 9 *Let $\gamma, \sigma_\gamma, \gamma'$ be as in Proposition 8. Then γ' is complete.*

Proof. Let $H \in K^\perp\alpha$ such that $\cap\gamma'(K^\perp\alpha) \subseteq H$. By Proposition 8, 2., then also $\cap\gamma(K^\perp\alpha) \subseteq H$, which yields $H \in \gamma'(K^\perp\alpha)$. This proves the completeness of γ' . \square

So $\gamma' = \gamma_{\sigma_\gamma}$ can be regarded as the *completion* of the selection function γ . The following Proposition summarizes that completeness is a necessary and sufficient condition for the circle starting from selection functions to close.

Proposition 10 *Let $\gamma, \sigma_\gamma, \gamma'$ be as in Proposition 8. Then $\gamma'(K^\perp\alpha) = \gamma(K^\perp\alpha)$ iff γ is complete.*

Proof. $\gamma(K^\perp\alpha) \subseteq \gamma'(K^\perp\alpha)$ holds in general, due to Proposition 8, 1. Let $H \in \gamma'(K^\perp\alpha)$; by (1), this means that $H \in K^\perp\alpha$ and $\cap\gamma(K^\perp\alpha) \subseteq H$. For each such H to be in $\gamma(K^\perp\alpha) \subseteq H$ is equivalent to the completeness of γ . \square

Propositions 1 and 10 immediately yield the following:

Corollary 2 *If the language \mathcal{L} is finite and K is a belief set, then $\gamma'(K^\perp\alpha) = \gamma(K^\perp\alpha)$.*

We will now focus on constructions that begin with incision functions. As in the previous case, one of the inclusions is straightforward.

Proposition 11 *Let σ be an incision function, γ_σ the selection function defined from σ using the Definition 11, and σ' the incision function defined from γ_σ using the Definition 10, *i.e.*, $\sigma' = \sigma_{\gamma_\sigma}$. Then it holds that $\sigma'(K^\perp\alpha) \subseteq \sigma(K^\perp\alpha)$.*

Proof. By definition, we have:

$$\sigma'(K^\perp\alpha) = K \setminus \cap\{H \in K^\perp\alpha : K \setminus \sigma(K^\perp\alpha) \subseteq H\}.$$

Suppose that $\beta \in \sigma'(K^\perp\alpha)$. Then there is $H' \in K^\perp\alpha$ such that $K \setminus \sigma(K^\perp\alpha) \subseteq H'$ and $\beta \notin H'$. Then $\beta \notin K \setminus \sigma(K^\perp\alpha)$. Since $\beta \in K$ then $\beta \in \sigma(K^\perp\alpha)$. \square

The following property is a straightforward rephrasing of the well-known relevance postulate, formulated by Hansson [10] for incision functions:

Relevance: For all $\beta \in \sigma(K^\perp\alpha)$, there is an X such that $(K \setminus \sigma(K^\perp\alpha)) \subseteq X \subseteq K$, $X \nvDash \alpha$ and $X \cup \{\beta\} \vdash \alpha$.

Proposition 12 *Let σ be an incision function and σ' be as defined in Proposition 11. Then it holds that:*

$$\sigma(K^\perp\alpha) \subseteq \sigma'(K^\perp\alpha)$$

if and only if σ satisfies relevance.

Proof. We will prove the statement in its contrapositive form, *i.e.*, $\sigma(K^\perp\alpha) \not\subseteq \sigma'(K^\perp\alpha)$ iff there is $\beta \in \sigma(K^\perp\alpha)$ such that for all X , $(K \setminus \sigma(K^\perp\alpha)) \subseteq X \subseteq K$ and $X \nvDash \alpha$ implies that $X \cup \{\beta\} \nvDash \alpha$.

First, let $\sigma(K^\perp\alpha) \not\subseteq \sigma'(K^\perp\alpha)$. Then there is $\beta \in \sigma(K^\perp\alpha)$ such that $\beta \notin \sigma'(K^\perp\alpha)$, *i.e.*, there is $\beta \in \sigma(K^\perp\alpha)$ such that for all $H \in K^\perp\alpha$ with $(K \setminus \sigma(K^\perp\alpha)) \subseteq H$, it holds that $\beta \in H$. Now, let $X \subseteq K$, $(K \setminus \sigma(K^\perp\alpha)) \subseteq X$ and $X \nvDash \alpha$. Then there is a maximal $H \in K^\perp\alpha$ with $X \subseteq H$, so $(K \setminus \sigma(K^\perp\alpha)) \subseteq X \subseteq H$ and hence $\beta \in H$. But then also $X \cup \{\beta\} \subseteq H$, and therefore $X \cup \{\beta\} \nvDash \alpha$, since $H \in K^\perp\alpha$.

To prove sufficiency, assume there is $\beta \in \sigma(K^\perp\alpha)$ such that for all X , $(K \setminus \sigma(K^\perp\alpha)) \subseteq X \subseteq K$ and $X \nvDash \alpha$ implies $X \cup \{\beta\} \nvDash \alpha$. Let $H \in K^\perp\alpha$ with $(K \setminus \sigma(K^\perp\alpha)) \subseteq H$. Then $H \nvDash \alpha$ and hence, by assumption, $H \cup \{\beta\} \nvDash \alpha$. But since H is an α -remainder and hence maximal, this means that $\beta \in H$. Therefore, $\beta \in \cap\{H \in K^\perp\alpha : (K \setminus \sigma(K^\perp\alpha)) \subseteq H\}$ and consequently, $\beta \notin \sigma'(K^\perp\alpha)$. \square

So, *relevance* is a necessary and sufficient condition for an incision function σ to guarantee that $\sigma = \sigma_{\gamma_\sigma}$. The following two propositions clarify the relationships between *relevance* and *smoothness*.

Proposition 13 If K is a belief set and σ is smooth, then it satisfies relevance.

Proof. Let $\beta \in \sigma(K^\perp\alpha)$. Assume by reductio that $(\neg\alpha \vee \beta) \in \sigma(K^\perp\alpha)$. It follows that there exists $H \in K^\perp\alpha$ such that $H \vdash \alpha$ and $H \setminus \{\neg\alpha \vee \beta\} \not\vdash \alpha$. Clearly, $(H \setminus \{\neg\alpha \vee \beta\}) \cup \{\neg\alpha \vee \beta\} \vdash \alpha$. By deduction theorem $(H \setminus \{\neg\alpha \vee \beta\}) \vdash (\neg\alpha \vee \beta) \rightarrow \alpha$. Hence $(H \setminus \{\neg\alpha \vee \beta\}) \vdash \alpha$. From this absurd we can conclude that $(\neg\alpha \vee \beta) \notin \sigma(K^\perp\alpha)$.

Let $H' = \{\neg\alpha \vee \beta, \alpha \vee \beta\}$. Since $H' \vdash \beta$ and $\beta \in \sigma(K^\perp\alpha)$, smoothness yields $H' \cap \sigma(K^\perp\alpha) \neq \emptyset$. Hence $(\alpha \vee \beta) \in \sigma(K^\perp\alpha)$. Smoothness yields also that $K \setminus \sigma(K^\perp\alpha) \not\vdash (\alpha \vee \beta)$. Let $H'' = (K \setminus \sigma(K^\perp\alpha)) \cup \{\alpha \vee \neg\beta\}$. H'' satisfies the conditions required for relevance. \square

Proposition 14 If σ satisfies relevance then it is smooth.

Proof. Assume that σ is not smooth. Then there exists H such that $H \subseteq K$, $H \vdash \beta$, $\beta \in \sigma(K^\perp\alpha)$ and such that $H \cap \sigma(K^\perp\alpha) = \emptyset$. Then $K \setminus \sigma(K^\perp\alpha) \vdash \beta$, from which it follows that relevance does not hold. \square

The following corollary is now immediate:

Corollary 3 If K is a belief set, then an incision function is smooth iff it satisfies relevance.

So, smoothness and relevance are closely related. However, smoothness is not enough to yield $\sigma(K^\perp\alpha) \subseteq \sigma'(K^\perp\alpha)$ and hence to close the circle (see Proposition 11), as the following example illustrates.

Example. Let p, q and r be logically independent sentences, and let $K = \{p, q, r\}$. Suppose that we want to contract K by $p \wedge (q \vee r)$. Then we have:

$$K^\perp(p \wedge (q \vee r)) = \{\{p, q\}, \{p, r\}\}.$$

Let σ be such that $\sigma(K^\perp(p \wedge (q \vee r))) = \{p, r\}$. Then $K \div_\sigma (p \wedge (q \vee r)) = \{q\}$. This kernel contraction is smooth. Hence, we have that $\sigma'(K^\perp(p \wedge (q \vee r))) = K \setminus \{q, r\} = \{p\}$. This means that:

$$\sigma(K^\perp(p \wedge (q \vee r))) = \{p, r\} \not\subseteq \{p\} = \sigma'(K^\perp(p \wedge (q \vee r))).$$

7 Conclusion

In this paper, we have investigated in detail the relations between partial meet and kernel contractions by showing how to define incision functions from selection functions and the other way round. We showed under which conditions going back and forth in this way yields identical functions. The properties that are needed to guarantee this are *completeness* for selection functions, and *relevance* for incision functions. We proved that *relevance* implies smoothness but not vice versa; in the special case when the belief base is a belief set, both properties for incision functions coincide.

Representing Relative Direction as a Binary Relation of Oriented Points

Reinhard Moratz¹

Abstract. A central issue in robotics is the representation of relative orientation. Currently, the standard solution utilizes metrical representations. The main reason for this might be that representing relatively fine distinctions is useful in many robotics tasks. If qualitative spatial constraint calculi are to be applied to cognitive robotics, they therefore have to afford relatively fine distinctions. The challenge for us then is to find a calculus which allows these fine distinctions, and yet is still simple enough to provide a provably minimal composition table.

In this paper we introduce a new calculus about oriented points which has a scalable granularity. In this calculus, named \mathcal{OPRA} , simple rules can generate the minimal composition table. Furthermore, the algebraic closure for a set of \mathcal{OPRA} statements is sufficient to solve knowledge integration tasks in robotics.

Keywords: Qualitative Spatial Reasoning, Cognitive Robotics

1 INTRODUCTION

Qualitative Reasoning about space abstracts from the physical world and enables computers to make predictions about spatial relations, even when a precise quantitative information is not available [2]. Spatial reasoning is then a central problem in formalizing common-sense knowledge [4]. The two main trends in Qualitative Spatial Reasoning are topological reasoning about regions [2, 16] and positional reasoning about point configurations [5]. Positional reasoning, i.e. distance and orientation, in particular is important for robot navigation [12].

In this paper we present the Oriented Point Algebra \mathcal{OPRA}_m which has a scalable granularity with parameter $m \in \mathbb{N}$. The motivation for this scalable granularity is that representing relatively fine distinctions is useful in many robotics tasks.

The rest of the paper is organized as follows: we will introduce the \mathcal{OPRA}_m calculus. First we will give a definition for the coarsest type ($m = 1$), followed by the model for arbitrary $m \in \mathbb{N}$. Then we will present an algorithm to generate the composition table. In the end we demonstrate the use of the new calculus for robot applications.

2 THE ORIENTED POINT ALGEBRA

Objects and locations are represented as simple, featureless points in aforementioned approaches on orientations. In contrast, our paper

presents a positional calculus which uses more complex basic entities: It is based on objects which are represented as oriented points. It is related to a calculus which is based on straight line segments (dipoles) [11]. Conceptually, the new calculus can be viewed as a transition from oriented line segments with concrete length to line segments with infinitely small length. In this conceptualization the length of the objects no longer has any importance. Thus, only the direction of the objects is modeled. *O-points*, our term for oriented points, are specified as pair of a point and a direction on the 2D-plane.

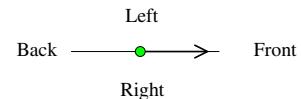

Figure 1. An oriented point and its qualitative spatial relative directions

2.1 Reasoning with Coarse O-Point Relations

In the coarsest representation a single o-point induces the sectors depicted in figure 1. “Front” and “Back” are linear sectors. “Left” and “Right” are half-planes. The position of the point itself is denoted as “Same”. A qualitative spatial relative orientation relation between two o-points is represented by the sector in which the second o-point lies with respect to the first one and by the sector in which the first one lies with respect to the second one.

For the general case of the two points having different positions we use the concatenated string of both sector names as the relation symbol. Then the configuration shown in figure 2 is expressed with the relation A RightLeft B . If both points share the same position the relation symbol starts with the word “Same” and the second substring denotes the direction of the second o-point with respect to the first one as shown in figure 3.

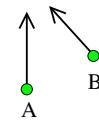

Figure 2. Qualitative spatial relation between two oriented points at different positions. The qualitative spatial relation depicted here is A RightLeft B .

Altogether we obtain 20 different atomic relations (four times four general relations plus four with the o-points at the same position). These relations are jointly exhaustive and pairwise disjoint (JEPD). The relation SameFront is the identity relation. We use \mathcal{OP}_1 to refer to the set of 20 atomic relations, and \mathcal{OPRA}_1 to refer to the power set of \mathcal{OP}_1 which contains all 2^{20} possible unions of the atomic relations.

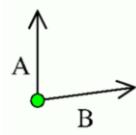

Figure 3. Qualitative spatial relation between two oriented points located at the same position. The qualitative spatial relation depicted here is $A \text{ SameRight } B$.

For reasoning about the o-point relations we apply constraint-based reasoning techniques which were originally introduced for temporal reasoning [1] and also proved valuable for spatial reasoning [16, 6]. In order to apply these techniques to a set of relations, the relations ideally should form a relation algebra [7], i.e. the atomic relations must be jointly exhaustive and pairwise disjoint and they must be closed under composition (\circ), intersection (\cap), complement (\neg), and converse (\sim). There must also be an empty relation, a universal relation (\top), and an identity relation. However, a new result from Renz and Ligozat [14] showed that the composition operation need not to be closed in order to successfully apply constraint-based reasoning techniques²

While the converse, the complement, and the intersection of relations can be computed from the set-theoretic definitions of the relations, the composition of relations must be computed based on the semantics of the relations. The compositions are usually computed only for the atomic relations and then stored in a composition table. The composition of compound relations can be obtained as the union of the compositions of the corresponding atomic relations. The compositions of the atomic relations can be deduced directly from the geometric semantics of the relations (see section 2.3).

O-point constraints are written as xRy where x, y are variables for o-points and R is a \mathcal{OPRA}_1 relation. Given a set Θ of o-point constraints, an important reasoning problem is deciding whether Θ is *consistent*, i.e., whether there is an assignment of all variables of Θ with dipoles such that all constraints are satisfied (a *solution*). We call this problem OPSAT. OPSAT is a Constraint Satisfaction Problem (CSP) [8] and can be solved using the standard methods developed for CSPs with infinite domains (see, e.g., [7]).

A partial method for determining inconsistency of a set of constraints Θ is the *path-consistency method* [8], which computes the algebraic closure on Θ . This method applies the following operation until a fixed point is reached:

$$\forall i, j, k : R_{ij} \leftarrow R_{ij} \cap (R_{ik} \circ R_{kj})$$

where i, j, k are nodes and R_{ij} is the relation between i and j . The resulting set of constraints is equivalent to the original set, i.e. it has the same set of solutions. If the empty relation occurs while performing this operation, Θ is inconsistent, otherwise the resulting set is path-consistent provided that the algebra has a strong composition. It was recently shown by Renz and Ligozat [14] that this algebraic closure procedure is also adequate for calculi with weak composition operation.

\mathcal{OPRA}_1 is very expressive already. Problems of pseudoline arrangements [17] can be expressed in \mathcal{OPRA}_1 . Since the stetchability of pseudoline problem is NP-hard [17], general OPSAT problems

² In section 2.3 we show how to generate a minimal composition table for \mathcal{OPRA} which guarantees at least a *weak* composition which is defined as minimal but not necessarily closed composition and is the substitute for the strong composition of a full relation algebra. Whether the \mathcal{OPRA} calculus is closed under composition is still an open question.

are NP-hard. However, sets of \mathcal{OPRA} relations can be expressed as equalities over polynomials with integer coefficients (which also holds for the finer grained o-point calculi introduced in the next section). Systems of such equalities can be solved using polynomial space [13].

2.2 Finer Grained O-Point Calculi

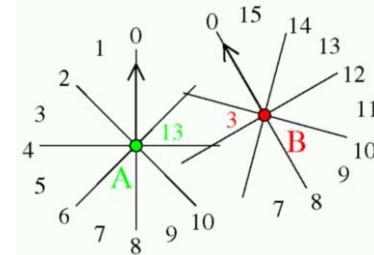

Figure 4. Two o-points in relation $A \text{ } 4\angle^3_{13} \text{ } B$

The design principle for \mathcal{OPRA}_1 can be generalized to calculi \mathcal{OPRA}_m with arbitrary $m \in \mathbb{N}$. Then an angular resolution of $\frac{2\pi}{4m}$ is used for the representation (a similar scheme for absolute direction instead of relative direction was recently designed by Renz and Mitra [15]).

To formally specify the o-point relations we use two-dimensional continuous space, in particular \mathbb{R}^2 . Every o-point S on the plane is an ordered pair of a point \mathbf{p}_S represented by its Cartesian coordinates x and y , with $x, y \in \mathbb{R}$ and a direction ϕ_S .

$$S = (\mathbf{p}_S, \phi_S), \quad \mathbf{p}_S = ((\mathbf{p}_S)_x, (\mathbf{p}_S)_y)$$

We distinguish the relative locations and orientations of the two o-points A and B expressed by a calculus \mathcal{OPRA}_m according to the following scheme. We use the symbol φ_{AB} for $\tan^{-1} \frac{(\mathbf{p}_B)_y - (\mathbf{p}_A)_y}{(\mathbf{p}_B)_x - (\mathbf{p}_A)_x}$ (\tan^{-1} has two arguments, the numerator, and the denominator, and maps to the interval $[0, 2\pi]$). According to the cyclic order of the directions it is appropriate to enumerate them by using the $4m$ elements of the cyclic group \mathcal{Z}_{4m} .

If $\mathbf{p}_A \neq \mathbf{p}_B$ the relation $A \text{ } m\angle_i^j \text{ } B$ ($i, j \in \mathcal{Z}_{4m}$) reads like this: Given a granularity m , the relative position of B with respect to A is described by j and the relative position of A with respect to B is described by i . Formally, it represents the following set of configurations:

$$\begin{aligned} & (((i \equiv_2 1) \wedge (2\pi \frac{i-1}{4m} < \varphi_{AB} - \phi_A < 2\pi \frac{i+1}{4m})) \\ & \vee ((i \equiv_2 0) \wedge (\varphi_{AB} - \phi_A = 2\pi \frac{i}{4m}))) \\ & \wedge (((j \equiv_2 1) \wedge (2\pi \frac{j-1}{4m} < \varphi_{AB} - \phi_B < 2\pi \frac{j+1}{4m})) \\ & \vee ((j \equiv_2 0) \wedge (\varphi_{AB} - \phi_B = 2\pi \frac{j}{4m}))) \end{aligned}$$

$a \equiv_2 b$ stands for $a \bmod 2 = b$. Figure 4 shows the resulting granularity for $m = 4$. Using this notation, a simple manipulation of the parameters yields the converse operation $(_m\angle_j^i)^\sim = {}_m\angle_i^j$.

If $\mathbf{p}_A = \mathbf{p}_B$, the relation $A \text{ } m\angle_i \text{ } B$ represents the following set of configurations:

$$\begin{aligned} & ((i \equiv_2 0) \wedge (\phi_B - \phi_A = 2\pi \frac{i}{4m})) \\ & \vee ((i \equiv_2 1) \wedge (2\pi \frac{i-1}{4m} < \phi_B - \phi_A < 2\pi \frac{i+1}{4m})) \end{aligned}$$

Hence the relation for two identical o-points $A = B$ for arbitrary $m \in \mathbb{N}$ is $A_m \angle 0B$. Using this notation a simple manipulation of the parameters yields the converse operation $(_m\angle_i)^\sim = {}_m\angle(4m - i)$.

The composition tables for the atomic relations of the OPRA_m calculi can be generated using a very simple enumeration strategy sketched in the following subsection.

In situations where the orientation of the second o-point is unknown, underspecified, or unimportant the notation $A \text{ } m\angle_i^? B$ expresses the information about the position of the second o-point without restricting the position of the first o-point with respect to the second one (e.g. the symbol $?$ denotes an index which can range over the whole set \mathcal{Z}_{4m}).

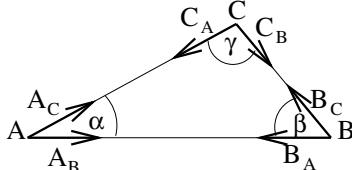

Figure 5. The sum of angles in a triangle equals π

2.3 Generating the composition table

The composition table can be viewed as a list (set) of all relation triples $Ar_{ab}B, Br_{bc}C, Cr_{ca}A$ for which r_{ab}, r_{bc} , and r_{ca} are consistent (A, B , and C being arbitrary o-points on the \mathbb{R}^2 plane). We give a very simple two-step procedure how to enumerate all these valid triples. Then we show that the list is complete.

In order to generate the o-point triple list we first look at general features of triangles on the 2D plane. With A_B we denote the o-point positioned at A and oriented towards position B . In the following, i , j , and k , and the according arithmetic operators are still defined in \mathcal{Z}_{4m} . For a triangle $(\alpha + \beta + \gamma = \pi)$ defined by the o-points A_B, B_C and C_A with $A_B \text{ } m\angle_i^? C_A, B_C \text{ } m\angle_j^? A_B$, and $C_A \text{ } m\angle_k^? B_C$ it holds that

$$2m - 1 \leq i + j + k \leq 2m + 1$$

The set of all possible qualitative triangle descriptions following the above scheme is denoted by T_m (which is enumerated by Algorithm 1).

$$T_m = \left\{ t_{(i,j,k)} \mid A_B \text{ } m\angle_i^? C_A \wedge B_C \text{ } m\angle_j^? A_B \wedge C_A \text{ } m\angle_k^? B_C \right\}$$

Now we can take each triangle description and generate the corresponding triples of OPRA_m relations. As a result we enumerated all triples of OPRA_m relations. But we might generate a specific triple several times which is no problem for our investigation and for the intended applications. Algorithm 2 (see appendix) gets a qualitative triangle (description) as input and generates all corresponding triples of OPRA_m relations. A consistent set of three OPRA_m relations $A \text{ } m\angle_{q_{ab}}^? B, B \text{ } m\angle_{q_{bc}}^? C$, and $C \text{ } m\angle_{q_{ca}}^? A$ can be represented as triple of pairs of the corresponding indices $\langle (q_{ab}, q_{ba}), (q_{bc}, q_{cb}), (q_{ca}, q_{ac}) \rangle$. Then algorithm 2 generates the set

$$\begin{aligned} C_{mijk} = & \left\{ \langle (q_{ab}^l, q_{ba}^l), (q_{bc}^l, q_{cb}^l), (q_{ca}^l, q_{ac}^l) \rangle \mid \right. \\ & A_B \text{ } m\angle_i^? C_A \wedge B_C \text{ } m\angle_j^? A_B \wedge C_A \text{ } m\angle_k^? B_C \quad \wedge \\ & \left. A \text{ } m\angle_{q_{ab}^l}^? B \wedge B \text{ } m\angle_{q_{bc}^l}^? C \wedge C \text{ } m\angle_{q_{ca}^l}^? A \right\} \end{aligned}$$

Note that A and A_B , B and B_C , C and C_A , respectively, have the same position on the \mathbb{R}^2 plane but not necessarily the same direction.

Now the composition table is generated by running algorithm 2 for every entry of the list generated by algorithm 1 and then deleting

multiple copies of the same entry. Using this list the composition of two OPRA_m relations $(m\angle_{q_{ab}}^? \circ m\angle_{q_{bc}}^?)$ can be found by collecting all the entries $m\angle_{q_{ca}^1}^?, m\angle_{q_{ca}^2}^?, \dots$ which can be combined with the two operands and yield entries in the list of consistent relation triples produced by algorithms 1 and 2.

Theorem 1 All OPRA triples for granularity m are generated by algorithms 1 and 2.

Proof Sketch. Each OPRA triple corresponds to a qualitative triangle. A qualitative triangle is characterised by its three angles. The first angle can be any of the $2m + 1$ convex angles, the second has to be chosen from the set of convex angles which close the triangle. Then there are at most three possibilities for the third angle left.

All combinations of relative position and relative orientation are found now. The absolute orientations of the three o-points now can be enumerated independently. \square

Theorem 2 Every OPRA triple generated by algorithms 1 and 2 has an associated realisation in the intended model, the \mathbb{R}^2 plane.

Proof Sketch. The qualitative triangle which corresponds to the OPRA triple can be constructed in a straightforward manner: First, one side is assigned length 1. In the next step both adjacent angles get permissible values with increment $\frac{1}{4} \cdot \frac{2\pi}{4m}$. The third angle necessarily has a correct assignment generated by the set of assignments for the first two angles. Also all constraints for the global orientations of the three o-points are satisfied by members of this small set. \square

There are methods under development to directly compute the OPRA composition [9]. The OPRA calculus can be used to express many other qualitative calculi [3].

3 APPLYING THE *OPRA* CALCULUS TO SPATIAL AGENTS

The composition table becomes fundamentally more compact if we focus on o-point relations which can be found between the six o-points of a triangle (see figure 5). For mappings between these relations we introduce the operation *reorientation* (with the symbol \curvearrowright):

$$C_B \angle_j^0 A_C \implies C_A ({}_m\angle_j^0) \curvearrowright B_C = C_A \angle_{-j}^0 B_C$$

We will now demonstrate how to integrate local knowledge into survey knowledge with the presented calculus. The context is a mobile robot able to perceive colors and to segment simple objects (see figure 6). Furthermore, the system is able to perform straight motion steps and turnings. Since the robot has no prior knowledge about the sizes of the objects and does not know whether the ground is perfectly flat, it cannot estimate their distances. Thus, the robot has only access to local orientation information relative to its position.

Figure 6. Speech commands to a robot in a knowledge integration scenario

Users interact with our system by verbally issuing simple requests to the system³. To demonstrate the capabilities of our system we give a detailed description how the system performs knowledge integration on a specific example (see figure 6⁴). Figure 7 shows a slightly different configuration from a bird's eye view, using icons for the objects. The perceived constraints are:

$$t1_d \quad {}_6\angle_{23}^0 \quad t2_{t1} \quad (1)$$

$$t1_d \quad {}_6\angle_{23}^? \quad C1 \quad (2)$$

$$t1_d \quad {}_6\angle_{23}^? \quad C2 \quad (3)$$

The task is to "move to the yellow cube behind the red disk", i.e. one of the relations $D_{t1} \angle_{[9,15]}^? C1$ or $D_{t1} \angle_{[9,15]}^? C2$ must hold (${}_m\angle_{[k,l]}^j = {}_m\angle_k^j \cup {}_m\angle_{k+1}^j \cup \dots \cup {}_m\angle_l^j$).

The knowledge represented with equations 2 and 3 does not help the robot to distinguish both cube positions with respect to the disk. So the robot must move to acquire additional knowledge. In our example the robot moves straight towards a position roughly in the center of the perceived scene (in figure 7 the starting position is marked with $t1$ and the second position is marked with $t2$). Note that the robot only made straight movements and therefore still knows the direction of

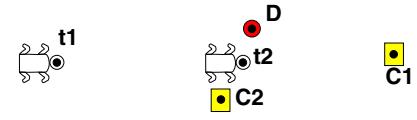

Figure 7. The two perspectives for the AIBO

its starting point. So the moving direction of the robot is still aligned with the robot's moving direction at the beginning. The corresponding directed line beginning with the starting point was also the justification for the knowledge represented in equation 1. The additional perceived knowledge at position $t2$ is:

$$t2_{t1} \quad {}_6\angle_{17}^0 \quad d_{t2} \quad (4)$$

$$t2_d \quad {}_6\angle_{19}^? \quad C1 \quad (5)$$

$$t2_d \quad {}_6\angle_{11}^? \quad C2 \quad (6)$$

Now the task is to use the perceived spatial knowledge for the decision which cube is in the referenced area. Constraint propagation until the algebraic closure is reached would be a solution (see section 2.1). Here we want to illustrate single reasoning steps and their effect in a demonstrative manner. We apply a composition on equations 1 and equation 4:

$$t1_d \quad {}_6\angle_{23}^0 \circ {}_6\angle_{17}^0 d_{t2} \implies t1_d \quad {}_6\angle_0^{[19,21]} d_{t2} \quad (7)$$

Then we apply a converse and a reorientation operation on equation 7:

$$d_{t1} \left(\left({}_6\angle_0^{[19,21]} \right) \curvearrowright \right) \curvearrowright t2_d \implies d_{t1} \quad {}_6\angle_{[3,5]}^0 t2_d \quad (8)$$

Now two compositions provide us further information (equation 8 composed with equation 5, equations 8, 6 respectively):

$$d_{t1} \quad {}_6\angle_{[3,5]}^0 \circ {}_6\angle_{19}^? C1 \implies d_{t1} \top C1 \quad (9)$$

$$d_{t1} \quad {}_6\angle_{[3,5]}^0 \circ {}_6\angle_{11}^? C2 \implies d_{t1} \quad {}_6\angle_{[1,5]}^? C2 \quad (10)$$

Equation 10 shows that cube 2 cannot be the goal cube. Equation 9 is the general relation, e.g. no information is produced. The relation between d_{t1} and $C1$ can be restricted better by composing the tautological constraint $d_{t1} \angle_0^0 t1_d$ with equation 2:

$$d_{t1} \angle_0^0 \circ {}_6\angle_{23}^? C1 \implies d_{t1} \angle_{[1,11]}^? C1 \quad (11)$$

As a result we could infer that cube 1 is the only cube which has a chance to be behind the disk.

For this scenario we generated ten random configurations and tested the reasoning. We only counted runs of the Aibo were no slipping of the legs distorted the straight movement. From the ten cases three could already be solved by local perception. Four cases made successful use of constraint propagation. Three cases were still ambiguous after constraint propagation. This means that in seven out of ten cases the chosen granularity was adequate in our scenario.

4 CONCLUSION

We presented a calculus for representing and reasoning about qualitative relative orientation information. Oriented points serve as the

³ for linguistic aspects of human robot interaction we refer to [10].

⁴ The distances on the image are smaller than in the real experiments for illustration purposes.

basic entities since they are the simplest spatial entities that have an intrinsic orientation. We identified systems of atomic relations on different granularity levels between o-points and identified a scheme for computing the calculi's composition tables based on their geometric semantics. We demonstrated on a small sample application how to represent spatial knowledge and perform reasoning in cognitive robotics with the new calculus.

Modular Equivalence for Normal Logic Programs

Emilia Oikarinen and Tomi Janhunen¹

Abstract. A Gaifman-Shapiro-style architecture of program modules is introduced in the case of normal logic programs under stable model semantics. The composition of program modules is suitably limited by module conditions which ensure the compatibility of the module system with stable models. The resulting module theorem properly strengthens Lifschitz and Turner's splitting set theorem [17] for normal logic programs. Consequently, the respective notion of equivalence between modules, i.e. modular equivalence, proves to be a congruence relation. Moreover, it is shown how our translation-based verification method [15] is accommodated to the case of modular equivalence; and how the verification of weak/visible equivalence can be optimized as a sequence of module-level tests.

1 INTRODUCTION

Answer set programming (ASP) is a promising constraint programming paradigm [20, 19, 11] in which problems are solved by capturing their solutions as *answer sets* or *stable models* of logic programs. The development and optimization of logic programs in ASP gives rise to a meta-level problem of verifying whether subsequent programs are equivalent. To solve this problem, a translation-based approach has been proposed and extended further [14, 23, 21, 25]. The underlying idea is to combine two logic programs P and Q under consideration into two logic programs $\text{EQT}(P, Q)$ and $\text{EQT}(Q, P)$ which have no stable models iff P and Q are *weakly equivalent*, i.e. have the same stable models. This enables the use of the same ASP solver, such as SMODELS or DLV, for the equivalence verification problem as for the search of stable models in general. First experimental results [14, 21] suggest that the translation-based method can be effective and sometimes much faster than a simple cross-check.

As a potential limitation, the translation-based method as described above treats programs as integral entities and therefore no computational advantage is sought by breaking programs into smaller parts, say *modules* of some kind. Such an optimization strategy is largely preempted by the fact that weak equivalence, denoted by \equiv , fails to be a *congruence relation* for \cup , i.e. weak equivalence is not preserved under substitutions in unions of programs. More formally put, $P \equiv Q$ does not imply $P \cup R \equiv Q \cup R$ in general. The same can be stated about *uniform equivalence* [22] but not about *strong equivalence* [16] which admits substitutions by definition.

From our point of view, strong equivalence seems inappropriate for *fully modularizing* the verification task of weak equivalence because programs P and Q may be weakly equivalent even if they build on respective modules $P_i \subseteq P$ and $Q_i \subseteq Q$ that are not strongly equivalent. For the same reason, program transformations that are known to preserve strong equivalence [4] do not provide an inclusive basis for reasoning about weak equivalence. Nevertheless, there are

cases where one can utilize the fact that strong equivalence implies weak equivalence. For instance, if P and Q are composed of strongly equivalent pairs of modules P_i and Q_i for all i , then P and Q can be directly inferred to be strongly/weakly equivalent. These observations about strong equivalence motivate the strive for a weaker congruence relation compatible with weak equivalence at program-level.

To address the lack of a suitable congruence relation in the context of ASP, we propose a new design in this article. The design superficially resembles that of Gaifman and Shapiro [10] but stable model semantics [12] and special module conditions are incorporated. The feasibility of the design is crystallized in a *module theorem* which shows the module system fully compatible with stable models. In fact, the module theorem established here is a proper strengthening of the splitting set theorem established by Lifschitz and Turner [17] in the case of normal logic programs. The main difference is that our result allows negative recursion between modules. Moreover, it enables the introduction of a notion of equivalence, i.e. *modular equivalence*, which turns out to be a proper congruence relation and reduces to weak equivalence for program modules which have a completely specified input and no hidden (auxiliary) atoms. Such modules correspond to normal logic programs without auxiliary atoms. If normal programs P and Q are composed of modularly equivalent modules P_i and Q_i for all i , then P and Q are modularly equivalent, or equivalently stated, weakly equivalent. The notion of modular equivalence opens immediately new prospects as regards the translation-based verification method [14, 21]. First, the method can be tuned for the task of verifying modular equivalence by attaching a *context generator* to program modules in analogy to [25]. Second, we demonstrate how the verification of weak equivalence can be reorganized as a sequence of tests, each of which concentrates on a pair of respective modules in the programs subject to the verification task.

The rest of this article is structured as follows. As a preparatory step, the syntax and semantics of normal logic programs is recalled in Section 2. A summary of equivalence relations follows in Section 3. Section 4 concentrates on specifying program modules as well as establishing the module theorem discussed above. The notion of modular equivalence is then presented in Section 5 which also includes a proof of the congruence property and a brief account of computational complexity. Moreover, connections between modular equivalence and the translation-based method for verifying weak equivalence [14] are worked out. Section 6 briefly contrasts our work with earlier approaches. Finally, a conclusion is given in Section 7.

2 NORMAL LOGIC PROGRAMS

We present *normal logic programs* in the *propositional* case.

Definition 1 A *normal logic program (NLP)* is a finite set of rules of the form $h \leftarrow B^+, \sim B^-$, where h is an atom, B^+ and B^- are sets of atoms, and $\sim B = \{\sim b \mid b \in B\}$ for any set of atoms B .

¹ Helsinki University of Technology (TKK), P.O. Box 5400, FI-02015 TKK, Finland. Email:{Emilia.Oikarinen,Tomi.Janhunen}@tkk.fi

The symbol “ \sim ” denotes *default negation* and we define *default literals* as atoms a or their default negations $\sim a$. A rule consists of a *head* h and a *body* $B^+ \cup \sim B^-$. A rule is a *fact* whenever its body is empty, and “ \leftarrow ” is omitted. A rule is *positive*, if $B^- = \emptyset$. A NLP consisting of positive rules only is a *positive logic program*.

The *Herbrand base* $\text{Hb}(P)$ of a NLP P is any fixed set of atoms containing all atoms appearing in the rules of P . Moreover, the base $\text{Hb}(P)$ is supposed to be finite whenever P is. Under this definition, the Herbrand base of P may contain atoms which have no occurrences in P . This aspect is useful e.g. when programs are optimized and there is a need to keep track of removed atoms. Given a NLP P , an *interpretation* M of P is a subset of $\text{Hb}(P)$ defining which atoms $a \in \text{Hb}(P)$ are true ($a \in M$) and which are false ($a \notin M$). An interpretation $M \subseteq \text{Hb}(P)$ is a (*classical*) *model* of P , denoted by $M \models P$ iff $B^+ \subseteq M$ and $B^- \cap M = \emptyset$ imply $h \in M$ for each rule $h \leftarrow B^+, \sim B^- \in P$. For a positive program P , an interpretation $M \subseteq \text{Hb}(P)$ is the (unique) *least model* of P , denoted by $\text{LM}(P)$, iff there is no $M' \models P$ such that $M' \subset M$. *Stable models* as proposed by Gelfond and Lifschitz [12] generalize least models for normal logic programs.

Definition 2 An interpretation $M \subseteq \text{Hb}(P)$ is a *stable model* of a NLP P iff $M = \text{LM}(P^M)$ where the Gelfond-Lifschitz reduct $P^M = \{h \leftarrow B^+ \mid h \leftarrow B^+, \sim B^- \in P \text{ and } M \cap B^- = \emptyset\}$.

Stable models are not necessarily unique in general: a NLP may have several stable models or no stable models at all. The set of stable models of a NLP P is denoted by $\text{SM}(P)$.

The *positive dependency relation* $\leq \subseteq \text{Hb}(P) \times \text{Hb}(P)$ of P is the reflexive and transitive closure of a relation \leq_1 defined as follows. Given $a, b \in \text{Hb}(P)$, we say that b depends directly on a , denoted $a \leq_1 b$, iff there is a rule $b \leftarrow B^+, \sim B^- \in P$ such that $a \in B^+$. The *positive dependency graph* of P , denoted by $\text{Dep}^+(P)$, is a graph with $\text{Hb}(P)$ and $\{\langle b, a \rangle \mid a \leq_1 b\}$ as the sets of vertices and edges, respectively. A *strongly connected component* of $\text{Dep}^+(P)$ is a maximal subset $C \subseteq \text{Hb}(P)$ such that $a \leq b$ holds for all $a, b \in C$. The strongly connected components of $\text{Dep}^+(P)$ partition $\text{Hb}(P)$ into equivalence classes. The dependency relation \leq can then be generalized for strongly connected components: $C_i \leq C_j$, i.e. C_j depends on C_i , iff $c_i \leq c_j$ for any $c_i \in C_i$ and any $c_j \in C_j$.

A *splitting set* for a NLP P [17] is any set $U \subseteq \text{Hb}(P)$ such that for every $h \leftarrow B^+, \sim B^- \in P$, if $h \in U$ then $B^+ \cup B^- \subseteq U$. The *bottom* of P relative to U is $b_U(P) = \{h \leftarrow B^+, \sim B^- \in P \mid \{h\} \cup B^+ \cup B^- \subseteq U\}$, and the *top* of P relative to U is $t_U(P) = P \setminus b_U(P)$. The top can be partially evaluated with respect to an interpretation $X \subseteq U$. The result is a program $e(t_U(P), X)$ that contains a rule $h \leftarrow (B^+ \setminus U), \sim(B^- \setminus U)$ for each $h \leftarrow B^+, \sim B^- \in t_U(P)$ such that $B^+ \cap U \subseteq X$ and $(B^- \cap U) \cap X = \emptyset$. Given a splitting set U for a NLP P , a *solution* to P with respect to U is a pair $\langle X, Y \rangle$ such that $X \subseteq U$, $Y \subseteq \text{Hb}(P) \setminus U$, $X \in \text{SM}(b_U(P))$, and $Y \in \text{SM}(e(t_U(P), X))$. The *splitting set theorem* by Lifschitz and Turner [17] relates solutions with stable models. Given a NLP P , a splitting set U for P , and $M \subseteq \text{Hb}(P)$, it holds that $M \in \text{SM}(P)$ iff $\langle M \cap U, M \setminus U \rangle$ is a solution to P with respect to U .

3 NOTIONS OF EQUIVALENCE

Next we briefly review a number of equivalence relations for NLPs. As stated in Section 1, two NLPs P and Q are (weakly) equivalent, denoted by $P \equiv Q$, iff $\text{SM}(P) = \text{SM}(Q)$. Lifschitz et al. [16] introduce a much stronger notion: P and Q are *strongly equivalent*,

denoted $P \equiv_s Q$, iff $P \cup R \equiv Q \cup R$ for any NLP R acting as a context. Yet another relation originates from the database community [22]: P and Q are *uniformly equivalent*, denoted $P \equiv_u Q$, iff $P \cup F \equiv Q \cup F$ for any set of facts F . It is clear that $P \equiv_s Q$ implies $P \equiv_u Q$ which implies $P \equiv Q$, but not vice versa (in both cases).

Strongly equivalent logic programs are semantics preserving substitutes of each other and thus \equiv_s can be understood as a *congruence relation* among NLPs, i.e. if $P \equiv_s Q$, then $P \cup R \equiv_s Q \cup R$ for all NLPs R . On the other hand, \equiv_u is not a congruence for \cup , as shown in Example 1 below and the same applies to \equiv . Thus \equiv and \equiv_u are best suited for program-level rather than module-level comparisons.

Example 1 [4, Example 1] Consider NLPs $P = \{a.\}$ and $Q = \{a \leftarrow \sim b. a \leftarrow b.\}$. It holds $P \equiv_u Q$, but $P \cup R \not\equiv Q \cup R$ for $R = \{b \leftarrow a.\}$. Thus $P \not\equiv_s Q$ and \equiv_u is not a congruence for \cup .

For $P \equiv Q$ to hold, the stable models in $\text{SM}(P)$ and $\text{SM}(Q)$ have to be identical subsets of $\text{Hb}(P)$ and $\text{Hb}(Q)$, respectively, and the same can be stated about \equiv_s and \equiv_u . This makes these notions of equivalence less useful if $\text{Hb}(P)$ and $\text{Hb}(Q)$ differ by some atoms which formalize some auxiliary concepts and are not trivially false. Following the ideas from [13] we partition $\text{Hb}(P)$ into its *visible* and *hidden* parts $\text{Hb}_v(P)$ and $\text{Hb}_h(P)$, respectively. The idea behind *visible equivalence* is that atoms in $\text{Hb}_h(P)$ and $\text{Hb}_h(Q)$ are local to P and Q and negligible as regards the equivalence of P and Q .

Definition 3 [13] Normal logic programs P and Q are *visibly equivalent*, denoted by $P \equiv_v Q$, iff $\text{Hb}_v(P) = \text{Hb}_v(Q)$ and there is a bijection $f : \text{SM}(P) \rightarrow \text{SM}(Q)$ such that for all interpretations $M \in \text{SM}(P)$, $M \cap \text{Hb}_v(P) = f(M) \cap \text{Hb}_v(Q)$.

Note that the number of stable models is preserved under \equiv_v . Such a strict correspondence of models is much dictated by the ASP methodology: the stable models of a program usually correspond to the solutions of the problem being solved and thus the exact preservation of models is highly significant. In the fully visible case, i.e. $\text{Hb}_h(P) = \text{Hb}_h(Q) = \emptyset$, the relation \equiv_v becomes very close to \equiv . The only difference is the requirement $\text{Hb}(P) = \text{Hb}(Q)$ insisted by \equiv_v . This is of little importance as Herbrand bases can always be extended to meet $\text{Hb}(P) = \text{Hb}(Q)$. Since weak equivalence is not a congruence, visible equivalence cannot be a congruence either.

The *relativized variants* of \equiv_s and \equiv_u introduced by Woltran [25] allow the context to be constrained using a set of atoms A .

Definition 4 Two NLPs P and Q are *strongly equivalent relative to A* , denoted by $P \equiv_s^A Q$, iff $P \cup R \equiv Q \cup R$ for all NLPs R over the set of atoms A ; *uniformly equivalent relative to A* , denoted by $P \equiv_u^A Q$, iff $P \cup F \equiv Q \cup F$ for all sets of facts $F \subseteq A$.

Setting $A = \emptyset$ in the above reduces both $P \equiv_s^A Q$ and $P \equiv_u^A Q$ to \equiv . Thus neither of them is a congruence for \cup .

Eiter et al. [7] use *equivalence frames* to capture various kinds of equivalence relations such as those defined above. The relation \equiv_v makes an exception in this respect as it does not fit into equivalence frames based on *projected answer sets*. A projective variant of Definition 3 would require $\{M \cap \text{Hb}_v(P) \mid M \in \text{SM}(P)\} = \{N \cap \text{Hb}_v(Q) \mid N \in \text{SM}(Q)\}$. As a consequence, the number of answer sets might not be preserved which we find to contrast the general nature of ASP as discussed after Definition 3.

4 MODULAR LOGIC PROGRAMS

We define *logic program modules* similarly to [10] but consider the case of NLPs instead of positive (disjunctive) logic programs.

Definition 5 A triple $\mathbb{P} = (P, I, O)$ is a logic program module, if

1. P is a finite set of rules of the form $h \leftarrow B^+, \sim B^-$;
2. I and O are sets of propositional atoms such that $I \cap O = \emptyset$; and
3. $\text{Head}(P) \cap I = \emptyset$ where $\text{Head}(P) = \{h \mid h \leftarrow B^+, \sim B^- \in P\}$.

The Herbrand base of module \mathbb{P} , $\text{Hb}(\mathbb{P})$, is the set of atoms appearing in P combined with $I \cup O$. Intuitively the set I defines the *input* of a module and the set O is the *output*. The atoms in $I \cup O$ are visible, i.e. the visible Herbrand base of module \mathbb{P} is $\text{Hb}_v(\mathbb{P}) = I \cup O$. Notice that $I \cup O$ can also contain atoms not appearing in P similarly to the possibility of having additional atoms in the Herbrand bases of NLPs. All other atoms are hidden, i.e. $\text{Hb}_h(\mathbb{P}) = \text{Hb}(\mathbb{P}) \setminus \text{Hb}_v(\mathbb{P})$.

For the composition of modules we take the union of the disjoint sets of rules involved in them in analogy to [10]. The conditions given in [10] are not yet sufficient for our purposes, and we impose a further restriction denying positive recursion between modules.

Definition 6 Consider $\mathbb{P}_1 = (P_1, I_1, O_1)$ and $\mathbb{P}_2 = (P_2, I_2, O_2)$ and let C_1, \dots, C_n be the strongly connected components of $\text{Dep}^+(P_1 \cup P_2)$. There is a positive recursion between \mathbb{P}_1 and \mathbb{P}_2 , if $C_i \cap O_1 \neq \emptyset$ and $C_i \cap O_2 \neq \emptyset$ for some component C_i .

The idea is that all inter-module dependencies go through the input/output interface of the modules, and hidden atoms are local to each module. If there is a strongly connected component C_i in $\text{Dep}^+(P_1 \cup P_2)$ containing atoms from both O_1 and O_2 , we know that, some output atom a of \mathbb{P}_1 depends on some output atom b of \mathbb{P}_2 which again depends on a . This yields a positive recursion.

Definition 7 The join of modules $\mathbb{P}_1 = (P_1, I_1, O_1)$ and $\mathbb{P}_2 = (P_2, I_2, O_2)$, denoted by $\mathbb{P}_1 \sqcup \mathbb{P}_2$, is defined if

1. $O_1 \cap O_2 = \emptyset$;
2. $\text{Hb}_h(\mathbb{P}_1) \cap \text{Hb}(\mathbb{P}_2) = \text{Hb}_h(\mathbb{P}_2) \cap \text{Hb}(\mathbb{P}_1) = \emptyset$; and
3. there is no positive recursion between \mathbb{P}_1 and \mathbb{P}_2 .

Then $\mathbb{P}_1 \sqcup \mathbb{P}_2 = (P_1 \cup P_2, (I_1 \setminus O_2) \cup (I_2 \setminus O_1), O_1 \cup O_2)$.

Note that the first condition is implied by the third, and the second can be circumvented in practice by renaming the hidden atoms uniquely for each module. The join operation is *commutative* and *associative* whenever the respective joins are defined. The following hold for $\mathbb{P}_1 \sqcup \mathbb{P}_2$: $P_1 \cap P_2 = \emptyset$, $\text{Hb}_h(\mathbb{P}_1) \cap \text{Hb}_h(\mathbb{P}_2) = \emptyset$, and $\text{Hb}_v(\mathbb{P}_1) \cap \text{Hb}_v(\mathbb{P}_2) = (I_1 \cap I_2) \cup (I_1 \cap O_2) \cup (I_2 \cap O_1)$. Also, $\text{Hb}(\mathbb{P}_1 \sqcup \mathbb{P}_2) = \text{Hb}(\mathbb{P}_1) \cup \text{Hb}(\mathbb{P}_2)$, and similarly for the hidden and visible part of $\text{Hb}(\mathbb{P}_1 \sqcup \mathbb{P}_2)$, respectively. The conditions above impose no restrictions on positive dependencies *inside* modules or on *negative* dependencies in general. The input of $\mathbb{P}_1 \sqcup \mathbb{P}_2$ can be smaller than the union of inputs of individual modules because \mathbb{P}_1 may provide input for \mathbb{P}_2 , and conversely, as demonstrated below.

Example 2 The join of $\mathbb{P} = (\{a \leftarrow \sim b\}, \{b\}, \{a\})$ and $\mathbb{Q} = (\{b \leftarrow \sim a\}, \{a\}, \{b\})$ is $\mathbb{P} \sqcup \mathbb{Q} = (\{a \leftarrow \sim b. b \leftarrow \sim a\}, \emptyset, \{a, b\})$.

The stable semantics of a module is defined with respect to a given input, i.e. a subset of the input atoms of the module. Input is seen as a set of facts (or a database) to be added to the module.

Definition 8 The instantiation of a module $\mathbb{P} = (P, I, O)$ with an input $A \subseteq I$ is $\mathbb{P}(A) = \mathbb{P} \sqcup \mathbb{F}_A$, where $\mathbb{F}_A = (\{a. \mid a \in A\}, \emptyset, I)$.

Note that $\mathbb{P}(A) = (P \cup \{a. \mid a \in A\}, \emptyset, I \cup O)$ is essentially a NLP with $\text{Hb}_v(\mathbb{P}(A)) = I \cup O$, and we can generalize the stable model semantics for modules. In the sequel $\mathbb{P}(A)$ is identified with the respective NLP $P \cup F_A$, where $F_A = \{a. \mid a \in A\}$, and $M \cap I$ acts as a particular input with respect to which the module is instantiated.

Definition 9 An interpretation $M \subseteq \text{Hb}(\mathbb{P})$ is a stable model of $\mathbb{P} = (P, I, O)$, denoted $M \in \text{SM}(\mathbb{P})$, iff $M = \text{LM}(P^M \cup F_{M \cap I})$.

A concept of *compatibility* is used to describe when $M_1 \in \text{SM}(\mathbb{P}_1)$ can be combined with $M_2 \in \text{SM}(\mathbb{P}_2)$: stable models M_1 and M_2 are *compatible*, iff $M_1 \cap \text{Hb}_v(\mathbb{P}_2) = M_2 \cap \text{Hb}_v(\mathbb{P}_1)$. Theorem 1 relates program-level stability with module-level stability.

Theorem 1 (Module theorem). If $\mathbb{P}_1 \sqcup \mathbb{P}_2$ is defined for modules \mathbb{P}_1 and \mathbb{P}_2 , then $M \in \text{SM}(\mathbb{P}_1 \sqcup \mathbb{P}_2)$ iff $M_1 = M \cap \text{Hb}(\mathbb{P}_1) \in \text{SM}(\mathbb{P}_1)$, $M_2 = M \cap \text{Hb}(\mathbb{P}_2) \in \text{SM}(\mathbb{P}_2)$, and M_1 and M_2 are compatible.

Proof sketch. Suppose $\mathbb{P} = \mathbb{P}_1 \sqcup \mathbb{P}_2 = (P, I, O)$ is defined for modules $\mathbb{P}_1 = (P_1, I_1, O_1)$ and $\mathbb{P}_2 = (P_2, I_2, O_2)$. “ \Rightarrow ” Let $M \in \text{SM}(\mathbb{P})$. Then $M_1 = M \cap \text{Hb}(\mathbb{P}_1)$ and $M_2 = M \cap \text{Hb}(\mathbb{P}_2)$ are clearly compatible and it is straightforward to show that conditions 1 and 2 in Definition 7 imply $M_1 \in \text{SM}(\mathbb{P}_1)$ and $M_2 \in \text{SM}(\mathbb{P}_2)$. “ \Leftarrow ” Let $M_1 \in \text{SM}(\mathbb{P}_1)$, and $M_2 \in \text{SM}(\mathbb{P}_2)$ be compatible and define $M = M_1 \cup M_2$. There is a strict total ordering $<$ for the strongly connected components C_i of $\text{Dep}^+(P)$ such that if $C_i < C_j$, then $C_i \leq C_j$ and $C_j \not\leq C_i$; or $C_i \not\leq C_j$ and $C_j \not\leq C_i$. Let $C_1 < \dots < C_n$ be such an ordering. Show that exactly one of the following holds for each C_i : (i) $C_i \subseteq I$, (ii) $C_i \subseteq O_1 \cup \text{Hb}_h(\mathbb{P}_1)$, or (iii) $C_i \subseteq O_2 \cup \text{Hb}_h(\mathbb{P}_2)$. Finally, show by induction that $M \cap (\cup_{i=1}^k C_i) = \text{LM}(P^M \cup F_{M \cap I}) \cap (\cup_{i=1}^k C_i)$ for $0 \leq k \leq n$ by applying the splitting set theorem [17] to $P^M \cup F_{M \cap I}$. \square

Example 3 shows that condition 3 in Definition 7 is necessary to guarantee that local stability implies global stability.

Example 3 Consider $\mathbb{P}_1 = (\{a \leftarrow b.\}, \{b\}, \{a\})$ and $\mathbb{P}_2 = (\{b \leftarrow a.\}, \{a\}, \{b\})$ with $\text{SM}(\mathbb{P}_1) = \text{SM}(\mathbb{P}_2) = \{\emptyset, \{a, b\}\}$. The join of \mathbb{P}_1 and \mathbb{P}_2 is not defined because of positive recursion (conditions 1 and 2 in Definition 7 are satisfied, however). For a NLP $P = \{a \leftarrow b. b \leftarrow a.\}$, we get $\text{SM}(P) = \{\emptyset\}$. Thus, the positive dependency between a and b excludes $\{a, b\}$ from $\text{SM}(P)$.

Theorem 1 is strictly stronger than the splitting set theorem [17] for NLPs. If U is a splitting set for a NLP P , then $P = \mathbb{B} \sqcup \mathbb{T} = (b_U(P), \emptyset, U) \sqcup (t_U(P), U, \text{Hb}(P) \setminus U)$, and furthermore $M_1 \in \text{SM}(\mathbb{B})$ and $M_2 \in \text{SM}(\mathbb{T})$ iff $\langle M_1, M_2 \setminus U \rangle$ is a solution for P with respect to U . On the other hand the splitting set theorem cannot be applied to e.g. $\mathbb{P} \sqcup \mathbb{Q}$ from Example 2, since neither $\{a\}$ nor $\{b\}$ is a splitting set. Our theorem also strengthens a module theorem given in [13, Theorem 6.22] to cover NLPs involving positive body literals. Theorem 1 can easily be generalized for modules consisting of several submodules. Although Theorem 1 enables the computation of stable models on a module-by-module basis, it leaves us the task of excluding mutually incompatible combinations of stable models.

5 MODULAR EQUIVALENCE

The notion of *modular equivalence* combines features from relativized uniform equivalence and visible equivalence.

Definition 10 Logic program modules $\mathbb{P} = (P, I_P, O_P)$ and $\mathbb{Q} = (Q, I_Q, O_Q)$ are modularly equivalent, denoted by $\mathbb{P} \equiv_m \mathbb{Q}$, iff

1. $I_P = I_Q = I$ and $O_P = O_Q = O$, and
2. $\mathbb{P}(A) \equiv_v \mathbb{Q}(A)$ for all $A \subseteq I$.

Modular equivalence is very close to \equiv_v defined for modules. As a matter of fact, if Definition 3 is generalized for modules, the second condition in Definition 10 can be revised to $\mathbb{P} \equiv_v \mathbb{Q}$. That, however,

is not enough to cover the first condition in Definition 10, as \equiv only enforces $\text{Hb}_v(\mathbb{P}) = \text{Hb}_v(\mathbb{Q})$. If $I = \emptyset$, modular equivalence coincides with visible equivalence. If $O = \emptyset$, then $\mathbb{P} \equiv_m \mathbb{Q}$ means that \mathbb{P} and \mathbb{Q} have the same number of stable models on each input.

Furthermore, in the *fully visible case*, i.e. if $\text{Hb}_h(\mathbb{P}) = \text{Hb}_h(\mathbb{Q}) = \emptyset$, modular equivalence can be seen as a special case of A -uniform equivalence for $A = I$. Recall, however, the restrictions $\text{Head}(P) \cap I = \text{Head}(Q) \cap I = \emptyset$ imposed by module structure. With a further restriction $I = \emptyset$, modular equivalence coincides with weak equivalence. Setting $I = \text{Hb}(\mathbb{P})$ would give uniform equivalence, but the restriction $\text{Head}(P) \cap I = \emptyset$ leaves room for the empty module only.

Since \equiv_v is not a congruence relation for \sqcup , neither is modular equivalence. The situation changes, however, if one considers the join operation \sqcup which suitably restricts possible contexts.

Theorem 2 *Let \mathbb{P}, \mathbb{Q} and \mathbb{R} be logic program modules. If $\mathbb{P} \equiv_m \mathbb{Q}$ and both $\mathbb{P} \sqcup \mathbb{R}$ and $\mathbb{Q} \sqcup \mathbb{R}$ are defined, then $\mathbb{P} \sqcup \mathbb{R} \equiv_m \mathbb{Q} \sqcup \mathbb{R}$.*

Proof sketch. Consider $\mathbb{P} = (P, I, O)$ and $\mathbb{Q} = (Q, I, O)$ such that $\mathbb{P} \equiv_m \mathbb{Q}$, and $\mathbb{R} = (R, I_R, O_R)$ such that $\mathbb{P} \sqcup \mathbb{R}$ and $\mathbb{Q} \sqcup \mathbb{R}$ are defined. It follows from Theorem 1 that $M_P = M \cap \text{Hb}(\mathbb{P}) \in \text{SM}(\mathbb{P})$ and $M_R = M \cap \text{Hb}(\mathbb{R}) \in \text{SM}(\mathbb{R})$ for any $M \in \text{SM}(\mathbb{P} \sqcup \mathbb{R})$. Since $\mathbb{P} \equiv_m \mathbb{Q}$, there is a bijection $f : \text{SM}(\mathbb{P}) \rightarrow \text{SM}(\mathbb{Q})$ such that $M_P \cap (O \cup I) = f(M_P) \cap (O \cup I)$. Define $M_Q = f(M_P)$ and apply Theorem 1 to show that $M_Q \cup M_R \in \text{SM}(\mathbb{Q} \sqcup \mathbb{R})$. Finally show that $g : \text{SM}(\mathbb{P} \sqcup \mathbb{R}) \rightarrow \text{SM}(\mathbb{Q} \sqcup \mathbb{R})$ defined as $g(M) = f(M \cap \text{Hb}(\mathbb{P})) \cup (M \cap \text{Hb}(\mathbb{R}))$ is a bijection satisfying conditions in Definition 3. Thus $\mathbb{P} \sqcup \mathbb{R} \equiv_m \mathbb{Q} \sqcup \mathbb{R}$. \square

It is instructive to consider a potentially stronger variant of \equiv_m defined in analogy to \equiv_s [16]: $\mathbb{P} \equiv_m^s \mathbb{Q}$ iff $\mathbb{P} \sqcup \mathbb{R} \equiv_m \mathbb{Q} \sqcup \mathbb{R}$ holds for all \mathbb{R} such that $\mathbb{P} \sqcup \mathbb{R}$ and $\mathbb{Q} \sqcup \mathbb{R}$ are defined. However, Theorem 2 implies that \equiv_m^s adds nothing to \equiv_m since $\mathbb{P} \equiv_m^s \mathbb{Q}$ iff $\mathbb{P} \equiv_m \mathbb{Q}$.

As regards the computational complexity, deciding \equiv_m is **coNP**-hard in general, since deciding $P \equiv Q$ reduces to deciding $(P, \emptyset, \text{Hb}(P)) \equiv_m (Q, \emptyset, \text{Hb}(Q))$. If $\text{Hb}_h(P) = \text{Hb}_h(Q) = \emptyset$, deciding $\mathbb{P} \equiv_m \mathbb{Q}$ reduces to deciding $P \equiv_u^I Q$ [25]. Thus deciding \equiv_m is **coNP**-complete in the fully visible case. In the other extreme, if $\text{Hb}_v(\mathbb{P}) = \text{Hb}_v(\mathbb{Q}) = \emptyset$, then $\mathbb{P} \equiv_m \mathbb{Q}$ iff $|\text{SM}(\mathbb{P})| = |\text{SM}(\mathbb{Q})|$. This suggests a much higher computational complexity of deciding \equiv_m in general because classical models can be captured with stable models [20] and the counting problem #SAT is **#P**-complete [24].

A way to govern the computational complexity is to limit the use of hidden atoms as in the case of \equiv_v [15]. Therefrom we adopt the property of having *enough visible atoms* (EVA). For an interpretation $M_v \subseteq \text{Hb}_v(P)$ for the visible part of a NLP P , the *hidden part* P_h/M_v of P relative M_v contains $h \leftarrow B_h^+, \sim B_h^-$ for each rule $h \leftarrow B^+, \sim B^- \in P$ such that $h \in \text{Hb}_h(P)$ and $M_v \models B_h^+ \cup \sim B_h^-$.

Definition 11 *A NLP P has enough visible atoms iff P_h/M_v has a unique stable model for every interpretation $M_v \subseteq \text{Hb}_v(P)$.*

The idea behind the EVA property is that the interpretation of $\text{Hb}_h(P)$ is uniquely determined for each interpretation of $\text{Hb}_v(P)$. Consequently, the stable models of P can be distinguished from each other on the basis of their visible parts. By the EVA assumption [15], the verification of \equiv_v becomes **coNP**-complete for SMODELS programs² involving hidden atoms—enabling the translation-based method [14] for \equiv_v . Although verifying the EVA property can be hard in general, there are syntactic subclasses of NLPs (e.g. those for which P_h/M_v is always stratified) with the EVA property. It should be stressed that the use of visible atoms is not limited in this setting.

² This class of programs includes normal logic programs.

As for \equiv_v , the EVA assumption is equally important in conjunction with \equiv_m which becomes evident once we work out the interconnections of \equiv_v and \equiv_m . We begin by describing ways in which modular equivalence can be exploited in the verification of visible/weak equivalence. One concrete step in this respect is to reduce the problem of verifying \equiv_m to that of \equiv_v by introducing a special module \mathbb{G}_I that acts as a context generator in analogy to [25].

Theorem 3 *If $\text{Hb}_v(\mathbb{P}) = \text{Hb}_v(\mathbb{Q}) = O \cup I$ holds for \mathbb{P} and \mathbb{Q} , then $\mathbb{P} \equiv_m \mathbb{Q}$ iff $\mathbb{P} \sqcup \mathbb{G}_I \equiv_v \mathbb{Q} \sqcup \mathbb{G}_I$ where $\mathbb{G}_I = (\{a \leftarrow \sim \bar{a}, \bar{a} \leftarrow \sim a \mid a \in I\}, \emptyset, I)$ generates all possible inputs for \mathbb{P} and \mathbb{Q} .*

Proof sketch. Note that \mathbb{G}_I has $2^{|I|}$ stable models of the form $A \cup \{\bar{a} \mid a \in I \setminus A\}$ where $A \subseteq I$. Thus $\mathbb{P} \equiv_v \mathbb{P} \sqcup \mathbb{G}_I$ and $\mathbb{Q} \equiv_v \mathbb{Q} \sqcup \mathbb{G}_I$ follow by Definitions 2 and 3 and Theorem 1. It follows that $\mathbb{P} \equiv_m \mathbb{Q}$ iff $\mathbb{P}(A) \equiv_v \mathbb{Q}(A)$ for all $A \subseteq I$ iff $\mathbb{P} \sqcup \mathbb{G}_I \equiv_v \mathbb{Q} \sqcup \mathbb{G}_I$. \square

Consequently, the translation-based method from [15] can be used to decide $\mathbb{P} \equiv_m \mathbb{Q}$ given that \mathbb{P} and \mathbb{Q} have enough visible atoms (\mathbb{G}_I has the EVA property trivially). The task is to show that $\text{EQT}(\mathbb{P} \sqcup \mathbb{G}_I, \mathbb{Q} \sqcup \mathbb{G}_I)$ and $\text{EQT}(\mathbb{Q} \sqcup \mathbb{G}_I, \mathbb{P} \sqcup \mathbb{G}_I)$ have no stable models.

The introduction of \equiv_m was much motivated by the need of modularizing the verification of \equiv .³ To make this idea clear, we propose a strategy to utilize \equiv_m in the task of verifying the visible/weak equivalence of P and Q . It is required that the module structure for P and Q is either specified explicitly or detected automatically by computing the strongly connected components of $\text{Dep}^+(P)$ and $\text{Dep}^+(Q)$. Assuming that Q is obtained from P through local modifications, it is likely that these components are pairwise compatible and we can partition P and Q so that $P = \mathbb{P}_1 \sqcup \dots \sqcup \mathbb{P}_n$ and $Q = \mathbb{Q}_1 \sqcup \dots \sqcup \mathbb{Q}_n$ where \mathbb{P}_i and \mathbb{Q}_i have the same input and output sets for all i and $\mathbb{P}_i = \mathbb{Q}_i$ might hold for a number of i 's. Now, verifying $\mathbb{P}_i \equiv_m \mathbb{Q}_i$ for every i is not of interest as $\mathbb{P}_i \not\equiv_m \mathbb{Q}_i$ does not necessarily imply $P \not\equiv_v Q$. However, the verification of $P \equiv_v Q$ can still be organized as a sequence of n module-level tests

$$\left(\bigsqcup_{j=1}^{i-1} \mathbb{Q}_j \right) \sqcup \mathbb{P}_i \sqcup \left(\bigsqcup_{j=i+1}^n \mathbb{P}_j \right) \equiv_m \left(\bigsqcup_{j=1}^{i-1} \mathbb{Q}_j \right) \sqcup \mathbb{Q}_i \sqcup \left(\bigsqcup_{j=i+1}^n \mathbb{P}_j \right) \quad (1)$$

where $1 \leq i \leq n$. The resulting chain of equalities conveys $P \equiv_v Q$ under the assumption that P and Q have a completely specified input. If not, then \equiv_m can be addressed in a similar fashion using (1).

Example 4 Consider $P = \mathbb{P}_1 \sqcup \mathbb{P}_2$ and $Q = \mathbb{Q}_1 \sqcup \mathbb{Q}_2$ where $\mathbb{P}_1 = (\{c \leftarrow \sim a.\}, \{a, b\}, \{c\})$, $\mathbb{P}_2 = (\{a \leftarrow b.\}, \emptyset, \{a, b\})$, $\mathbb{Q}_1 = (\{c \leftarrow \sim b.\}, \{a, b\}, \{c\})$ and $\mathbb{Q}_2 = (\{b \leftarrow a.\}, \emptyset, \{a, b\})$. Now $\mathbb{P}_1 \not\equiv_m \mathbb{Q}_1$ but $\mathbb{P}_1 \equiv_v \mathbb{Q}_1$ for all inputs generated by \mathbb{P}_2 and \mathbb{Q}_2 . Thus $\mathbb{P}_1 \sqcup \mathbb{P}_2 \equiv_m \mathbb{Q}_1 \sqcup \mathbb{Q}_2 \equiv_m \mathbb{Q}_1 \sqcup \mathbb{Q}_2$, $P \equiv_v Q$ and $P \equiv Q$.

The programs involved in each test (1) differ in \mathbb{P}_i and \mathbb{Q}_i for which the other modules form a common context, say \mathbb{C}_i . A way to optimize the verification of $\mathbb{P}_i \sqcup \mathbb{C}_i \equiv_m \mathbb{Q}_i \sqcup \mathbb{C}_i$ is to view \mathbb{C}_i as a module generating input for \mathbb{P}_i and \mathbb{Q}_i and to adjust the method from [15] to use $\text{EQT}(\mathbb{P}_i, \mathbb{Q}_i) \sqcup \mathbb{C}_i$ rather than $\text{EQT}(\mathbb{P}_i \sqcup \mathbb{C}_i, \mathbb{Q}_i \sqcup \mathbb{C}_i)$. We expect computational advantage from this strategy especially when the context \mathbb{C}_i is clearly larger than the modules \mathbb{P}_i and \mathbb{Q}_i .

6 RELATED WORK

The notion of modular equivalence is already contrasted with other equivalence relations in Sections 3 and 5.

³ Recall that \equiv_v coincides with \equiv for programs P and Q having equal and fully visible Herbrand bases.

Bugliesi et al. [2] present an extensive survey of modularity in conventional logic programming. Two mainstream programming disciplines can be identified: *programming-in-the-large* where programs are composed with algebraic operators and *programming-in-the-small* with abstraction mechanisms. Our approach belongs to the former discipline due to resemblance to [10] but stable model semantics and the denial of positive recursion between modules can be pointed out as obvious differences. Eiter et al. [6] present a programming-in-the-small approach to ASP and view program modules as *generalized quantifiers* the definitions of which are allowed to nest, i.e. P can refer to another module Q by using it as a generalized quantifier.

A variety of module conditions (cf. Definition 7) have been introduced. Maher [18] forbids all recursion between modules and considers Przymusinski's *perfect models* rather than stable models. Brogi et al. [1] employ operators for program composition and visibility conditions that correspond to the second item in Definition 7. However, their approach covers only positive programs and the least model semantics. Etalle and Gabbrielli [8] also seek congruence relations but for *constraint logic programs*. Their module architecture is based on a condition similar to ours, i.e. $\text{Hb}(P) \cap \text{Hb}(Q) \subseteq \text{Hb}_v(P) \cap \text{Hb}_v(Q)$, but no distinction of input and output is made.

Eiter, Gottlob, and Mannila [5] consider *disjunctive logic programs* as a query language for relational databases. Thus normal programs with variables are covered as a special case. A query program π is instantiated with respect to an input database D confined by an input schema \mathbf{R} . The semantics of π determines e.g. the stable models of $\pi[D]$ which are projected with respect to an output schema \mathbf{S} . In view of our work, π can be understood as a program module \mathbb{P} with input I and output O based on \mathbf{R} and \mathbf{S} , respectively, so that $\pi[D]$ corresponds to $\mathbb{P}(D)$. Their module architecture enables a generalization of splitting sets as both *positive and negative dependencies* are taken into account and no inter-module recursion is tolerated.

Faber et al. [9] apply the *magic set method* in the evaluation of Datalog programs with negation, i.e. effectively normal programs. This involves the concept of an *independent set* S of a program P which is a specialization of a splitting set. The rough idea is that S gives rise to a *module* $T = \{h \leftarrow B^+, \sim B^- \in P \mid h \in S\}$ of P so that $T \subseteq P$ and $\text{Head}(T) = S$ and the semantics of S is not affected by $P \setminus T$. Like splitting sets, independent sets are not that flexible in parceling NLPs. E.g., the splitting achieved in Example 2 is impossible. In view of our results, the account of *dangerous rules* unnecessarily pushes negative recursion inside modules. Moreover, the module theorem of Faber et al. [9] is weaker than Theorem 1.

7 CONCLUSION

In this article, we propose a module architecture for answer set programming. The compatibility of the module system and stable models is achieved by denying positive recursion between modules. A number of interesting results is obtained. First, the splitting set theorem [17] is generalized to a case where negative recursion is allowed between modules. Second, the respective equivalence relation \equiv_m is a proper congruence relation for the join operation \sqcup between modules. Third, the verification of modular equivalence can be accomplished with existing methods so that specialized solvers need not be developed. Last but not least, we have a preliminary plan how the task of verifying weak equivalence can be modularized using \equiv_m .

Yet the potential gain from the modular verification strategy has to be evaluated by conducting experiments. A further theoretical question is how the existing model theory based on *SE-models* and *UE-models* [3] is tailored to the case of modular equivalence. There is

also a need to expand the module architecture and module theorem proposed here to cover other classes of logic programs such as e.g. weight constraint programs, and disjunctive/nested programs.

Preference representation with 3-points intervals

Öztürk Meltem and Tsoukiàs Alexis¹

Abstract. In this article we are interested in the representation of qualitative preferences with the help of 3-points intervals (a vector of three increasingly ordered points). Preferences are crucial when an agent has to autonomously make a choice over several possible actions. We provide first of all an axiomatization in order to characterize our representation and then we construct a general framework for the comparison of 3-points intervals. Our study shows that from the fifteen possible different ways to compare 3-points intervals, seven different preference structures can be defined, allowing the representation of sophisticated preferences. We show the usefulness of our results in two classical problematics: the comparison of alternatives and the numerical representation of preference structures. Concerning the former one, we propose procedures to construct non classical preference relations (intransitive preferences for example) over objects being described by three ordered points. Concerning the latter one, assuming that preferences on the pairwise comparisons of objects are known, we show how to associate a 3-points interval to every object, and how to define some comparison rules on these intervals in order to have a compact representation of preferences described with these pairwise comparisons.

1 Introduction

The notion of preference, initially introduced by economists ([3, 6]) and researchers on Decision Making (DM) ([13, 11, 18, 17, 15]), has recently received an increasing attention in AI where artificial agents play the role of automated decision makers ([19, 7]).

In DM, preferences are used for two different problematics ([21]): the *comparison problem* and the *numerical representation problem*. These two problems arise naturally in AI since comparing objects and establishing preference (or any other order relations) is a key issue in knowledge representation and elicitation.

The *comparison problem* deals with the construction of preference relations over each pair of alternatives. In such a case evaluations of alternatives are known and may have different nature: numbers, colors, symbols, figures, intervals, fuzzy numbers, etc. The construction of relations may not be an easy task even with quantitative evaluations. For instance, consider a maximization problem with three alternatives (a , b and c) evaluated by numbers ($g(a) = 25$, $g(b) = 11$ and $g(c) = 9$). Depending on the context and/or the decision maker, we may have different relations. One solution may be to say that there are only strict preferences (a is strictly preferred to b and c (aPb and aPc) and b is strictly preferred to c (bPc)) while in a different context the alternatives b and c may be considered as indifferent (bIc) since the difference between their evaluation is not significant. It is clear that the relations obtained in the two different contexts do not have the same properties and they do not lead to the same model.

The numerical representation problem goes in the opposite way. The preference on each pair of alternatives being known, the problem is to check if there exists (and under which conditions) one or more real valued functions which, when applied to the set of alternatives, will return the preferences of the decision maker. As an example, consider three alternatives a , b and c for which the decision maker claims that he is indifferent between c and b and he strictly prefers c to a and b to a . There are several different numerical representations which could account for such preferences. One option may be to associate intervals $[0, 1]$ to a , $[2, 4]$ to b and $[3, 6]$ to c under the rules “ x is preferred to y iff the interval of x is completely to the right of the interval of y (no intersection) ”.

We consider both types of problems with a special attention to an interval representation. Comparing intervals is a problem relevant to several disciplines. We need intervals in order to take into account intransitivity of indifference due to the presence of one or more thresholds, to compare time intervals ([2]), or to represent imprecision or uncertainty (the price of x lies between A and B, the quality of y lies between “medium” and “good” ...). In this article, we make use of a special type of intervals that we call “3-points intervals” (intervals with an intermediate point). Such intervals contain only ordinal information (the distances between points are not important) which allows us to represent qualitative evaluations. Qualitative approaches become more and more attractive in AI since the only existing knowledge may be qualitative or it may be easier to get qualitative information from experts or qualitative rules may be easier and faster (see [4] and [5]).

The main contribution of this article is to propose a general framework for the comparison of 3-points intervals. The general advantage of these intervals is their capacity of representation, especially for sophisticated preferences. Our results are useful for both of the problematics. Concerning the comparison problem, our work shows how to compare two intervals having only ordinal information in order to fit some desired properties such as transitivity of preference, intransitivity of indifference etc. Concerning the numerical representation problem, there are two main advantages. First of all the use of 3-points intervals allows to represent complex preferences. For instance, the use of simple numbers remains inefficient in the majority of cases (only total orders and weak orders have a representation with numbers), such a reason has led to the use of intervals for different preference structures ([12, 8, 20, 16]). There are many results concerning the classical intervals (2-points intervals), however such intervals may appear insufficient face to more complex preferences (for example when the preference is intransitive). For that reason we are interested in 3-points intervals for which there is a limited number of research ([10]). Another advantage is related to the cardinality of the set of alternatives. When there are too many alternatives (let n be the number of alternatives), it can be preferable to stock only the 3-points interval representation of each alternative ($3 * n$ informa-

¹ LAMSADE - CNRS, Université Paris Dauphine, email: {ozturm, tsoukiás}@lamsade.dauphine.fr

tion) instead of stocking all the pairwise comparisons of alternatives ($\frac{n(n-1)}{2}$ information). From this point of view we can say that 3-points interval representation proposes a compact representation for complex preferences.

We organize the paper in the following way: in section 2 we introduce basic notations, we propose an axiomatization for the characterization of the 3-points interval representation. A general type of representation satisfying such axioms are also presented in this section. In section 3 we propose an exhaustive analysis of all the preference structures having a 3-points interval representation and in section 4 we conclude with some future research directions.

2 Basic notions and 3-points interval representation

In this paper we study complete preference structures with two binary relations: the strict preference relation P which is an asymmetric relation and the indifference relation I which is the symmetric complement of P . We introduce first of all some notions that we will use in the axiomatization.

We call a “3-points interval” an interval $x = [f_1(x), f_3(x)]$ with an intermediate point $f_2(x)$ (i.e. $f_1(x) < f_2(x) < f_3(x)$).

Then, we introduce a new notion that we call the “relative position” and that we denote by φ . The notation $\varphi(x, y)$ represents the position of the interval x with respect to the interval y ($\varphi(x, y) \neq \varphi(y, x)$).

Definition 1 (Relative position) *The relative position $\varphi(x, y)$ is the 3-tuple $(\varphi_1(x, y), \varphi_2(x, y), \varphi_3(x, y))$ where $\varphi_i(x, y)$ represents the number of j such that $f_i(x) < f_j(y)$.*

Intuitively, φ represents to what extend the position of two intervals is close to the case of two disjoint intervals, case which guarantees a strict preference. The following example illustrates the previous definition.

Example 1 *Let x and y be two 3-points intervals represented in figure 1, then $\varphi(x, y) = (1, 0, 0)$. $\varphi_1(x, y) = 1$ since there is only $f_3(y)$ being greater than $f_1(x)$ and $\varphi_2(x, y) = \varphi_3(x, y) = 0$ since $f_2(x)$ and $f_3(x)$ are greater than all the points of y .*

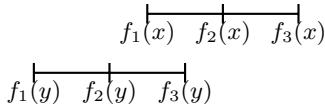

Figure 1. Relative position $\varphi(x, y) = (1, 0, 0)$

Let us remark that there are $20 \binom{(2*3)!}{(3!)^2}$ different relative positions when two 3-points intervals are compared.

The strict preference between two intervals depends on their relative positions and naturally there are some relative positions which are more suitable for the representation of a strict preference than others. For example the case where two intervals are disjoint is more suitable for a strict preference than a case where one interval is included to another. For such a purpose we introduce a new binary relation, called “stronger than”, on the set of relative positions.

Definition 2 (“Stronger than” relation) *Let φ and φ' be two relative positions, then we say that φ is “stronger than” φ' and note $\varphi \triangleright \varphi'$ if $\forall i \in \{1, \dots, n\}, \varphi_i \leq \varphi'_i$.*

We present an example showing how we define a “stronger than” relation.

Example 2 *Let $\varphi(x, y)$ and $\varphi(x, t)$ be two relative positions of the figure 2. We have $\varphi(x, y) = (1, 1, 0)$, $\varphi(x, t) = (2, 1, 0)$. We get “ $\varphi(x, y)$ is stronger than $\varphi(x, t)$ ” since $1 \leq 2$, $1 \leq 1$ and $0 \leq 0$.*

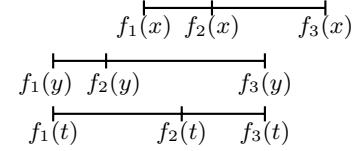

Figure 2. Example: $(1, 1, 0) \triangleright (2, 1, 0)$

The “stronger than” relation satisfies some classical properties:

Proposition 1 \triangleright is a partial order (reflexive, antisymmetric and transitive) defining a lattice on the set of possible relative positions.

Proof. \triangleright is a partial order since it is induced from the relation “ $<$ ” which is reflexive, antisymmetric and transitive. ■

Let us remark that the relation \triangleright is not complete: for example we have $(2, 0, 0) \not\triangleright (1, 1, 0)$ and $(1, 1, 0) \not\triangleright (2, 0, 0)$. We present in figure 3 the graph of the relation \triangleright .

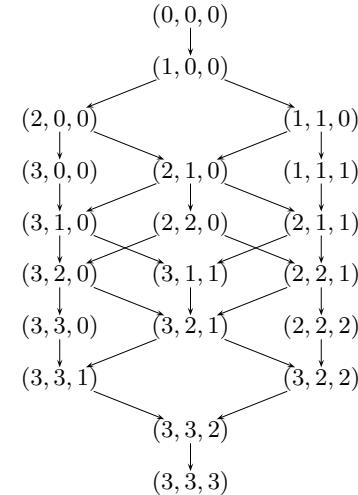

Figure 3. Graph of the stronger than relation

We are ready now to define the strict preference relation P and the indifference relation I . We will define P as a set of relative positions, satisfying some constraints, and construct I as the complement of P . For such a purpose we propose an axiomatization:

Axiome 1 *The relation $P \cup I$ is complete and I is the complement of P (i.e. $I(x, y) \Leftrightarrow \neg P(x, y) \wedge \neg P(y, x)$).*

Axiome 2 *The relations $P(x, y)$ and $I(x, y)$ depends only on the relative position of x and y .*

Axiome 3 *If a relative position φ is in the set of the strict preference P then all the relative positions which are stronger than φ are also in the set of P .*

Axiome 4 *If for all i , $f_i(x) < f_i(y)$ then $P(x, y)$ is not satisfied.*

Axiome 5 The set of relative positions forming P has one and only one weakest relative position (relative position which is weak than every relative position of the set).

Axiom 1 shows that P and I are exhaustive and exclusive, axiom 2 presents the comparison parameters and axiom 3 guarantees the monotonicity. Every relative position is not a good candidate to represent a strict preference. Axiom 4 eliminates some undesired situations in the definition of P . The role of the strongest relative position of a set of P is very important since we can determine all the other elements of the set by the help of the strongest one. Axiom 5 guarantees a unique representation for the strict preference relations by forbidding the existence of more than one strongest relative positions in their set.

It is easy to calculate the number of sets satisfying such axioms. Since every set has just one strongest relative position, every relative position may present one set, of course except the ones which do not satisfy the axiom 4. The number of relative positions with “for all i , $f_i(x) < f_i(y)$ ” is five ($\frac{1}{3+1} \binom{6}{3}$). Since there are, in total, twenty relative positions, the number of sets satisfying axioms 1-5 is fifteen.

We can present now the 3-points interval representation of a preference structure satisfying axioms 1-5. First of all, let's give a formal definition of the preference structure induced by the different possible relative positions of 3-points intervals.

Definition 3 Let $\varphi = (\varphi_1, \varphi_2, \varphi_3)$ be a 3-tuple in $\{0, 1, 2, 3\}$, and x and y two 3-points intervals. The preference relations $P_{\leq\varphi}, I_{\leq\varphi}$ associated to φ is defined as

$$\begin{aligned} P_{\leq\varphi}(x, y) &\iff \varphi(x, y) \triangleright \varphi \\ I_{\leq\varphi}(x, y) &\iff \neg P_{\leq\varphi}(x, y) \wedge \neg P_{\leq\varphi}(y, x) \end{aligned}$$

Now, consider the preference relation $P_{\leq(2,0,0)}$. Then $P_{\leq(2,0,0)}(x, y)$ iff $f_1(y) < f_1(x)$, $f_3(y) < f_2(x)$ and $f_3(y) < f_3(x)$. We can remark that the third inequality is redundant. This motivates the definition of the component set of a triple φ .

Definition 4 Let $\varphi = (\varphi_1, \varphi_2, \varphi_3)$ be a 3-tuple in $\{0, 1, 2, 3\}$. The component set $Cp_{\leq\varphi}$ associated to φ is the set of couples $(3 - \varphi_i, i)$ such that there is no $i' < i$ with $\varphi_{i'} \leq \varphi_i$.

For instance, $Cp_{\leq(2,0,0)} = \{(1, 1), (3, 2)\}$. Hence, $Cp_{\leq\varphi}$ represents the set of couples of points that are sufficient to be compared. Conditions on the elements of $Cp_{\leq\varphi}$ guarantees the minimality of the representation. The set $Cp_{\leq\varphi}$ contains all the information concerning the preference structure.

It is easy to verify that the preference structure associated to a triple φ verifies axioms 1,2,3 and 5. Following definition 4, one can show that axiom 4 is verified by $P_{\leq\varphi}$ iff $Cp_{\leq\varphi}$ contains at least one (i, j) with $i \geq j$.

3 3-points interval comparisons

In this section we analyze in details the fifteen sets of P satisfying our axiomatization. Let us remind that each set represents a strict preference relation which has a 3-points interval representation and the component set $Cp_{\leq\varphi}$ has the whole information about this representation.

Our study shows that from the fifteen sets of P , seven different preference structures can be defined, some of them having more than

one 3-points interval representation. For the sake of clarity, we will first of all present the classical definition of these seven structures, then give their equivalent characterization with 3-points intervals by the help of component sets and finally present in table 1 all the 3-points interval representations of these preference structures.

An exhaustive study of the 3-points intervals shows that weak orders and bi-weak orders have three different 3-points interval representations while three-weak orders have one, interval orders have three, split interval orders have one, triangle orders have two and intransitive orders have two. We present first of all the definition of each preference structure that we cited:

Let P be a binary relation on a finite set A and I be the symmetric complement of P , then

- $P \cup I$ is a *weak order* if and only if there exists a real-valued function f defined on A such that

$$\forall x, y \in A, xPy \iff f(x) > f(y)$$
- $P \cup I$ is a *bi-weak order* if and only if there exist two different real-valued functions f_1 and f_2 defined on A such that

$$\forall x, y \in A, xPy \iff \begin{cases} f_1(x) > f_1(y) \\ f_2(x) > f_2(y) \end{cases}$$

It is easy to see that bi-weak orders are defined as the intersection of two weak orders.
- $P \cup I$ is a *3-weak order* if and only if it is defined as the intersection of three weak orders.
- $P \cup I$ is an *interval order* if and only if there exist two real-valued functions f_1 and f_2 , defined on A such that

$$\begin{cases} \forall x, y \in A, xPy \iff f_1(x) > f_2(y) \\ \forall x \in A, f_2(x) > f_1(x) \end{cases}$$
- $P \cup I$ is a *split interval order* if and only if there exist three real-valued functions f_1 , f_2 and f_3 defined on A such that

$$\begin{cases} \forall x, y \in A, xPy \iff \begin{cases} f_1(x) > f_2(y), \\ f_2(x) > f_3(y), \\ \forall x \in A, f_3(x) > f_2(x) > f_1(x) \end{cases} \end{cases}$$
- $P \cup I$ is a *triangle order* if and only if it is defined as the intersection of one weak order and one interval order.
- $P \cup I$ is an *intransitive order* if and only if P is intransitive.

From these seven structures weak orders are the most used ones. Their difference from linear orders (total orders) comes from the fact that weak orders may have equivalence classes (two different objects may be considered as indifferent) which is forbidden in the case of linear orders. Bi-weak orders are also known structures, especially for the researchers of DM. They are equivalent to bilinear orders (interested reader may find more details in [9]). Three-weak orders were born from the generalization of bi-weak orders (for more details see [14]). Interval orders have been introduced by Fishburn ([8]). The relaxation of the coherence condition of semiorders (semiorders have an interval representation where each interval has the same length) has led to interval orders which are especially used in the presence of discrimination thresholds in order to represent intransitive indifference. Split interval orders are especially studied by mathematicians ([10]) and allow the representation of very sophisticated preferences. The name of triangle orders comes from their classical representa-

tion: an object is preferred to another one if and only if the triangle representing the first object is completely to the right of the triangle representing the second one (no intersection)(more details can be found in [14]). Intransitive orders are marginal orders, however they are used in some special domains (such as the biology in the case of cellule comparison or the chemistry in the case of molecular connection [1]). Circles are used in order to represent such structures: an object is preferred to another one if and only if the circle representing the first object is completely to the right of the circle representing the second one (circles may have different diameters). Unfortunately, we can not give here more details about these seven structures, interested reader may find more information in the cited references.

Let us remark that the classical representation of the majority of these structures do not make use of intervals (intervals can be seen as vectors of some ordered points). For instance weak orders use simple numbers while bi-weak orders (resp. three-weak orders) utilize two, not necessarily ordered numbers (resp. three points) (for instance we can have $f_1 < f_2$ or $f_2 < f_1$). Triangle orders are represented by triangles and intransitive orders by circles. Our study shows that all these seven structures have a 3-points interval representation. We will present now the general form of these representations by the help of component sets. We begin by some propositions concerning the transitivity properties since they are fundamental for some preference structures :

- $P_{\leq\varphi}$ is transitive if and only if $\forall(i, j) \in Cp_{\leq\varphi}, i \geq j$,
- $I_{\leq\varphi}$ is transitive if and only if $\exists i, Cp_{\leq\varphi} = \{(i, i)\}$,
- $P_{\leq\varphi} \cup I_{\leq\varphi}$ is a weak order if and only if $\exists i, Cp_{\leq\varphi} = \{(i, i)\}$,
- $P_{\leq\varphi} \cup I_{\leq\varphi}$ is a bi-weak order if and only if $|Cp_{\leq\varphi}| = 2$ and $\forall(i, j) \in Cp_{\leq\varphi}, i = j$,
- $P_{\leq\varphi} \cup I_{\leq\varphi}$ is a 3-weak order if and only if $|Cp_{\leq\varphi}| = 3$ and $\forall(i, j) \in Cp_{\leq\varphi}, i = j$,
- $P_{\leq\varphi} \cup I_{\leq\varphi}$ is an interval order if and only if $Cp = \{(i, j)\}$ where $i \geq j$,
- $P_{\leq\varphi} \cup I_{\leq\varphi}$ is a triangle order if and only if $Cp_{\leq\varphi} = \{(l, l), (i, j)\}$, where $i \geq j$,
- $P_{\leq\varphi} \cup I_{\leq\varphi}$ is a intransitive order if and only if $\exists(i, j) \in Cp_{\leq\varphi}, i < j$.

We present now the key-steps of the proofs of these general propositions.

- **The transitivity of $P_{\leq\varphi}$:**
 - If $\forall(i, j) \in Cp_{\leq\varphi}, i \geq j$ then $P_{\leq\varphi}$ is transitive: obvious.
 - If $P_{\leq\varphi}$ is transitive then $\forall(i, j) \in Cp_{\leq\varphi}, i \geq j$: we prove this result by showing that if $\exists(i, j) \in Cp_{\leq\varphi} i < j \implies \exists x, y, z, P_{\leq\varphi}(x, y) \wedge P_{\leq\varphi}(y, z)$ and $\neg P_{\leq\varphi}(x, z)$.
- **The transitivity of $I_{\leq\varphi}$:**
 - $Cp_{\leq\varphi} = \{(i, i)\}$ implies $I_{\leq\varphi}$ is transitive: obvious.
 - $I_{\leq\varphi}$ is transitive implies $Cp_{\leq\varphi} = \{(i, i)\}$: we prove this result by contradiction. Supposing that $I_{\leq\varphi}$ is transitive we analyze two different cases: $\exists(i, j) \in Cp_{\leq\varphi}, i \neq j$, and $\forall(i, j) \in Cp_{\leq\varphi}, i = j$ and $|Cp_{\leq\varphi}| > 1$. We show that these two

cases are contradictory with the transitivity of $I_{\leq\varphi}$.

- **Weak order:**

- If $Cp_{\leq\varphi} = \{(i, i)\}$ then $P_{\leq\varphi} \cup I_{\leq\varphi}$ is a weak order: we prove that $I_{\leq\varphi}$ and $P_{\leq\varphi}$ are transitive and $P_{\leq\varphi} \cup I_{\leq\varphi}$ is reflexive and complete.

- If $P_{\leq\varphi} \cup I_{\leq\varphi}$ is a weak order then $Cp_{\leq\varphi} = \{(i, i)\}$: the key idea is the transitivity of $I_{\leq\varphi}$. If $P_{\leq\varphi} \cup I_{\leq\varphi}$ is a weak order then $I_{\leq\varphi}$ is transitive and if $I_{\leq\varphi}$ is transitive then $Cp_{\leq\varphi} = \{(i, i)\}$.

- **Bi-weak order:** the proof follows directly from the one of weak orders.

- **Three-weak order:** the proof follows directly from the one of weak orders.

- **Interval order:** for this proof we make use of the relational characterization of an interval order: $P \cup I$ is an interval order if

$$\begin{cases} P.I.P \subset P, \\ P \cup I \text{ is reflexive and complete.} \end{cases}$$

where $P.I.P \subset P$ means $\forall x, y, z, t$, if $P(x, y) \wedge I(y, z) \wedge P(z, t)$ then $P(x, t)$.

We prove first of all that $P_{\leq\varphi}.I_{\leq\varphi}.P_{\leq\varphi} \subset P_{\leq\varphi}$ iff $Cp = \{(i, j)\}$ where $i \geq j$:

- If $Cp = \{(i, j)\}$ where $i \geq j$ then $P_{\leq\varphi}.I_{\leq\varphi}.P_{\leq\varphi} \subset P_{\leq\varphi}$: obvious.

- If $P_{\leq\varphi}.I_{\leq\varphi}.P_{\leq\varphi} \subset P_{\leq\varphi}$ then $Cp = \{(i, j)\}$ where $i \geq j$: first of all if $Cp = \{(i, j)\}$ with $i < j$ then $P_{\leq\varphi}$ is not transitive. In this case it is easy to see that when $I_{\leq\varphi}$ is the identity $P_{\leq\varphi}.I_{\leq\varphi}.P_{\leq\varphi} \subset P_{\leq\varphi}$ is not satisfied. We prove then that if $|Cp_{\leq\varphi}| > 1$ then $\neg(P_{\leq\varphi}.I_{\leq\varphi}.P_{\leq\varphi} \subset P_{\leq\varphi})$. We analyze two cases where $|Cp_{\leq\varphi}| > 1$: $\exists(i, j) \in Cp_{\leq\varphi}, i < j$ and $\forall(i, j) \in Cp_{\leq\varphi}, i \geq j$. The first one provides an intransitive $P_{\leq\varphi}$. The key point of the analysis of the second case is the definition of $I_{\leq\varphi}$ when $|Cp_{\leq\varphi}| > 1$: let $(i, j), (l, m)$ be elements of $Cp_{\leq\varphi}$ then $f_i(x) \geq f_j(y) \wedge f_l(y) \geq f_m(x)$ with $(i, j) \neq (l, m) \implies I_{\leq\varphi}(x, y)$. It is easy to see that this implication has one part where a point of x is greater than a point of y and another part which inverses such inequality. In this case one can always find four elements w, x, y, z such that $P_{\leq\varphi}(w, x), I_{\leq\varphi}(x, y), P_{\leq\varphi}(y, z)$ and $\neg P_{\leq\varphi}(w, z)$.

We can now proof the characterization of interval orders:

- If $Cp = \{(i, j)\}$ where $i \geq j$ then $P_{\leq\varphi} \cup I_{\leq\varphi}$ is an interval order: we prove that $P_{\leq\varphi} \cup I_{\leq\varphi}$ is reflexive and complete and $P_{\leq\varphi}.I_{\leq\varphi}.P_{\leq\varphi} \subset P_{\leq\varphi}$.

- If $P_{\leq\varphi} \cup I_{\leq\varphi}$ is an interval order then $Cp = \{(i, j)\}$ where $i \geq j$: if $P_{\leq\varphi} \cup I_{\leq\varphi}$ is an interval order then $P_{\leq\varphi}.I_{\leq\varphi}.P_{\leq\varphi} \subset P_{\leq\varphi}$ which implies $|Cp_{\leq\varphi}| = 1$.

- **Triangle order:** the proof follows directly from the ones of weak orders and of interval orders.

- **Intransitive order:** the proof follows directly from the transitivity of $P_{\leq\varphi}$.

These propositions give us general representations of structures in the sense that these are also true for intervals having more than 3 points. We can conclude now this section by presenting all the 3-points interval representations for the seven preference structures in table 1.

Preference Structure	$\langle P_{\leq\varphi}, I_{\leq\varphi} \rangle$ interval representation
Weak Orders	$Cp_{\leq(3,3,0)} = \{(3,3)\}$ $Cp_{\leq(3,1,1)} = \{(2,2)\}$ $Cp_{\leq(2,2,2)} = \{(1,1)\}$
Bi-weak Orders	$Cp_{\leq(3,1,0)} = \{(2,2), (3,3)\}$ $Cp_{\leq(2,1,1)} = \{(1,1), (2,2)\}$ $Cp_{\leq(2,2,0)} = \{(1,1), (3,3)\}$
Three-Weak Orders	$Cp_{\leq(2,1,0)} = \{(1,1), (2,2), (3,3)\}$
Interval Orders	$Cp_{\leq(0,0,0)} = \{(3,1)\}$ $Cp_{\leq(3,0,0)} = \{(3,2)\}$ $Cp_{\leq(1,1,1)} = \{(2,1)\}$
Split Interval Orders	$Cp_{\leq(1,0,0)} = \{(3,2), (2,1)\}$
Triangle Orders	$Cp_{\leq(1,1,0)} = \{(2,1), (3,3)\}$ $Cp_{\leq(2,0,0)} = \{(1,1), (3,2)\}$
Intransitive Orders	$Cp_{\leq(3,2,0)} = \{(3,3), (1,2)\}$ $Cp_{\leq(2,2,1)} = \{(1,1), (2,3)\}$

Table 1. Preference structures with 3-points interval representation

4 Conclusion

Our study provides an exhaustive view of the comparison of 3-points intervals. Concerning the comparison problem, we have defined and analyzed all the possible 3-points interval comparison procedures that satisfy our axiomatization. Our analysis allows us to know which procedure provides which preference structure and to detect the properties of the resulted preference relations. Concerning the numerical representation problem, we know now all the preference structures having a 3-points interval representation. When ordered points are used, the use of exactly three points is optimal for three-weak orders, triangle orders, split interval orders and intransitive orders, however weak orders, bi-weak orders and interval orders need less than three ordered points. The classical representation of triangle orders and intransitive orders make use of geometric figures (dimension two). As a result they have more complicated comparison rules (for example the comparison of circles is done by a quadratic function) and the representation of preferences needs more space. By proposing a 3-points interval representation we facilitate the comparison rules and the preference representation. We show also that preference structures may have more than one representation.

A possible interesting extension would be the generalization of our study in the case n -points intervals. Such a generalization would offer a general framework for the comparison of ordinal intervals and would allow a systematic study of all the preference structures having an interval representation (for instance for $n=4$ there are 56 sets of P , some of them are already known thanks to the propositions that we presented in this paper).

ACKNOWLEDGEMENTS

This work has been supported by the ANR project PHAC which is gratefully acknowledged. We would like to thank Bruno Escoffier and Olivier Spanjaard for many fruitful discussions on this paper and three anonymous referees for their useful comments.

Reference-dependent Qualitative Models for Decision Making under Uncertainty

Patrice Perny and Antoine Rolland¹

Abstract. The aim of this paper is to introduce and investigate a new family of purely qualitative models for decision making under uncertainty. Such models do not require any numerical representation and rely only on the definition of a preference relation over consequences and a relative likelihood relation on the set of events. Within this family, we focus on decision rules using reference levels in the comparison of acts. We investigate both the descriptive potential of such rules and their axiomatic foundations. We introduce in a Savage-like framework, a new axiom requiring that the Decision Maker's preference between two acts depends on the respective positions of their consequences relatively to reference levels. Under this assumption we determine the only possible form of the decision rule and characterize some particular instances of this rule under transitivity constraints.

1 INTRODUCTION

In the past decade, Decision Making under uncertainty has received much attention in Artificial Intelligence. This is also a traditional topic in Economics where several important results have been published, justifying the use of various criteria, for the comparison of actions under risk and uncertainty. The multiplicity of studies and models developed is easily explainable by the variability of contexts for decision making and the diversity of decision making behaviors we want to describe, explain or simulate. In Decision Theory, axiomatic analysis began with the seminal work of Von Neumann and Morgenstern [16] and Savage [17] providing the foundations of the expected utility model (EU). Despite its normative appeal, the descriptive limits of EU have led mathematical economists to study alternatives to Savage's theory and to propose various sophisticated extensions of EU, e.g non-additive integrals like CEU [18]. In this direction, most decision models rely on a cardinal numerical representation of preference (utilities) and uncertainty (probabilities, belief functions and other capacities). Besides this very active current, a parallel stream, with a different focus, is presently developing in AI. Indeed, the need of expressive languages for preference handling and reasoning as well as the aim of developing autonomous decision-making agents in real contexts (with poor information) has led researchers to investigate qualitative models. Although less ambitious in their descriptive and prescriptive objectives, they are more operational in practice because they require less information about preference and likelihood of events. In this direction, several qualitative alternatives to EU have been investigated [2, 3, 7, 15, 8, 13, 14, 19].

As pointed out in [4], most of these models, quantitative or qualitative, rely on a numerical representation where utility and uncertainty are commensurate. To escape this assumption which is not always

seen as natural, recent papers (see e.g. [5, 4]) investigate an alternative approach based on purely qualitative models, i.e. models that only require the definition of a preference order over consequences and a relative likelihood relation on the set of events. This is the case of Likely Dominance Rules [6, 4] that have been recently introduced in AI and characterized by an Ordinal Invariance Axiom (OI) stating that preferences between two acts only depend on the relative position of their consequences for each state. Unfortunately such models do not offer much flexibility to describe beliefs and preferences in practice. On one hand, due to OI they satisfy (as EU) Savage's "Sure Thing Principle" which is sometimes contradicted by observed decision making behaviors. On the other hand, the needs to compose purely ordinal and non-commensurate information (likelihood of events, preferences over consequences) induces a conflict between descriptive and normative objectives. Either preferences rely on a coarse belief structure induced by the existence of a predominant event masking any other event in the analysis or they violate minimal transitivity properties required to justify choices or rankings over acts (this is a consequence of Arrow's theorem, see [1, 4]). To overcome these descriptive and prescriptive limitations, we investigate in this paper an alternative framework (escaping OI) for purely qualitative models. It is based on the introduction of an axiom requiring that preferences between acts depend on the respective position of their consequences (for each state) relatively to reference levels.

The paper is organized as follows: in Section 2, we provide various simple examples showing the descriptive potential of qualitative models based on reference levels. Then, we introduce in Section 3 an axiomatic framework for reference-dependent qualitative models; we determine the possible forms of admissible decision rules. Finally we characterize in Section 4 some particular instance of these rules and discuss the results in the light of Arrow's theorem and extensions.

2 REFERENCE-DEPENDENT PREFERENCES

2.1 Preliminary definitions and notations

We consider here decision-making problems under uncertainty characterized by a 4-tuple $(S, X, \mathcal{A}, \succsim)$, where S is a finite set of the possible *states of nature*, X is the set of the possible *consequences* of acts, $\mathcal{A} = X^S$ is the set of *potential acts*, that is the set of functions $f : S \rightarrow X$, and \succsim is a *preference relation* on \mathcal{A} . Within \mathcal{A} there exist acts leading to the same consequence for all states in S . These acts are called *constant acts* and denoted f_x for any $x \in X$. For any preference relation \succsim , its asymmetric part defines a strict preference denoted \succ and defined by: $x \succ y \Leftrightarrow (x \succsim y \text{ and not}(y \succsim x))$; its symmetric part defines an indifference relation denoted \sim and defined by $x \sim y \Leftrightarrow (x \succsim y \text{ and } y \succsim x)$. If \succsim is transitive, then

¹ LIP6 – University of Paris 6, France, email: firstname.name@lip6.fr

relations \succ and \sim are transitive. A relation \succsim is said to be *quasi-transitive* if its asymmetric part \succ is transitive.

Following Savage terminology, we call *event* any subset A of S . For any pair of acts f and g , the act fAg is defined by: $fAg(s) = f(s)$ if $s \in A$ and $g(s)$ if $s \notin A$. To simplify notation, whenever f or g is a constant act f_x we write fAx (resp. xAg) instead of fAf_x (resp. f_xAg). An event A is said to be null if and only if: $\forall f, g, h \in \mathcal{A} : fAh \sim gAh$. Any event $A \subseteq S$ able to make a discrimination for at least one pair of acts is not null.

2.2 Motivating examples

In order to introduce, by example, likelihood dominance rules as well as reference-dependent models, consider the following game:

Example 1 Consider a two-player game with 3 fair dice with unusual points (see [12]) $f = (1, 4, 4, 4, 4, 4)$, $g = (3, 3, 3, 3, 3, 6)$ and $h = (2, 2, 2, 5, 5, 5)$. Player 1 gets a choice of whichever die he wants, then Player 2 picks one of the remaining dice. They each roll n times, and whoever scores higher the most times, wins. As the second player, which die should we pick?

This can be formalized by considering 8 (virtual) states corresponding to all possible combinations of outcomes, as follows:

	s_1	s_2	s_3	s_4	s_5	s_6	s_7	s_8
P	5/72	5/72	1/72	1/72	25/72	25/72	5/72	5/72
f	1	1	1	1	4	4	4	4
g	3	3	6	6	3	3	6	6
h	2	5	2	5	2	5	2	5

Here preferences over dice can be stated by a Likely Dominance Rule (LDR, [4]): $f \succsim g \Leftrightarrow \{s \in S, f(s) \geq g(s)\} \succsim_{\Lambda} \{s \in S, g(s) \geq f(s)\}$ where \succsim_{Λ} is a likelihood relation on the sets of events $\Lambda = 2^S$ induced by the probability of events. Such a definition only uses two binary relations (\geq and \succsim_{Λ}). Note that we have here: $P(f > g) = 50/72$, $P(g > h) = 42/72$, $P(h > f) = 42/72$, which means that $f \succ g$, $g \succ h$ and $h \succ f$ yielding to intransitive preferences. This gives a winning strategy to Player 2 who can always choose a better die than Player 1. The possibility of describing intransitive preferences is typical of Likely Dominance Rule as defined in [4] to compare acts in decision making problems under uncertainty. A variant of the game consists in changing the rule into: “whoever scores higher or equal than ‘4’ the most times, wins”. Here preferences over dice are defined by: $f \succsim g \Leftrightarrow \{s \in S, f(s) \geq 4\} \succsim_{\Lambda} \{s \in S, g(s) \geq 4\}$. In this case, the introduction of reference level ‘4’ yields a transitive preference order: $f \succ h \succ g$. Such a model is an example of reference-depend LDR we intend to investigate in the paper.

Example 2 We consider the “Ellsberg” example [9] with an urn containing blue, red, and green balls. We only know that the proportion of blue balls is 1/3. The player is invited to pay \$p to play one of the following games f and g : he draws a ball then f wins \$ $q > 3p$ if the ball is blue and g wins \$ q if the ball is red. Then he has a second choice between two other games: f' wins \$ q if the ball is blue or green, g' wins \$ q if the ball is red or green.

Experiments show that people often prefer f to g (because they are not sure that there is at least 1/3 of red balls in the urn) but prefer g' to f' (because they are sure there is 2/3 of red or green balls). Such a decision problem can be formalized as follows: We consider 3 states s_1 (blue), s_2 (red), s_3 (green) and the two possible consequences $x = q - p$, $y = -p$. The 4 games are represented by acts f, g, f', g' with the following consequences:

	f	g	f'	g'
s_1	x	y	x	y
s_2	y	x	y	x
s_3	y	y	x	x

Such preferences are not compatible with the so-called “Sure-thing Principle” (P2) introduced by Savage [17] in the characterization of EU. This principle states that the preference $f \succsim g$ does not depend on states where the two acts have the same consequences. Here this principle is violated because we have $f \succ g$ and $g' \succ f'$, a strict preference reversal only due to a shift from y to x on s_3 . This reversal makes impossible to represent such preferences by EU or by its qualitative counterparts proposed in [7]. Remark that $\{s \in S, f(s) \geq g(s)\} = \{s \in S, f'(s) \geq g'(s)\} = \{s_1, s_3\}$ and $\{s \in S, g(s) \geq f(s)\} = \{s \in S, g'(s) \geq f'(s)\} = \{s_2, s_3\}$. Then the different status given to pairs (f, g) and (f', g') show that preferences between two acts do not only depend on the relative position of their consequences for each state. This makes it impossible to represent such preferences with an LDR. However, the introduction of a reference level can easily solve the problem. Indeed preferences can be explained by the following reference-dependent rule:

$$f \succsim g \iff \{s \in S, f(s) \geq 0\} \succsim_{\Lambda} \{s \in S, g(s) \geq 0\} \quad (1)$$

with $s_1 \succsim_{\Lambda} s_2$ and $\{s_2, s_3\} \succsim_{\Lambda} \{s_1, s_3\}$. These examples show that the introduction of one (or several) reference levels can facilitate the description of observed preferences in some cases. We investigate now in a more formal framework reference-depend ordinal models.

3 AN AXIOMATIC FRAMEWORK

3.1 Axioms

We introduce in this section some axioms for reference-dependent preferences. We start from axioms considered by Savage [17] in the characterization of the EU model and introduce some variations more suitable in our framework. Then we will introduce more specific axioms designed to capture reference-dependent preferences. In the original framework, Savage assumes that Decision Maker’s (DM) preferences over acts have a complete weak order structure (P1 principle). This is necessary to characterize the EU model which requires, by definition, completeness and transitivity of preferences.

Axiom P1. \succsim is a complete weak-order on \mathcal{A} , i.e., \succsim is reflexive, complete and transitive.

We consider here a wider class of models including partial preference structures not necessarily transitive. Hence, we recall the P1 principle of Savage and introduce a weak version relaxing transitivity for quasi-transitivity:

Axiom WP1. \succsim is reflexive and quasi-transitive and its restriction to constant acts is a complete order.

The second axiom of Savage is the so-called *sure-thing principle* (P2). As mentioned above, it requires that the preference between two acts fAh and gAh does not depend on the choice of h . This axiom does not necessarily hold when reference levels are used in a decision models. This is quite natural as reference-dependent preferences might be such that $fAh \succ gAh$ and $gAh' \succ fAh'$, as shown by Example 2. In this example indeed, setting $A = \{s_1, s_2\}$ we have $f = fAy$, $g = gAy$, $f' = fAx$, and $g' = gAx$. Hence $f \succ g$ and $g' \succ f'$ contradict P2. This strict preference reversal would also contradict a weaker version of P2 considered in the axiomatization of qualitative utilities [8].

In order to reveal Decision Maker's preferences over certain consequences, the comparison of constant acts is of particular interest. We can indeed consider the following relation:

$$\forall x, y \in X, (x \succsim_X y \Leftrightarrow f_x \succsim f_y) \quad (2)$$

This definition is self consistent provided that the preference over constant acts should not admit rank reversal of type $f_x Ah \succ f_y Ah$ and $f_x Ah' \prec f_y Ah'$. This can be captured by the following Savage's P3 postulate:

$$\text{Axiom P3. } \forall A \subseteq S, \forall h \in A, (x \succsim_X y \Leftrightarrow f_x Ah \succsim f_y Ah).$$

However, $x \succ_X y$ is not always sufficient to justify a preference of type $f_x Ah \succ f_y Ah$. For example, when A is a weakly plausible event, we might have: $f_x Ah \sim f_y Ah$ for some h . This justifies the following weakening of P3:

$$\text{Axiom WP3. } \forall A \subseteq S, \forall h \in A, (x \succ_X y \Rightarrow f_x Ah \succsim f_y Ah).$$

The fourth principle P4 is introduced by Savage to reveal from \succsim a consistent likelihood relation over the set of events. This axiom writes as follows:

$$\text{Axiom P4. } \forall A, B \subseteq S, \forall x, y, x', y' \in X : x \succ_X y \text{ and } x' \succ_X y', xAy \succsim xBy \Leftrightarrow x'Ay' \succsim x'By'.$$

We will not directly use P4 here, as it is a by-product of a stronger axiom introduced later. We introduce now the P5 principle of Savage requiring that preferences over constant acts are not trivial.

$$\text{Axiom P5. } \exists x, y \in X \text{ s.t. } f_x \succ f_y \text{ (i.e. } x \succ_X y\text{).}$$

Under WP1 and P5 we know that \sim_X , the symmetric part of \succsim_X is an equivalence relation with at least two classes. Assuming there exist $q+1$ distinct equivalence classes ($1 \leq q < |X|$), r_i will denote any element of X representing class i , in such a way that $f_{r_i} \succ_X f_{r_{i+1}}$, $i = 1, \dots, q$. The set of all but the worst reference levels is denoted $\mathcal{R} = \{r_1, \dots, r_q\}$ and represents the various significant separating levels in X . In the next section, to avoid trivial cases, we will consider SP5, a slight reinforcement of P5 requiring 4 distincts preference levels on the consequence scale. This means that at least 3 different reference levels do exist, which implies that the structure is rich enough to allow problematic situations as Condorcet triples (see Example 5). The axiom writes as follows:

$$\text{Axiom SP5. } \exists x, y, z, w \in X \text{ s.t. } f_x \succ f_y \succ f_z \succ f_w.$$

We introduce now a more specific axiom stating that preferences over acts only depend on the respective positions of their consequences relatively to these *reference levels*. To this end, the following *reference events* have a particular importance:

$$\forall r \in \mathcal{R}, F_r = \{s \in S, f(s) \succsim_X r\} \quad (3)$$

For acts g, h, \dots we will use the notations G_r, H_r, \dots respectively. For the sake of simplicity, event F_{r_k} will be denoted F_k , for $k = 1, \dots, q$. With these notations, the axiom writes:

$$\text{Axiom SRL (Separability w.r.t. Reference Levels) } \forall f, g, f', g' \in \mathcal{A}, \forall i, j \in \{1, \dots, q\},$$

$$\left. \begin{array}{l} F_i = F'_j, G_i = G'_j \\ \forall k \neq i, F_k = G_k \\ \forall k \neq j, F'_k = G'_k \end{array} \right\} \Rightarrow [f \succsim g \Leftrightarrow f' \succsim g']$$

A direct consequence of SRL is the following:

$$\text{Axiom DRE (Dependence w.r.t. Reference Event)}$$

$$\left. \begin{array}{l} \forall r \in \mathcal{R}, F_r = F'_r \\ \forall r \in \mathcal{R}, G_r = G'_r \end{array} \right\} \Rightarrow [f \succsim g \Leftrightarrow f' \succsim g']$$

Axiom DRE requires that the preference between two acts only depends on the respective position of their consequences (for each state) with respect to reference levels in \mathcal{R} . In this respect, it can be seen as the natural variant of the Ordinal Invariance Axiom [4] enforcing ordinal comparisons between acts to rely on reference levels. It can easily be shown that SRL implies DRE, but the converse is not true as can be seen in the following example.

Example 3 Suppose that $S = \{s_1, s_2, s_3, s_4\}$ and consider x, y, z 3 consequences of X such that $x \succ_X y \succ_X z$. Consider two reference levels $r_1 = x, r_2 = y$ and 4 acts $f, g, f', g' \in \mathcal{A}$ such that:

	s_1	s_2	s_3	s_4		s_1	s_2	s_3	s_4	
f	x	y	y	z		f'	y	x	y	z
g	x	y	z	y		g'	y	x	z	y

We have $F_1 = G_1 = \{s_1\}$, $F'_1 = G'_1 = \{s_2\}$, $F_2 = F'_2 = \{s_1, s_2, s_3\}$ and $G_2 = G'_2 = \{s_1, s_2, s_4\}$. If $f \succ g$ and $g' \succ f'$, then axiom SRL does not hold (just choose $q = 2, i = j = 2, k = 1$ in the formulation of SRL). Yet this situation is compatible with DRE.

In the context of reference-dependent models, the relative likelihood of events can be assessed by observing conflicting events in the respective comparison of consequences of two acts f and g relatively to reference levels. Following this idea, a relative likelihood relation \succsim_Λ over the set of events $\Lambda = 2^S$ might be derived from \succsim by setting, for all $A, B \subseteq S$:

$$A \succsim_\Lambda B \Leftrightarrow \exists f, g \in \mathcal{A}, \exists r \in \mathcal{R}, \left\{ \begin{array}{l} F_r = A, G_r = B \\ \forall t \in \mathcal{R} - \{r\}, F_t = G_t \\ f \succsim g \end{array} \right. \quad (4)$$

Such a construction only makes sense if there is no antagonist pairs of acts (f, g) and (f', g') inducing respectively $A \succsim_\Lambda B$ and $B \succsim_\Lambda A$ by Equation (4). Axiom SRL excludes such situations: suppose that two subsets of S , A and B are such that there exists $f, g \in X$, $f', g' \in X$ such that $f \succsim g$ implies $A \succsim_\Lambda B$ and $g' \succ f'$ implies $B \succsim_\Lambda A$. If $f \succsim g$ implies $A \succsim_\Lambda B$, it means that $\exists r \in \mathcal{R}, F_r = A$, $G_r = B$ and $\forall p \neq r, F_p = G_p$. If $g' \succ f'$ implies $B \succsim_\Lambda A$, it means that $\exists r' \in \mathcal{R}, F'_{r'} = A, G'_{r'} = B$ and $\forall p \neq r', F'_p = G'_p$. Such a situation is not compatible with the respect of axiom SRL.

3.2 Ordinal reference dependent rules

Under SRL we can define, for any reference level $r \in \mathcal{R}$ a reference-based preference relation \succsim_r over acts by:

$$f \succsim_r g \Leftrightarrow F_r \succsim_\Lambda G_r \quad (5)$$

The profile $(\succsim_{r_1}, \dots, \succsim_{r_q})$ of reference-based preferences relations contains any useful information that might be used in an ordinal reference dependent model. We introduce now an axiom of *ordinal invariance with respect to reference-based preferences* (OIRP) requiring that preferences between two acts only depend on the relative position of these acts in the q reference-based preferences relations.

$$\text{Axiom OIRP } \forall f, g, f', g' \in \mathcal{A}:$$

$$\left. \begin{array}{l} \forall r \in \mathcal{R}, f \succsim_r g \Leftrightarrow f' \succsim_r g' \\ \forall r \in \mathcal{R}, g \succsim_r f \Leftrightarrow g' \succsim_r f' \end{array} \right\} \Rightarrow [f \succsim g \Leftrightarrow f' \succsim g']$$

This axiom is a transposition to reference-based preferences of the OI axiom used in [4] to characterize Likely Dominance Rules. Without OIRP, nothing guarantees that the preference between two acts f and g only depends on the status of relations $\succsim_{r_j}, j = 1, \dots, q$ on the pair (f, g) .

Example 4 Suppose that x, y, z, w are four consequences of X such that $x \succ_X y \succ_X z \succ_X w$. Let x, y and z be three reference levels and f, g, f', g' be four acts of \mathcal{A} such that:

$s_1 \quad s_2 \quad s_3$			$s_1 \quad s_2 \quad s_3$		
$f \quad x \quad y \quad w$	$f' \quad x \quad w \quad w$		$g \quad y \quad y \quad z$	$g' \quad y \quad z \quad z$	

Suppose that the DM beliefs about possible events are such that $A \succsim_\Lambda B \Leftrightarrow |A| \geq |B|$ (which means that, for example, $(x, y, y) \succ (y, y, y)$). Then we have $f \succ_x g$, $f \sim_y g$, $f \prec_z g$ and $f' \succ_x g'$, $f' \sim_y g'$, $f' \prec_z g'$. If DM preferences are such that $f \succ g$ and $g' \succ f'$, which does not contradict axiom SRL, then nothing in the profile $(\succsim_x, \succsim_y, \succsim_z)$ can explain the different status of pairs (f, g) and (f', g') according to \succsim . OIRP precisely avoids such preference situations. Actually it avoids any situation where a preference between two acts might depend on other acts (an idea closed to Arrow independence of irrelevant alternative [1]).

Hence SRL and OIRP characterize an interesting class of reference-dependent preferences that can be obtained by ordinal aggregation of the profile $(\succsim_{r_1}, \dots, \succsim_{r_q})$. Among others, one can check that the combination of SRL and OIRP implies P4. We can now state a proposition giving the general form of such reference-based likely dominance rules (RLD rules for short). Note that the following proposition is to be interpreted under the WP3 assumption, although not formally necessary to establish the result.

Proposition 1 If the preference relation \succsim on \mathcal{A} satisfies axioms SRL and OIRP, then there exists a relation \succsim_R defined on $R = 2^{\mathcal{R}}$ such that:

$$f \succsim g \Leftrightarrow \{r \in \mathcal{R}, f \succsim_r g\} \succsim_R \{r \in \mathcal{R}, g \succsim_r f\} \quad (6)$$

Proof. Thanks to SRL, an importance relation \succsim_Λ can soundly be revealed from \succsim by Equation (4). We then define a relation \succsim_R on the subsets of \mathcal{R} as follows: consider Q and Q' two subsets of \mathcal{R} , $Q \succsim_R Q' \Leftrightarrow \exists f, g \in \mathcal{A}$ such that $[Q = \{r \in \mathcal{R}, F_r \succsim_\Lambda G_r\}, Q' = \{r \in \mathcal{R}, G_r \succsim_\Lambda F_r\}]$ and $f \succsim g$. Hence, suppose that there are two couples of $\mathcal{A} \times \mathcal{A}$ f, g and f', g' such that $Q = \{r \in \mathcal{R}, F_r \succsim_\Lambda G_r\} = \{r \in \mathcal{R}, F'_r \succsim_\Lambda G'_r\}$ and $Q' = \{r \in \mathcal{R}, G_r \succsim_\Lambda F_r\} = \{r \in \mathcal{R}, G'_r \succsim_\Lambda F'_r\}$. Thanks to axiom OIRP, we have $f \succsim g \Leftrightarrow f' \succsim g'$, which showss that relation \succsim_R is soundly defined. Indeed, we cannot have $Q \succsim_R Q'$ with a pair (f, g) and $Q \prec_R Q'$ with another pair (f', g') . \square

Relation \succsim_R reflects the relative importance attached to subsets of consequences by the DM. The reference-based rule given in Equation (6) is formally equivalent to a Likely Dominance Rule [4] applied on reference-dependent relations \succsim_r for all $r \in \mathcal{R}$ instead of state-dependent relations \succsim_s defined by $f \succsim_s g \Leftrightarrow f(s) \succsim_X g(s)$, for all $s \in S$. In the next section, we investigate the structure of such rules under the assumption of transitivity for \succsim .

4 AXIOMATIC CHARACTERIZATION

The axioms used to establish Proposition 1 are not sufficient to derive a fully operational decision rule. Indeed, nothing guarantees that \succsim constructed according to Equation (6) is transitive or even quasi-transitive. The following example shows indeed that natural relations \succsim_R based on a majority rule might fail to produce transitive relations, as Condorcet's triplets can appear in the profile $(\succsim_{r_1}, \dots, \succsim_{r_q})$:

Example 5 Under SP5, we can assume that there exist $r_1, r_2, r_3 \in \mathcal{R}, x, y, z, w \in X$ so that $x \succsim_X r_1 \succ_X y \succsim_X r_2 \succ_X z \succsim_X r_3 \succ_X w$. Let \succsim_Λ be such that $\{s_1, s_2, s_3\} \succsim_\Lambda \{s_1, s_2\} \succsim_\Lambda \{s_1, s_3\} \succsim_\Lambda \{s_2, s_3\}$ and $f = (x, w, z), g = (z, x, z)$ and $h = (y, y, w)$. Then we have $\begin{cases} F_1 = \{s_1\} & F_2 = \{s_1\} & F_3 = \{s_1, s_3\} \\ G_1 = \{s_2\} & G_2 = \{s_2\} & G_3 = \{s_1, s_2, s_3\} \\ H_1 = \emptyset & H_2 = \{s_1, s_2\} & H_3 = \{s_1, s_2\} \end{cases}$ which implies that $f \succsim_1 g \succsim_1 h, h \succsim_2 f \succsim_2 g$ and $g \succsim_3 h \succsim_3 f$

Note that we get a profile forming a *Condorcet triple* which would induce $f \succ g, g \succ h$ and $h \succ f$ if the importance relation \succsim_R is such that: $Q \succsim_R Q' \Leftrightarrow |Q| \geq |Q'|$. Such a preference would not be very helpful for decision making due to the existence of preference cycles. For this reason, we investigate now the impact of transitivity requirements on \succsim in our framework.

Under SRL and OIRP assumptions, if P1 and WP3 hold then nice properties of the importance relation \succsim_Λ appear. A first one is that \succsim_Λ is a transitive relation, which derives from Equation (4) and transitivity of \succsim . A second one is monotonicity defined as follow:

Axiom MON (monotonicity w.r.t. set inclusion). Preference relation \succsim , satisfying axioms SRL and OIRP is said to be monotonic if $\forall A, B, C, D \subseteq S$, we have:

$$[A \subseteq B \text{ and } C \subseteq D] \Rightarrow [A \succsim_S D \Rightarrow B \succsim_S C]$$

Proposition 2 Under SRL and OIRP, (P1 and WP3) \Rightarrow MON

Proof: We first establish the following:

Lemma: let $r, r' \in \mathcal{R}$ such that $r \succ r', f = rAr', g = rBr'$. Then $A \subseteq B \Leftrightarrow g \succsim f$.

Proof of the lemma: Suppose that $A \subseteq B$. WP3 gives immediately that $rB \cap \bar{A}f \succsim r'B \cap \bar{A}f$, and as $g = rB \cap \bar{A}f$ and $f = r'B \cap \bar{A}f$, it gives immediately that $g \succsim f$.

We prove now the proposition. Let $A, B, C, D \subseteq S$ such that $A \subseteq B$ and $C \subseteq D$. Let $r_k, r_{k+1} \in \mathcal{R}$ such that $r_1 \succ_X \dots \succ_X r_k \succ_X r_{k+1} \succ_X \dots \succ_X r_q$. Let $f, g, f', g' \in \mathcal{A}$ such that: $f = r_k A r_{k+1}$, $g = r_k B r_{k+1}$, $f' = r_k C r_{k+1}$, $g' = r_k D r_{k+1}$. If $f \succsim g'$ we have $A \succsim_\Lambda D$ by definition of \succsim_Λ . Then, the lemma gives $B \succsim_\Lambda A$, and so $B \succsim_\Lambda D$ by transitivity of \succsim_Λ . Finally, by contraposition of the lemma, we have $B \succsim_\Lambda C$, which proves MON. \square

We want now to characterize the structure of decision rules defining, from any profile $(\succsim_{r_1}, \dots, \succsim_{r_q})$, a transitive preference relation \succsim on \mathcal{A} using Equation (6) while satisfying the following axiom named IRP for *Independence for Reference-based Preferences*:

Axiom IRP For all \succsim and \succsim' inducing reference sets \mathcal{R} and \mathcal{R}' of same cardinality, $\forall f, g, f', g' \in \mathcal{A}$:

$$\forall r \in \mathcal{R}, \forall r' \in \mathcal{R}', \quad \begin{cases} f \succsim_r g \Leftrightarrow f' \succsim'_{r'} g' \\ g \succsim_r f \Leftrightarrow g' \succsim'_{r'} f' \end{cases} \Rightarrow [f \succsim g \Leftrightarrow f' \succsim' g']$$

We can now establish the following representation theorem:

Theorem 1 If the preference relation \succsim on \mathcal{A} satisfies P1, WP3, SP5, SRL and IRP then there exists a permutation σ on $\{1, \dots, q\}$, and a likelihood relation \succsim_Λ on the subsets of S such that:

$$\begin{aligned} f \succ g &\Leftrightarrow F_{\sigma(1)} \succsim_\Lambda G_{\sigma(1)} \\ &\text{or} \quad F_{\sigma(1)} \sim_\Lambda G_{\sigma(1)} \text{ and } F_{\sigma(2)} \succsim_\Lambda G_{\sigma(2)} \\ &\dots \\ &\text{or} \quad \forall i \neq q, F_{\sigma(i)} \sim_L G_{\sigma(i)} \text{ and } F_{\sigma(q)} \succsim_\Lambda G_{\sigma(q)} \\ f \sim g &\Leftrightarrow \forall i = 1, \dots, q, F_i \sim_\Lambda G_i \end{aligned}$$

Sketch of the proof. Under P1 and SP5, we know there exists at least $q \geq 3$ reference levels in $\mathcal{R} = \{r_1, \dots, r_q\}$ so that $f_{r_1} \succ \dots \succ f_{r_q}$. Then, the proof proceeds as in the Fishburn's characterization result for lexicographic preferences [11], translated from a product

set to Arrow's original framework [1]. Before, we have to prove that profiles $(\succsim_{r_1}, \dots, \succsim_{r_q})$ have the adequate structure. To this end, we first show that \succsim_R satisfies the strong Pareto principle, i.e. $(\forall r \in \mathcal{R}, f \succ_r g) \Rightarrow f \succ g$. This is due to the following property: $\forall r \in \mathcal{R} - \{r_i\}$, $r_i \succsim_r r_{i+1}$, and $r_i \succ r_{i+1}$ by definition of reference levels and $r_i \succsim_{r_i} r_{i+1}$ since $S \succsim_\Delta \emptyset$ thanks to P5 (actually SP5). So $\forall f, g \in \mathcal{A}, [\forall r \in \mathcal{R}, f \succsim_r g \text{ and } \exists r \in \mathcal{R}, f \succ_r g]$ implies $f \succ g$ which proves the strong Pareto principle. Then our IRP axiom plays the role of Fishburn's non-compensation axiom on product sets. Finally the richness of the product set structure exploited in Fishburn's result is obtained here by the diversity of relationship between acts due to the existence of Condorcet triples illustrated by Example 5. \square

Theorem 1 shows that, under IRP and the transitivity requirement (P1), RLD rules necessarily perform a lexicographic aggregation of relations \succsim_{r_i} , $i = 1, \dots, q$, thus inducing the existence of a 'dictator' among reference levels (a transposition of Arrow's theorem), and even the existence of a hierarchy of reference levels. Reference r_i is only allowed to discriminate between two acts f and g when reference levels r_k , $k < i$ (higher in the hierarchy) are useless in the comparing f and g . The hierarchy order is completely characterized by permutation σ on $\{1, \dots, q\}$ and can easily be revealed by observing preferences between $r_{j+1}Ar_{j-1}$ and r_j for any j where A is such that $N \succsim_\Delta A \succsim_\Delta \emptyset$. Indeed, $r_{j+1}Ar_{j-1} \succ r_j$ implies that r_{j+1} is above r_j in the hierarchy and vice versa. A very natural example of RLD rule is given by choosing $\sigma(k) = q+1-k$. It amounts to comparing two acts f and g by observing their respective potential to yield consequences better than a minimal reference level. If this is not sufficient to discriminate them, then a second (more demanding) level is considered and so on...

The key point with such aggregation procedures is that the hierachic structure does not apply on *states* (as is the case for usual LDR rules induced by axiom OI, see [4]) but on *consequences*. This leaves room for various types of complete monotonic likelihood relations \succsim_Δ , as those induced by capacities (additive or not, decomposable or not). In this respect, this offers much more descriptive possibilities than LDR rules. Moreover, preferences induced by LDR rules are, by construction, compatible with the qualitative counterpart of stochastic dominance \succsim_Δ defined on \mathcal{A} by:

$$f \succsim_\Delta g \Leftrightarrow \forall x \in X, \{s \in S, f(s) \succsim_X x\} \succsim_\Delta \{s \in S, g(s) \succsim_X x\}$$

5 CONCLUSION

We have investigated new qualitative models for decision making under uncertainty, characterized by the introduction of reference levels. The main features of the resulting RLD rules are the following:

1) *level of information required*: models are purely ordinal. The decision rule is completely characterized by two binary relations \succsim_Δ (relative likelihood on events) and \succsim_X (preference over consequences). This departs from the great majority of models based on a numerical qualitative or quantitative decision criterion, the definition of which relies on the existence of certainty equivalent implicitly merging utility and uncertainty scales into a single one [4].

2) *prescriptive potential*: although based on purely ordinal methods, they are fully compatible with the transitivity of preferences (even if a probabilistic likelihood relation is used). The use of reference levels and reference events indeed overcomes the usual limitations of purely ordinal aggregation methods, by moving the application point of Arrow-like theorems. The introduction of SRL instead of OI exchanges the role of events and consequences in the ordinal aggregation. Thus, \succsim is obtained by aggregation of reference-dependent relations $\succsim_r, r \in \mathcal{R}$ instead of state-dependent preferences $\succsim_s, s \in S$.

As an important consequence we get Theorem 1 showing that necessary lexicographic structures induced by transitivity emerge on the space of consequences rather than on the space of events (see LDR [4]). In our opinion, this is much more satisfactory.

3) *Descriptive potential*: many recent studies in decision making under uncertainty concern the violation of the sure-thing principle P2 and the need of models to capture such sophisticated preferences. As Choquet expected utility [18] is a useful extension of EU in the field of quantitative models, as Sugeno Expected Utility [8] is a useful extension of qualitative utility, RLD rules provide a new family of Dominance Rules allowing, if necessary, violations of P2.

As future works, we wish to investigate a weaker version of SRL, leaving room for a set of q possibly different reference-dependent likelihood relations. More crucially, we have to investigate the connections of our approach (under the completeness assumption) with the Sugeno integral and with possibilistic lexicographic decision rules proposed in [10]. Finally, we intend to extend our characterization results under quasi-transitivity and/or without completeness of preferences. This might be a step towards the definition of new qualitative decision models.

Decision with uncertainties, feasibilities, and utilities: towards a unified algebraic framework

Cédric Pralet^{1,3} and Gérard Verfaillie² and Thomas Schiex³

Abstract. Several formalisms exist to express and solve decision problems. Each is designed to capture different kinds of knowledge: utilities expressing preferences, uncertainties on the environment, or feasibility constraints on the decisions, with a possible sequential aspect. Despite the fact that every framework relies on specific properties exploited by dedicated algorithms, these formalisms present interesting similarities.

In this paper, we show that it is possible to capture these similarities in a generic algebraic framework for sequential decision making with uncertainties, feasibilities, and utilities. This framework subsumes several existing approaches, from constraint satisfaction problems to quantified boolean formulas, Bayesian networks or possibilistic Markov decision processes. We introduce this framework using a toy example, increasingly sophisticated by uncertainties, feasibilities and possible observations. This leads to a formal definition of the framework together with dedicated queries representing usual decision problems. Generic algorithms for solving the considered queries should allow to both factorize existing algorithmic works and allow for cross-fertilization between the subsumed formalisms.

1 Introduction and notations

The notion of decision problems covers a large spectrum of problems, from pure utility optimization problems to problems involving uncertainties, possible unfeasibilities and partial observability. A large number of frameworks have therefore been proposed to model and solve such problems. Our aim here is to define a general framework based on graphical models (to capture locality of information and independence) enriched by an algebraic framework allowing to design algorithms and prove properties. All proofs are omitted for lack of space and available in [27].

In the following, $\text{Dom}(x)$ denotes the set of values a variable x may take. By extension, for a sequence of variables S , $\text{Dom}(S) = \prod_{x \in S} \text{Dom}(x)$. Given a set E , a *local function* L is a function $L : \text{Dom}(S(L)) \rightarrow E$, where $S(L)$ is the scope of L . The *elimination of a set of variables* S' from L with any given associative commutative operator op on E is defined as $(op_{S'} L)(A) = op_{A' \in \text{Dom}(S')} L(A.A')$ for any assignment A of $S - S'$. Boolean values are denoted t and f .

We start with a first basic example using just utilities.

Example John faces three doors A, B, C. One of the doors hides a treasure, another a gangster. John can decide to open one door. The gangster will rob him 4,000€ but the treasure is worth 10,000€.

¹ LAAS-CNRS, Toulouse, France cprale@laas.fr

² ONERA, Toulouse, France gerard.verfaillie@onera.fr

³ INRA, Castanet-Tolosan, France tschiex@toulouse.inra.fr

Modeling To compactly represent the environment and the decisions, we introduce three variables: (1) two *environment variables*: one for the gangster door (denoted ga), and one for the treasure door (tr); (2) one *decision variable* (do), representing the door John decides to open. Every variable has $\{A, B, C\}$ as domain. Decision variables are variables whose value is controlled by an agent. Otherwise they are environment variables.

Then, we need two local *utility functions* U_1, U_2 to represent utilities: (1) U_1 expresses that if John opens the gangster door, he must pay 4,000€ (soft constraint $do = ga$, with utility degree $-4,000\text{€}$ if satisfied, and 0 otherwise); (2) U_2 expresses that if John opens the treasure door, he wins 10,000€ (soft constraint $do = tr$, with utility degree $10,000\text{€}$ if satisfied, and 0 otherwise).

Associated query Which door John should open if he knows that the gangster is behind door A and that the treasure is behind door C (no uncertainties)? Obviously, he should open door C.

1.1 Adding uncertainties

In real problems, the environment may not be completely known: there may be uncertainties (here called *plausibilities*) as well as possible *observations* on this uncertain environment. We sophisticate our treasure quest problem to integrate such aspects.

Example The treasure and the gangster are not behind the same door, and all situations are equiprobable. John is accompanied by Peter. Each of them can decide to listen in to door A, B, or C to try to detect the dog of the gangster. The probability of hearing something is 0.8 if one listens in to the gangster door, 0.4 for a door next to the gangster one, and 0 otherwise.

Modeling To capture these new specifications, we define (1) four more variables: two decision variables li_J and li_P , with $\{A, B, C\}$ as domain, model the doors to which John and Peter listen in, and two environment variables he_J and he_P , with $\{yes, no\}$ as domain, model whether John and Peter hear the dog; (2) four local *plausibility functions*: $P_1 : ga \neq tr$ and $P_2 = 1/6$ model probability distribution on the gangster and treasure positions; $P_3 = P(he_J | li_J, ga)$ defines the probability that John hears something given the door to which he listens in and the gangster door; similarly, P_4 corresponds to $P(he_P | li_P, ga)$. Implicitly, the local plausibilities satisfy normalization conditions. First, as the treasure and the gangster are somewhere, $\sum_{ga, tr} P_1 \times P_2 = 1$. Then, as John and Peter hear something or not, $\sum_{he_J} P_3 = 1$ and $\sum_{he_P} P_4 = 1$.

Associated queries What are the decision rules that maximize the expected utility, if first Peter and John listen in, and then John decides to open a door knowing what has been heard?

A classical approach to answer such a query is to use a *decision tree*. In this tree, variables can be considered in the order $li_J \rightarrow li_P \rightarrow he_J \rightarrow he_P \rightarrow do \rightarrow ga \rightarrow tr$ (first, John and Peter choose a door to listen in, then they listen and depending on the listening, John decides which door to open; finally the gangster and the treasure are behind a given door with a certain probability). An internal node n in the tree corresponds to a variable x , and an edge in the tree is labeled with an assignment $x = a$ of the variable x associated with the node above. If x is an environment variable, this edge is weighted by the probability $P(x = a | A)$, where A is the assignment corresponding to the path from the root to x .

The utility of a leaf node is the global utility $(U_1 + U_2)(A)$ of the complete assignment A associated with it. The utility of an internal decision node is given by the value of an optimal children (and it is possible to record an associated optimal decision). The utility of an internal environment node is given by the probabilistic expected utility of the values of its children nodes. The global expected utility is the utility of the root node. It can be proved [27] that such a decision tree procedure can be reduced to the computation of

$$\max_{li_J, li_P} \sum_{he_J, he_P} \max_{do} \sum_{ga, tr} ((\prod_{i \in [1, 4]} P_i) \times (\sum_{i \in [1, 2]} U_i))$$

In other words, the decision tree procedure is equivalent to a sequence of *variable eliminations* on a *combination of local functions*. Optimal decision rules can be recorded during the computation.

Different elimination sequences capture different problems or situations: if John thinks that Peter is a traitor and let him choose a door to listen in first (pessimistic attitude concerning the other agent), the sequence of elimination $\min_{li_P} \max_{li_J} \sum_{he_J, he_P} \max_{do} \sum_{ga, tr}$ is adequate (li_P is eliminated with min). If one assumes that Peter does not even tell John what he has heard (John does not observe he_P), then the sequence of elimination becomes $\min_{li_P} \max_{li_J} \sum_{he_J} \max_{do} \sum_{he_P} \sum_{ga, tr}$.

1.2 Adding feasibilities

In some cases, conditions may have to be satisfied for a decision to be feasible. Unfeasibility is *not* infinite negative utility: an adversary cannot reach the former but seeks the latter.

Example *John and Peter cannot eavesdrop to the same door and door A is locked.*

Modeling This is achieved using two local *feasibility functions*: $F_1 : li_J \neq li_P$ and $F_2 : do \neq A$. We assume that at least one decision is feasible in any situation (no dead-end). It can be represented with two normalization conditions on feasibilities: $\vee_{li_J, li_P} F_1 = t$ and $\vee_{do} F_2 = t$. A decision tree procedure to answer queries is then equivalent to compute

$$\min_{li_P} \max_{li_J} \sum_{he_J} \max_{he_P} \sum_{do} \sum_{ga, tr} ((\bigwedge_{i \in [1, 2]} F_i) \star (\prod_{i \in [1, 4]} P_i) \times (\sum_{i \in [1, 2]} U_i))$$

which uses a special operator \star for masking unfeasible decisions: if we denote the utility of unfeasible situations by \diamond , then \diamond should be an identity for elimination operators $op(e, \diamond) = e$ for any elimination operator op , and annihilator for combination operators $(\diamond \otimes e = \diamond$ for any combination operator \otimes) since the combination of an unfeasible decision with other decisions is unfeasible. Then \star is the operator that associates \diamond with unfeasible decisions: \star is defined by $f \star \alpha = \diamond$ and $t \star \alpha = \alpha$. Together, \diamond and \star exclude unfeasible situations from elimination domains.

Globally, the knowledge modeled with variables and local functions forms a *composite graphical model* defined by a DAG capturing normalization conditions on plausibilities and feasibilities (Figure 1(a))⁴, and a network of local functions (Figure 1(b)). The network involves several types of variables (decision and environment variables) and several types of local functions (local utility, plausibility and feasibility functions).

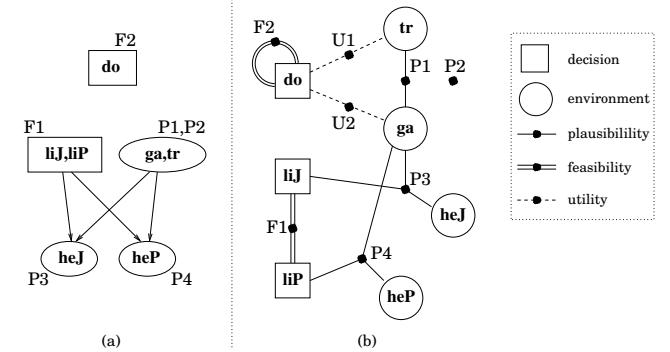

Figure 1. Composite graphical model (a) DAG capturing normalization conditions; (b) Network of local functions.

1.3 Other operators for plausibilities and utilities

The previous problem uses probabilities to model uncertainties. Under independence hypothesis, probabilities are combined with an operator $\otimes_p = \times$, and are eliminated (marginalized) with an operator $\oplus_p = +$. However, other uncertainty theories, such as possibility degrees [11] or κ -rankings [33], use other instantiations of \otimes_p/\oplus_p .

Utilities considered so far are additive (using $\otimes_u = +$). However, utilities may express preferences combined with $\otimes_u = \min$.

Probabilistic expected utility is defined as $\sum_i p_i \times u_i$: plausibilities and utilities are combined with $\otimes_{pu} = \times$ and elimination on utilities weighted by plausibilities is done with $\oplus_u = +$. Other formalisms use an expected utility defined as $\oplus_u (p_i \otimes_{pu} u_i)$ using other instantiations of \oplus_u and \otimes_{pu} :

	E_p	\oplus_p	\otimes_p	E_u	\otimes_u	\oplus_u	\otimes_{pu}
1	\mathbb{R}^+	+	\times	$\mathbb{R} \cup \{-\infty\}$	+	+	\times
2	\mathbb{R}^+	+	\times	\mathbb{R}^+	\times	+	\times
3	$[0, 1]$	\max	\min	$[0, 1]$	\min	\max	\min
4	$[0, 1]$	\max	\min	$[0, 1]$	\min	\min	$\max(1-p, u)$
5	$\mathbb{N} \cup \{\infty\}$	\min	$+$	$\mathbb{N} \cup \{\infty\}$	$+$	\min	$+$

Table 1. Operators with - 1. probabilistic expected utility - 2. probabilistic expected satisfaction - 3. optimistic and 4. pessimistic probabilistic expected utility - 5. qualitative utility with κ -rankings and with only positive utilities.

Towards a generic framework After this informal introduction, it is now possible to give a formal definition of the *Plausibility-Feasibility-Utility* (PFU) framework. This framework combines graphical models concepts (locality, conditional independence) with a flexible algebraic definition of expected utility in an *algebraic graphical model* (Section 2). We then show how queries on these networks allow to solve decision problems, with or without partial observability.

Ideally, such queries should reduce to a sequence of variable eliminations on a combination of local functions such as

$$\max_{x_1, x_2} \min_{x_3} \oplus_u \max_{x_4, x_5} \max_{x_6} ((\bigwedge_{F_i \in F} F_i) \star (\otimes_p P_i) \otimes_{pu} (\otimes_u U_i))$$

⁴ If P denotes the set of local plausibility functions associated with a node corresponding to a set of variables S , this means that $\sum_S (\prod_{P_i \in P} P_i) = 1$. If F denotes the set of local feasibility functions associated with a node corresponding to a set of variable S , this means that $\vee_S (\bigwedge_{F_i \in F} F_i) = t$.

2 An algebraic graphical model

2.1 Algebraic structure (plausibility/utility model)

Plausibility structure We define a *plausibility structure* as a triple $(E_p, \oplus_p, \otimes_p)$, where E_p is a set of plausibility degrees, equipped with a partial order \preceq_p , \oplus_p is an elimination operator on plausibilities, and \otimes_p is a combination operator on plausibilities. \oplus_p and \otimes_p satisfy some sensible axioms inspired by Friedman & Halpern's algebraic plausibility measures [14, 17]. The difference with their work is that we extend the operators \oplus_p and \otimes_p so that they become closed in E_p . This allows to define $(E_p, \oplus_p, \otimes_p)$ as a commutative semi-ring (the identity for \oplus_p is noted 0_p and the identity for \otimes_p is noted 1_p), where \oplus_p and \otimes_p are monotonic, and where 0_p (associated with impossibility) is the minimum element in E_p .

Utility structure We define a *utility structure* as a pair (E_u, \otimes_u) , where E_u is a set of utility degrees, (equipped with a partial order \preceq_u) and \otimes_u is the operator used to combine utilities. We assume that \otimes_u is monotonic and that (E_u, \otimes_u) is a commutative semi-group (\otimes_u associative and commutative, so that combined utilities do not depend on the way the combination is done).

Expected utility structure To simultaneously take into account plausibilities and utilities, we define an *expected utility structure*. This structure, inspired from Chu-Halpern's work on generalized expected utility [8] (as in algebraic MDP [26]), is a tuple $(E_p, E_u, \oplus_u, \otimes_{pu})$ where \oplus_u (operator on E_u) together with $\otimes_{pu} : E_p \times E_u \rightarrow E_u$ define the generalized expected utility formula $\oplus_u^i (p_i \otimes_{pu} u_i)$. We extend [8] in order to be able to deal with sequential decision processes. For operational reasons, \oplus_u and \otimes_{pu} are also closed. This defines $(E_p, E_u, \oplus_u, \otimes_{pu})$ as a semi-module on $(E_p, \oplus_p, \otimes_p)$, with monotonicity axioms on \oplus_u and \otimes_{pu} . Note that all the structures in Table 1 are expected utility structures.

Implicit assumptions As a set E_p of plausibility degrees and a set E_u of utility degrees are defined, plausibilities and utilities must be cardinal: purely ordinal approaches (e.g. CP-nets [4]) are not captured. As \otimes_{pu} takes values in E_u , it is implicitly assumed that plausibilities and utilities are commensurable: works as [13] are not captured either. Finally, some axioms entail that only distributional plausibilities are covered (the plausibility of a set of variable assignments is determined by the plausibilities of each covered complete assignment): belief functions [30] are not captured.

Algebraic structure for the treasure problem The plausibility structure is $(\mathbb{R}^+, +, \times)$ ($E_p = \mathbb{R}^+$ and not $[0, 1]$ in order for $+$ to be closed in E_p), the utility structure is $(\mathbb{R}, +)$, and the expected utility structure is $(\mathbb{R}^+, \mathbb{R}, +, \times)$.

2.2 A generic graphical model

Following the graphical model concepts, the environment and the decisions are now represented by environment and decision variables while the relations between these variables (plausibility, feasibility, and utility relations) are represented as local functions. Together, these define a composite and generic graphical model called a *Plausibility-Feasibility-Utility (PFU) network*.

Definition 1 A PFU network is a tuple (V, G, P, F, U) where:

- V is a set of variables, partitioned into V_D (set of decision variables) and V_E (set of environment variables).

- G is a DAG whose vertices are a partition of V (vertices of G are sets of variables called components), such that each vertex of G is composed of variables of the same nature (decision or environment). We note C_D the set of decision components and C_E the set of environment components.
- $P = \{P_1, P_2, \dots\}$ is a finite set of local plausibility functions; each P_i is associated with a component $c \in C_E$ denoted $c(P_i)$, such that the scope $S(P_i) \subset (c \cup pa_G(c))$. For any $c \in C_E$, $\oplus_p(\otimes_{p c(P_i)=c} P_i) = 1_p$ must hold.
- $F = \{F_1, F_2, \dots\}$ is a finite set of local feasibility functions; each F_i is associated with a component $c \in C_D$ denoted $c(F_i)$, such that the scope $S(F_i) \subset (c \cup pa_G(c))$. For any $c \in C_D$, we have $\vee_c (\wedge_{c(F_i)=c} F_i) = t$.
- $U = \{U_1, U_2, \dots\}$ is a finite set local utility functions.

The decomposition of global plausibility, feasibility, and utility degrees as sets of local functions is semantically justified by the notion of *conditional independence*. We provide an intuitive justification for plausibilities. Let us say that \mathcal{P}_S is a plausibility distribution on S iff $\oplus_{p_S} \mathcal{P}_S = 1_p$ (for probabilities, it simply means that a probability distribution sums up to 1). \mathcal{P}_S defines a plausibility distribution on any subset S' of S by $\mathcal{P}_{S'} = \oplus_{p_{S-S'}} \mathcal{P}_S$.

To define conditional independence, we introduce a conditioning function \otimes_p (verifying some sensible properties, see [27]) allowing to define conditional plausibility distributions by $\mathcal{P}_{S_1|S_2} = \mathcal{P}_{S_1, S_2} \otimes_p \mathcal{P}_{S_2}$ (for probabilities, \otimes_p is the division). Then, for any disjoint sets of variables S_1, S_2, S_3 , we say that S_1 is *conditionally independent* of S_2 given S_3 iff $\mathcal{P}_{S_1, S_2|S_3} = \mathcal{P}_{S_1|S_3} \otimes_p \mathcal{P}_{S_2|S_3}$.

Last, a DAG G of components is said to be *compatible* with a plausibility distribution \mathcal{P}_S iff for any component c of the DAG, c is conditionally independent of its non descendants in G given the set $pa_G(c)$ of its parents in G . Similarly to Bayesian networks [25], it is possible to prove [27] that:

Theorem 1 If G is a DAG compatible with \mathcal{P}_S , then $\mathcal{P}_S = \otimes_{p_{c \in G}} \mathcal{P}_{c|pa_G(c)}$.

Thanks to Theorem 1⁵, a DAG compatible with a global plausibility distribution enables to factorize it as a combination of local functions $L_{c, pa_G(c)}$ ($L_{c, pa_G(c)} = \mathcal{P}_{c|pa_G(c)}$) such that $\oplus_{p_c} L_{c, pa_G(c)} = 1_p$ for any component c of G . Each $L_{c, pa_G(c)}$ may be further decomposed to give local plausibility functions P_i associated with c (denoted $c(P_i) = c$) thus verifying $\oplus_{p_c} (\otimes_{p_{c(P_i)=c}} P_i) = 1_p$. This two-step factorization justifies the DAG in a PFU network and the normalization conditions it encodes.

Similar results can be established for feasibilities. As for utilities, PFU networks implicitly assume that a global utility degree \mathcal{U}_V on all variables can be decomposed as a set of local utility functions U_i . One may assume that this decomposition is directly obtained, as it is done with CSP [22] or is justified by a notion of conditional independence in the case $\otimes_u = +$ as in [1].

Example The PFU network of our example appears in Figure 1.

Subsumption results CSP [22] can be modeled as $(V, G, \emptyset, \emptyset, U)$ where V contains the CSP variables, the DAG G is reduced to one decision component equal to V and U is the set of constraints (by normalization, feasibilities cannot represent inconsistent CSP).

⁵ And with some technical steps induced by the fact that we do not work on plausibility distributions on V , but on plausibility distributions on V_E for any assignment of V_D .

It is also possible to capture valued [2], quantified [3], mixed [12], stochastic [34] CSP, or SAT, QBF, and extended stochastic SAT [21].

Bayesian networks [25] are captured by a PFU network $(V, G, P, \emptyset, \emptyset)$, where P contains the original probability tables. Chain graphs [15], Markov random fields [7] are also subsumed.

Finite-horizon probabilistic MDP [28, 23] are captured by (V, G, P, \emptyset, U) where V_D and V_E are the set of decisions d_t and states $s - t$ respectively (one for each time-step t), G is a DAG looking like the unrolled MDP, P contains the probability distributions $P_{s_{t+1} | s_t, d_t}$, and U contains the additive rewards R_{s_t, d_t} . It is also possible to model finite-horizon probabilistic MDP [29], MDP based on κ -rankings, partially observable (PO) MDP, factored or not [5, 6].

Influence diagrams [18], including a probabilistic variant, can be represented as a tuple (V, G, P, \emptyset, U) . For valuation networks [32], a set F of local feasibility functions is added.

3 Reasoning about PFU networks via queries

In this section, we assume that a *sequence of decisions* must be performed, and that the order in which decisions are made and the environment is observed is known. We also make a *no-forgetting* assumption, that is, when making a decision, an agent is aware of all previous decisions and observations. Finally, the order on utility degrees is assumed to be total.

Under such assumptions, we want to express sequential decision making problems on PFU networks, taking into account possible partial observability and cooperative or antagonist agents in the environment. To capture such problems, we use a sequence Sov of operator-variable(s) pairs that captures:

- *possible unobservabilities*: the order in which decisions are made and environment variables observed is specified by Sov . If the value of he_P is known when John chooses a door to open, then Sov contains $\dots(\oplus_u, he_P)\dots(\max, do)\dots$. Otherwise, a sequence like $\dots(\max, do)\dots(\oplus_u, he_P)\dots$ is used;
- *optimistic/pessimistic attitude* concerning the decision makers: if Peter acts cooperatively (we are optimistic about Peter's decision) then (\max, li_P) appears in Sov . If instead Peter is considered as an antagonist agent then (\min, li_P) is used.

Example For the last query in §1.1, Sov equals $(\min, \{li_P\}).(\max, \{li_J\}).(+, \{he_J\}).(\max, \{do\}).(+, \{he_P\}).(+, \{ga, tr\})$.

Definition 2 A query Q on a PFU network is a pair (\mathcal{N}, Sov) where (1) \mathcal{N} is a PFU network; (2) Sov is a sequence of operator-variable(s) pairs such that the operators are \min , \max or \oplus_u , and such that each variable appears at most once in Sov .

Correct queries Not all queries are meaningful. The main condition for a query to be *correct* is that it must not contain a pair x, y of variables of different nature such that x belongs to an ascendant component of y in the DAG of the PFU network and x appears after y in Sov . This would mean that x is assigned after y , breaking causality. For example, the pair $\dots(+, he_J)\dots(\max, li_J)\dots$ is not correct since John cannot hear something at the door he has chosen to eavesdrop before this choice is done.

3.1 Answering queries

Answering a query Q consists in computing the expected utility associated with the situation modeled by the sequence Sov and the network \mathcal{N} of the query Q .

Decision tree approach A first approach to answer queries in the general case (not only for probabilistic expected utility) uses decision trees. In this case, variables are considered as they appear in Sov , and edges in the tree are weighted by conditional plausibilities of the form $\mathcal{P}(x = a | A)$ for the internal nodes associated with environment variables, and by conditional feasibilities of the form $\mathcal{F}(x = a | A)$ for internal nodes associated with decision variables.

Then the expected utility of a query (and associated optimal decision rules specifying which decision to take given the previous observed variables) can be defined with a decision tree procedure similar to the procedure described in 1.1 (the utility of a leaf node is given by the combination of the local utilities U_i , the utility of an internal environment node is given by the expected utility of its children, and the utility of an internal decision node is given by the optimal utility of its feasible children nodes).

A more operational approach The advantage of the decision tree procedure is that it has clear semantic foundations. But besides the possibly exponential size tree, its drawback is that each internal node of the decision tree may require the computation of $\mathcal{P}(x = a | A)$ or $\mathcal{F}(x = a | A)$ which are not usually directly available in the network \mathcal{N} and which may require exponential time to compute. Fortunately, it is possible to show [27] that the decision tree procedure (called the semantic answer to Q) is equivalent to a direct algebraic approach (called the operational answer to Q) which requires only the local functions available in the original PFU network.

Theorem 2 Answering a query with a decision tree is equivalent to compute $Ans(Q) = Sov((\bigwedge_{F_i \in F} F_i) * (\bigotimes_{P_i \in P} P_i) \otimes_{pu} (\bigotimes_{U_i \in U} U_i))$

Furthermore, the optimal decision rules obtained are the same as in the decision tree approach.

3.2 Subsumption of classical queries

Most usual queries on existing formalisms can be reduced to PFU queries: finding a solution for a SAT problem, a CSP [22] or a valued CSP [2] corresponds to a sequence $Sov = (\max, V)$. For QBF or quantified CSP [3], Sov alternates \min (for universal quantification) and \max (for existential quantification). With mixed or probabilistic CSP [12], Sov looks like $(\oplus_u, V_E).(\max, V_D)$ if a conditional decision is sought and $(\max, V_D).(\oplus_u, V_E)$ if an unconditional decision is sought. The situation is similar with conformant or probabilistic planning [16].

Queries on Bayesian networks [25] look like $(+, S)$ to compute a probability distribution on $V - S$, (\max, V) to solve a Most Probable Explanation problem, and $(\max, V_D).(+, V_E)$ to solve Maximum A Posteriori problems.

With stochastic CSP [34] or influence diagrams [18], the sequence alternates $+$ on environment variables and \max on decision variables. With finite-horizon MDP, Sov looks like $(\max, d_1).(\oplus_u, s_2)\dots(\max, d_T).(\oplus_u, s_T)$. With finite-horizon POMDP, observations o_t are added (one for each time-step t), and $Sov = (\max, d_1).(\oplus_u, o_2)\dots(\max, d_T).(\oplus_u, o_T).(\oplus_u, \{s_1, \dots, s_T\})$: this captures the fact that states remains unobserved for POMDP.

4 Gains and costs

A better understanding As it subsumes many queries on existing graphical models, the PFU framework enables to better understand the similarities and differences between the subsumed formalisms.

It defines a common basis for people of different communities to communicate.

Increased expressiveness The PFU framework offers several variabilities: (1) variability of the algebraic structure, which captures probabilistic expected utility, probabilistic expected satisfaction, possibilistic pessimistic utility, possibilistic optimistic utility or qualitative utility with κ -rankings; (2) variability of the network which exploits oriented and non-oriented independences as well as normalization conditions; (3) variability of the queries which can capture state (un)observability and cooperative/antagonist attitudes.

It is therefore more expressive than each of the frameworks it subsumes, and it also covers yet unpublished formalisms (such as possibilistic influence diagrams, or stochastic CSP extended to cope with the fact that decisions may influence the environment).

Generic algorithms Computing the answer to a correct query is obviously PSPACE-hard since PFU queries capture QBF. It is easy to define, from Theorem 2, a polynomial space tree search algorithm which computes the answer to a correct query. Similarly, it is possible to define a generic variable elimination algorithm to compute $Ans(Q)$ [10]. The PFU algebraic framework is an opportunity to identify sufficient or necessary conditions for existing algorithms to be applicable [24], or to define new techniques from which each subsumed formalism could benefit. Bounding and local consistencies [22, 9, 20] could be integrated to speed up the resolution.

As a result, the PFU framework can be seen as an opportunity to integrate in a generic framework techniques developed in different subsumed formalisms, and thus to allow for cross-fertilization.

5 Conclusion

In this paper⁶, a generic algebraic framework for sequential decision making has been defined. It combines an algebraic structure that specifies how to combine and synthesize information together with a graphical model specifying local plausibility, feasibility, and utility functions. Queries can capture possible (un)observabilities or antagonist agents.

The generalized expected utility associated with a query can be computed by a sequence of variable eliminations on a combination of local functions. Compared to *valuation algebras* [31, 19], a related generic framework, the PFU framework uses several combination (\wedge , \star , \otimes_p , \otimes_{pu} , \otimes_u) and elimination operators (min, max, \oplus_u). Moreover, the semantic justifications of the definition of PFU networks, which lie in the notion of conditional independence, allow to include a DAG capturing normalization conditions in the network definition.

The obtained framework not only subsumes many queries on existing formalisms, but it also enables to define yet unpublished formalisms. From an algorithmic point of view, generic schemes that integrate techniques used in subsumed formalisms can be developed.

Using Occlusion Calculi to Interpret Digital Images

David Randell¹ and Mark Witkowski¹

Abstract. This paper reports on an investigation using occlusion calculi to interpret digital images. Using a minimal set of digital, region-relation detectors, and assuming a continuous interpretation of physical space, we show how existing calculi can be augmented and embedded in the *Event Calculus* to interpolate and recover a larger set of occlusion relations than are otherwise available at the basic detector level.¹

1 INTRODUCTION

Abstracting and reasoning about high-level symbolic spatial information about extended bodies (or regions) has long been a motivating ontological assumption used in *Qualitative Spatial Reasoning (QSR)* research. That several suitably expressive *QSR* logics have subsequently turned out to have interesting and useful computational properties has added to this general degree of confidence in their use [2,3]. *QSR* applications cover such diverse areas as querying spatial databases linked to *GIS*, the encoding of vague concepts, and in processing visual information using real-world images [3,10]. In terms of practical applications however, few have applied themselves to the task of deploying these logics on simulated or real-world machine-vision systems.

Given the relative absence of published work along these latter lines, plus the fact that *QSR* has now been an active research topic in AI for at least 17 years, it is perhaps time to enquire why, and despite the large number of spatial logics *QSR* has spawned, *QSR* has not made more headway here than it has. To this end, we have honed in on a subset of *QSR* logics known as *occlusion calculi* [5, 8, 10, 11] and in particular have singled out Galton's *Lines Of Sight (LOS-14)* calculus [5] with which to interpret 3D convex bodies in terms of their projected images. We wish to examine to what extent occlusion calculi can be used to interpret idealised, real-world two-dimensional digital images returned by a camera.

If we assume (as we do) that our regions are derived directly as the segmented images of physical bodies, then spatial occlusion events becomes a significant issue as several ontological assumptions of existing *QSR* logics (e.g. that the extent of the regions in question is known *a priori*, and that the embedding space is continuous) no longer hold. As we show, these and other assumptions have significant ramifications for digital geometry [7] and *QSR* logics in general.

In order to strengthen and simplify our example, we (i) modify the ontological base on which the original *LOS-14* calculus was built to handle a *discrete* (digitised) rather than a continuous model of space, (ii) embed the logic in an abductive inferential framework using the *Event Calculus* and exploit Conceptual Neighbourhood Diagrams (CNDs) in order to interpolate (by abduction) spatial relations not directly encoded in our set of region-relation detectors, (iii) simplify the segmentation process by individuating regions as aggregates of pixels falling within a specific colour-hue range, and (iv) assume a computational model of region identity, to track regions over time (e.g. [12]).

The rest of this paper is structured as follows. In section 2 we introduce occlusion calculi. Three important limiting assumptions are challenged, (i) that the extent of regions is known *a priori*, (ii) that embedding space is continuous, and (iii) that region boundary information can be reliably extracted from real images. In section 3 we introduce a discrete mereotopological theory. This is used to define the logical properties of regions and relations extracted from segmented digitised images, and specify the logical properties of a small set of region, and region-relation detectors. In section 4 the detectors are mapped to the relation set of *LOS-14*. Section 5 presents an overview of a practical implementation of the detectors. In section 6, the *Event Calculus* is used to abductively infer occlusion relations from an assumed temporal succession of detector states extracted from a sequence of images. Concluding remarks are made in section 7.

2 OCCLUSION CALCULI

Region-based Occlusion Calculi for vision applications originated with Galton's *Lines of Sight* paper (*LOS-14*) [5]; this was followed by *The Region Occlusion Calculus (ROC-20)* [10], [11], and Kohler's *Occlusion Calculus* [8]. These calculi spring from the general development of *QSR* formalisms, calculi and algebras that have been developed over the years for modelling sub-theories of space. In contrast to other *QSR* spatial formalisms, occlusion calculi adopt a distinctive *viewpoint-centred* model of space where visual spatial relations on bodies (or regions) are mapped to corresponding spatial relations on their images.

At least two of these logics (*LOS-14* and *ROC-20*) assume a continuous embedding model of space, and each factors out a *Jointly Exhaustive and Pairwise Disjoint (JEPD)* set of relations. Constraints on the interpretation of the regions, primitive functions and relations used, mean the degree of theory overlap between them varies. For example, Galton's *LOS-14*, defined on discrete convex bodies, identifies 14 *JEPD* relations (see Figure 1), whereas *ROC-20* relaxing this convexity constraint identifies 20. All the relations defined in *LOS-14* have analogues in *ROC-20*, and both are built on the set of relations identified in the spatial logic *RCC-8* [9]. In contrast, Kohler's *Occlusion Calculus* builds on the weaker set of relations defined in the spatial logic *RCC-5* [2].

As is common with many *QSR* theories, each *JEPD* relation set is re-worked into a conceptual neighbourhood diagram (*CND*). These diagrams encode the continuous transitions allowed between pairs of spatial relations [4]. For example, in *LOS-14*, a direct transition exists between *C/2* (clears), and *JC/2* (just clears) but not between *C/2* and *PH/2* (partially hides); where here and elsewhere, the *R/n* notation used, identifies an n-ary relation. The same *CND* can also be used to justify interpolated relations, as in the case where *JC/2* is inferred given a detected transition between *C/2* and *PH/2* – see Figure 1.

2.1 Occlusion Calculi: some assumptions

Given that all the occlusion calculi described here are to a large extent, theoretically motivated, their ontological assumptions need to be carefully examined given we seek to ground the logical primitives in real image data.

The first assumption noted is that the extent of the bodies is assumed known *a priori*, or is at least directly inferable from other information present. However, in the presence of opacity, the mode and extent of visual overlap between bodies is more often than not indeterminate. For example, consider the *CND* of *LOS-14* depicted in Figure 1. Of the 14 possible occlusion relations, 12 rely on part of one body being hidden by another, while only 8 have both bodies directly visible. On the assumption that the physical bodies giving rise to image regions are opaque, and therefore that their hidden extent cannot be determined from any given viewpoint, only three distinct relations of this type can be reliably distinguished. This is discussed in detail later.

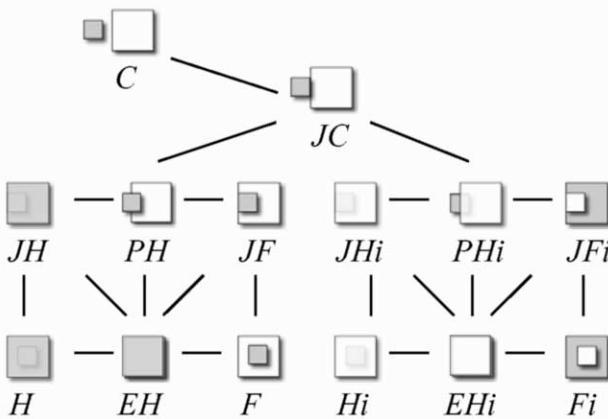

Figure 1: The conceptual neighbourhood diagram LOS-14

The second assumption is that all the existing occlusion calculi assume a *continuous* model of space. As is now well known, the spatial logic *RCC8* used in [5,7,9] disallows *atomic* regions; otherwise the whole calculus is rendered inconsistent [9]. Yet clearly, the space modelled by pixel-arrays is discrete, and if individual pixels here cannot be treated as atomic regions, how then can digital images provide a model for these calculi? The continuous vs. discrete issue for *QSR* formalisms is also discussed in [6], [13] where discrete variants of the *RCC8* calculus are motivated and developed. Also, and related to this point, is how we interpret the primitives of these logics. Take for example the relation *C/2* used in *LOS-14* (see Figure 1), or its analogue relation *NonOccludesDC/2* used in *ROC-20*. Whether we choose to interpret these relations in terms of lines of sight (as in *LOS-14*) or as a pencil of half-lines extending from some viewpoint point v , to infinity (as in *ROC-20*), a fundamental difference arises when using the projective plane defined on the real numbers compared with a viewer-centred discrete interpretation of space. In the first case, the spatial relation $C(A,B)$ is always true whatever the image scale assumed. But in the latter case, whether or not A and B are visually separated depends upon other parameters of the physical system being modelled, such as the image scale or the resolution of the imaging system. This is, of course, an example of the *granularity* issue that is well known in AI research.

The third and last assumption highlighted here is that region-boundary information can be reliably extracted from digitised images. The emphasis on boundaries is a direct consequence of adopting mereotopological logics, for it is precisely the mode of

contact between the visual boundaries of regions that determines what spatial relation is true. However, the reliable interpretation of boundary information from real-world digital images is problematic and detectors based on this information tend to be brittle and often unreliable in use.

These assumptions are of course by no means exhaustive. For example, sensor noise, fast sampling rates, the effects of variable lighting conditions, of shadows and specular reflections all affect the segmentation of the raw digital data returned by any current physical imaging system. However, the main assumptions stemming from the ontology and models used in occlusion calculi have been identified. It is specifically these assumptions that we now address in a *dynamic QSR* framework.

3 DISCRETE MEREOPOLOGY

We use Galton's *two-sorted mereotopological logic* [6] as a *specification language* to define the logical properties of our region and region-relation detectors defined on aggregates of pixels as regions. Two sorts are declared: *pixels* (*cells* in Galton's case) and *regions* as aggregates of pixels.

In [6], definitions of the classical mereological relations and the Boolean composition of regions are given and interpreted set-theoretically. A null region \emptyset is declared, that contains no pixels, and the universal region U , that contains every pixel in the embedding space. Containment of a pixel x in a region X is modelled as set membership, i.e. as $x \in X$; and adjacency of two pixels is captured by the reflexive, symmetric relation $A(x,y)$, meaning pixel x is adjacent to or equal to pixel y . We use a square-based pixel array, and adjacency here is interpreted as 8-adjacency, meaning every non-boundary pixel of the array is surround by 8 neighbours forming a combined 3x3 pixel matrix.

The basic relation-based definitions proceed as follows. Inclusion between regions is defined as: $X \subseteq Y \equiv \forall x \in X \rightarrow x \in Y$, and the (non-null) part/whole relation as: $P(X,Y) \equiv X \subseteq Y \wedge X \neq \emptyset$. Overlap is defined as: $O(X,Y) \equiv X \cap Y \neq \emptyset$. For the weaker relation of connection (or contact) between regions, the adjacency relation now appears: $C(X,Y) \equiv \exists x \exists y [x \in X \wedge y \in Y \wedge A(x,y)]$. This enables the external connection relation: $EC(X,Y)$ and the remaining discrete analogue counterparts of the *RCC8* relations and other related concepts (For example, Galton defines neighbourhood, boundary, interior, closure and covers metric spaces, change and continuity) to be defined. To avoid confusion with the *RCC8* relations these will be referred to as *RCC8D* [6]. We will use only three of these *RCC8D* relations: DisConnected, $DC(X,Y)$; Externally Connected, $EC(X,Y)$; and Non Tangential Proper Part, $NTPP(X,Y)$, mirroring the detectors. Taking $U-X$ as the region difference between U and X , these are defined as follows: $DC(X,Y) \equiv \neg C(X,Y)$, $EC(X,Y) \equiv C(X,Y) \wedge \neg O(X,Y)$, and $NTPP(X,Y) \equiv DC(X,U-Y)$.

While *CNDs* exist for discrete mereotopological logics (e.g. *RCC8D*), the effect of the digital sampling serves to significantly increase the number of possible distinct relation-relation transitions when compared with their continuous counterparts. Here, we assume an underlying continuous model of physical space while sampling the relations into a discrete representation. This has the advantage of (i) allowing physically realisable interpretations of 'anomalous' transitions close to the resolution limit of the detectors, and (ii) exploiting much stronger constraints on possible transitions than directly supported by the discrete model of space.

3.1 Extensions

A finite disjoint set of individual region-membership predicates: R_1, \dots, R_n , is defined on aggregates of pixels. The exact nature of the membership property R_i need not concern us here; but will typically range over some physical property predicated on bodies, such as colour as assumed in our worked example. As uniform patches of colour are used as the basis of both object (or body) and region-identity, and is used by our region segmentation algorithm to label individual regions, we can state the equivalence: $R(X) \equiv \forall x/x \in X \rightarrow R(\{x\})$. Another property, that of a maximally-connected region, $\text{Max}(X)$, is also adopted; in which aggregates of adjacent pixels satisfying property R_i are clustered into connected subsets. This ensures a minimal number of explicitly labelled regions at the detector level: $\text{Max}(X) \equiv V_{i=1}^n [R_i(X) \wedge \forall x \forall y/x \in X \wedge y \notin X \wedge A(x,y)] \rightarrow \neg R_i(\{y\})$. While not developed here, individual regions can then be classified into connected and disconnected (i.e. scattered) regions, see [6] for details. Finally, an additional property of *well-formed region* (wfr) is defined on aggregated sets of pixels as satisfying the definition: $\text{Region}(X) \equiv V_{i=1}^n [R_i(X) \wedge \forall x/x \in X \rightarrow \exists y \exists z \exists u [y \in X \wedge z \in X \wedge u \in X \wedge x \neq y \wedge x \neq z \wedge x \neq u \wedge y \neq z \wedge u \neq z \wedge A(x,y) \wedge A(x,z) \wedge A(u,y)]]$. A well-formed region defines a set of pixels X , satisfying some property R , where every pixel element of X has at least 3 distinct immediate neighbours of that set. Regions not satisfying this condition are passed to our algorithm for pre-processing prior to segmentation and labelling of the regions.

4 REGION CONTACT DETECTORS

The simplest detectors report whether or not a labelled region X (from viewpoint v) is detected: $\text{visible}(X,v) = \text{true}$, iff from v , pixel-region X is detected in the pixel-array, otherwise false. This allows us to infer when, for example, $\text{visible}(a,v) = \text{false}$, that a exists but is hidden from v . These relations (with their reified regions) re-appear as the primitive relation: $\text{Visible}(x,v)$ in the object language.

The pixel-aggregate detector definitions for DC^* , EC^* and $NTPP^*$ are now as follows (see Figure 2 for examples):

$$\begin{aligned} DC^*(X,Y) &\equiv V_{i=1,j=1}^n [R_i(X) \wedge R_j(Y)] \wedge \\ &\quad \neg \exists x \exists y [x \in X \wedge y \in Y \wedge A(x,y)] \\ EC^*(X,Y) &\equiv V_{i=1,j=1}^n [R_i(X) \wedge R_j(Y)] \wedge \\ &\quad \exists x \exists y [x \in X \wedge y \in Y \wedge A(x,y)] \wedge \neg NTPP^*(X,Y) \\ NTPP^*(X,Y) &\equiv V_{i=1,j=1}^n [R_i(X) \wedge R_j(Y)] \wedge \\ &\quad [NTPP(X,Y) \wedge Y' = X + Y] \end{aligned}$$

Each of these relations are mapped to three implemented detectors, dc^* , ec^* and $ntpp^*$, with $ntpp^*$ as the inverse of $ntpp$. Note that the $ntpp^*$ detector does not of itself embody the transitive property of the (*RCC8* and *RCC8D*) relation $NTPP/2$, as the detector operates locally. Thus, if $ntpp^*(A,B)$ and $ntpp^*(B,C)$, then $dc^*(A,C)$ will be initially reported. However, as the domain model restricts bodies to convex regions, we infer $ntpp^*(A,C)$ via its mapping to $NTPP/2$. The justification for labelling embedded nested regions as $NTPP^*$ (as shown in Figure 2) follows from the (*RCC8* and *RCC8D*) theorem: $\forall xyz [NTPP(\text{sum}(x,y),z) \rightarrow [NTPP(x,z) \wedge NTPP(y,z)]]$, i.e. every part of a non-tangential part of region forms a non-tangential relationship to the whole.

In terms of the *LOS-14* occlusion relations mapping to the relation detectors, only one is clearly unambiguous, namely C , which maps to DC^* ; while the others: JC, PH, JF, JFi map to EC^* ; and F , which maps to $NTPP^*$, are either ambiguous or

reintroduce some other assumption into the interpretation. In the case of the latter, for example, a one-one mapping is only possible if we make (as we do) the additional convexity assumption. Having now reduced the 14 occlusion relations down to a detector that can only distinguish three classes of relations, how then can we recover the missing ones?

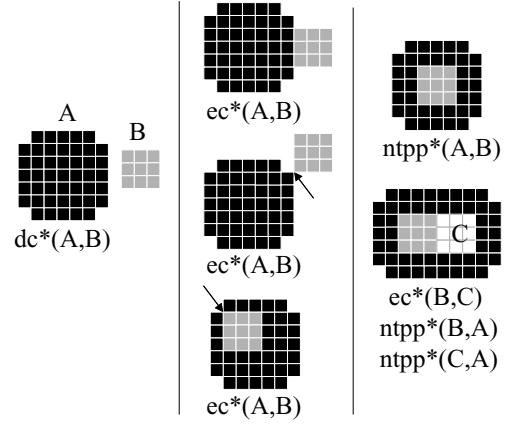

Figure 2: Discrete digitised regions

4.1 Mapping between Bodies and Regions

To illustrate the interplay between bodies and digitised regions we now embed the relations: DC^* , EC^* and $NTPP^*$ (and the inverse relation $NTPP^*$) into *LOS-14*. An explicit viewpoint variable, v , and an image function $\text{image}(x,v)$, that maps body x , and viewpoint v to its projected image is added, and each dyadic *LOS-14* relation, is re-worked into a ternary relation – see [10] for further details.

The first set of axioms map the occlusion relations to their *RCC8D* spatial relations on images; then following the group of definitions, another group of axioms map between selected *LOS-14* relations and the primitive region-relation detectors. For brevity we omit from the antecedents of these axioms conjuncts that encode the visibility or otherwise of bodies given particular occlusion relationships. However, these can be inferred from the model used to illustrate the CND in Figure 1.

$$\begin{aligned} \forall x \forall y \forall v [C(x,y,v) &\rightarrow DC(\text{image}(x,v), \text{image}(y,v))] \\ \forall x \forall y \forall v [JC(x,y,v) &\rightarrow EC(\text{image}(x,v), \text{image}(y,v))] \\ \forall x \forall y \forall v [PH(x,y,v) &\rightarrow PO(\text{image}(x,v), \text{image}(y,v))] \\ \forall x \forall y \forall v [JF(x,y,v) &\rightarrow TPP(\text{image}(x,v), \text{image}(y,v))] \\ \forall x \forall y \forall v [F(x,y,v) &\rightarrow NTPP(\text{image}(x,v), \text{image}(y,v))] \\ \forall x \forall y \forall v [JH(x,y,v) &\rightarrow TPPi(\text{image}(x,v), \text{image}(y,v))] \\ \forall x \forall y \forall v [H(x,y,v) &\rightarrow NTPPi(\text{image}(x,v), \text{image}(y,v))] \\ \forall x \forall y \forall v [EH(x,y,v) &\rightarrow EQ(\text{image}(x,v), \text{image}(y,v))] \\ PHi(x,y,v) &\equiv \text{def. } PH(y,x,v), JHi(x,y,v) \equiv \text{def. } JH(y,x,v) \\ JFi(x,y,v) &\equiv \text{def. } JF(y,x,v), Hi(x,y,v) \equiv \text{def. } H(y,x,v) \\ Fi(x,y,v) &\equiv \text{def. } F(y,x,v), EH(x,y,v) \equiv \text{def. } EH(y,x,v) \\ \forall x \forall y \forall v [C(x,y,v) &\rightarrow DC^*(\text{image}(x,v), \text{image}(y,v))] \\ \forall x \forall y \forall v [\Phi(x,y,v) &\rightarrow EC^*(\text{image}(x,v), \text{image}(y,v))] \\ \text{where: } \Phi &\in \{JC, PH, JF, JFi, PHi\} \\ \forall x \forall y \forall v [F(x,y,v) &\rightarrow NTPP^*(\text{image}(x,v), \text{image}(y,v))] \end{aligned}$$

5 THE DETECTOR ALGORITHM

This section summarises the main points of the algorithm (and program) used to implement the detectors and transform input

bitmap images to regions and extract the QSR relations between them. The (C++) program accepts as input bitmap images (of size x by y) and, in step 1, assigns a region value in the range 0 to $\text{maxr}-1$ (max regions) for each unique colour value encountered (the array r). Test images may be prepared using the block fill tool in any standard bitmap manipulation program. The program also allows camera images to be grabbed directly using a Videre Mega-D firewire camera or imported via bitmap images. Prior to use, real images are subjected to a hue separation process to extract distinct regions. The resulting region based image is subjected to a region-conditioning process that implements the notion of well-formed region (wfr) introduced earlier in section 3.1. Every pixel with fewer than three like neighbours is converted to the identity of the majority of adjacent pixels (or arbitrarily where the count is equal). The process is applied iteratively until the segmentation results in a set of labelled regions X_1, \dots, X_n that satisfy $\text{Region}(X_1) \& \dots \& \text{Region}(X_n)$. This sequence of activities is indicated below by `get_regions()`. The process has the additional effect of overcoming the effects of region boundary pixel aliasing inherent in digital imaging, and of removing “speckle” noise pixel groups. The image regions are considered to be embedded in a background area, which is not taken as a region.

In step 2 the `relations` array, which records the detector relations between all combinations of regions, is initialised to `dc*` (`DCSTAR`). The image sized array `mask` is used to track those pixels and regions that have been processed. It is initialised to discount all background pixels.

In step 3 each region value is compared to its neighbour (here, `neighbour()` returns the coordinates of an adjacent pixel) and processes each region as it encounters each new region edge. `TraceOutline()` recursively traces around the outside edge of the new region building a mask (`omask`) of those connected edge pixels. Note that here `all_neighbours()` successively returns the coordinates of all eight connected pixels. Next, `FillRegion()` applies a recursive flood-fill to the current region, noting the edge pixels encountered (`IsEdge()`). Any edge pixel (that also belongs to a region) that has previously been tagged in `omask` as an outside region indicates that the current and touching regions form a symmetric `ec*` relationship (`SetECRegion()`), and that any other connected region must therefore form an (asymmetric) internal `ntpp*/ntppi*` relationship (`SetNTPPRegion()`). Note that under this arrangement evidence of an `ntpp*` relation effectively takes precedence over that for an `ec*` one. This process is repeated until all regions have been processed. Finally the `relations` array is displayed and reformatted for further processing (Figure 4).

```

process(raw_image)
{ // Step 1: convert image to regions
  proc_image = get_regions(raw_image);
  forevery(x, y)
    r(x,y) := ToRegionValue(proc_image[x,y]);
  // Step 2: initialise relations[] to dc*
  forevery(i < maxr, j < maxr)
    relations[i,j] := DCSTAR;
  initialise(mask);
  // Step 3: process all regions
  forevery(x, y)
    { p = r[x,y]
      if(p != r[neighbour(p)] && !mask[neighbour(p)])
        { clear(omask);
          cval := r[neighbour(p)];
          TraceOutline(cval,x,y);
          FillRegion(cval,x,y); } }
  Display_regions(r); }
TraceOutline(cval,x,y)

```

```

{ if(r[x,y] == cval) return;
  if(omask[x,y]) return;
  if(IsOuterEdge(cval,x,y)) return;
  omask(x,y) := 1;
  forevery({x',y'} := all_neighbours(x,y))
    TraceOutline(cval,x',y'); }

FillRegion(cval,x,y)
{ if(mask[x,y]) return;
  if(r[x,y] != cval) return;
  IsEdge(cval,x,y);
  mask[x,y] := 1;
  forevery({x',y'} := all_neighbours(x,y))
    FillRegion(cval,x',y'); }

bool IsOuterEdge(cval,x,y)
{ result := false;
  if(r[x,y] == cval) return(result);
  forevery({x',y'} := all_neighbours(x,y))
    { if(r[x',y'] == cval)
      { omask[x',y'] := 1; result := true; } }
  return(result); }

IsEdge(cval,x,y)
{ forevery({x',y'} := all_neighbours(x,y))
  { if(cval != r(x',y'))
    if(omask[x',y'])
      SetECRegion(x,y,x',y');
    else
      SetNTPPRegion(x,y,x',y'); }

SetECRegion(x1,y1,x2,y2)
{ if(relations[r[x1,y1],r[x2,y2]] == DCSTAR)
  { relations[r[x1,y1],r[x2,y2]] = ECSTAR;
    relations[r[x2,y2],r[x1,y1]] = ECSTAR; } }

SetNTPPRegion(x1, y1, x2, y2)
{ relations[r[x1,y1],r[x2,y2]] = NTPPISTAR;
  relations[r[x2,y2],r[x1,y1]] = NTPPSTAR; }

```

Figure 3 shows one part-processed image in a sequence captured from the viewpoint of our upper torso humanoid robot *Ludwig*. The objects are each of a distinctive colour and the raw image was captured using a Canon A80 digital camera, then suitably cropped and re-sized, but otherwise unmodified, prior to presentation to the program. The hue bands were adjusted by hand to achieve a clear region segmentation. Figure 4 shows the result of applying the algorithm to the image; note the diagonal symmetry.

6 RECOVERING OCCLUSION RELATIONS

We use the *Event Calculus* [14,15], with its primitive ontology of actions (and events), fluents, and time points, for representing and reasoning about occlusion events over time. For the purposes of this paper we will restrict our discussion to the *Happens*(α, t) and the *HoldsAt*(β, t) predicates. Visual occlusion events are modelled as time indexed *fluents* arising from the result of actions, e.g. moving and changing the viewpoint. Thus, for example, where from viewpoint v , body A partially hides body B at time t : this becomes: *HoldsAt*($PH(A, B, v), t$).

As a simple example, consider the sequence where two bodies A and B pass through the *LOS-14* transition path: $C(A, B) \rightarrow JC(A, B) \rightarrow PH(A, B) \rightarrow JF(A, B) \rightarrow F(A, B)$ respectively from times $t0$ to $t4$ – see Figure 1. In the interest of clarity only, we will assume a set of totally ordered time points: $t0$ through to $t4$. We also will assume that throughout this period the bodies are visible. Initially, we infer $C(A, B)$ at $t0$ (from dc*) and $F(A, B)$ (from ntpp*) at $t4$, while all the intermediate states between the time points $t1$ to $t3$ currently remain indistinguishable. This is resolved as follows.

From *Happens*(dc*(image($A, v0$), image($B, v0$), $t0$)) we can abductively infer *HoldsAt*($C(A, B, v0), t0$), and from the change of the detector at $t1$ (with only one direct CND transition) that *HoldsAt*($JC(A, B, v1), t1$) occurred. Given *Happens*(ntpp*(image($A, v4$), image($B, v4$), $t4$)) we know *HoldsAt*($F(A, B, v4), t4$). From the CND only *EH*(A, B) and *JF*(A, B) neighbour *F*(A, B). However, given that during period from $t0$ to $t4$, the detection of both A and B took place, then *EH*(A, B) at $t3$ is ruled out – leaving *HoldsAt*($JF(A, B, v3), t3$). And given it is not possible to pass from *JF* directly to *JC* without passing through *PH* (from the CND), then another event is interpolated, namely: *HoldsAt*($PH(A, B, v2), t2$) thus completing the sequence and satisfying the constraints imposed by the CND.

As for the remaining paths, clearly, parity of reasoning accounts for the path: $C(A, B) \rightarrow JC(A, B) \rightarrow PH(A, B) \rightarrow JF(A, B) \rightarrow Fi(A, B)$. By registering when a body is or is not visible, other sequences can be similarly determined: for example, $PH \rightarrow EH \rightarrow F$ (and its inverse sequence). It turns out that within this dynamic setting, 10 of the 14 relations (interpreted as occlusion events) can now be accounted for, leaving each of the pairs: JH and H ; and JHi and Hi as necessarily indeterminate. Hence, despite the paucity of the visual detectors as to occlusion events, and with minimal modelling assumptions, it becomes possible to infer the occlusion of bodies in three-dimensional space. A similar approach appears in [16] where *Aspect Graphs* replace the role of CNDs.

7 CONCLUSIONS

This paper demonstrates how, within an abductive framework, a rich set of occlusion spatial relations can be reliably inferred using a sparse and simple set of region-relation detectors. The decision to use simple detectors is justified on several grounds. Firstly, the difficult task of providing a clear interpretation for the detection of fine-tuned spatial relationships is now transferred to the inference mechanism. Constraints within the domain theory and associated CND are used in the recovery and justification of the interpolated relation made. Secondly, the sparse set of detectors is robust in use and hence less likely to return hypotheses that will later need to be revised. Thirdly, that the theoretically motivated minimal 3-adjacency neighbourhood property of pixels in segmented regions (and assumed by our algorithm) has additional practical consequence of providing a despeckle and general clean-up operation on raw images. This not only reduces the need to label more potential

regions, it also reduces the need to explain away data not directly supported by the intended model.

We have concentrated on region-contact spatial relations. However, other spatial logics can be similarly grounded in image data to capture more detail in the model. For example, variants on Allen's Interval logic [1] can be used to encode regions being to the left/right or above/below each other - see [10] for an example of this. While *LOS-14* assumes a domain of discrete convex bodies, the segmentation algorithm used does not capture this geometric property. However, by implementing this geometrical property, 7 of the 14 *LOS-14* relations can be directly detected. In the case where convexity condition no longer applies, *ROC-20* can be used to replace *LOS-14* and similarly mapped to the set of detectors – see [10] for the mapping between the relation sets: *ROC-20*, *LOS-14* and *RCC-8*.

Abductive Logic Programming in the Clinical Management of HIV/AIDS

Oliver Ray¹ and Athos Antoniades¹ and Antonis Kakas¹ and Ioannis Demetriadis²

Abstract. This paper presents a new Abductive Logic Programming (ALP) approach for assisting clinicians in the selection of anti-retroviral drugs for patients infected with Human Immunodeficiency Virus (HIV). The approach is comparable to laboratory genotypic resistance testing in that it aims to determine which viral mutations a patient is carrying and predict which drugs they are most likely resistant to. But, instead of genetically analysing samples of the virus taken from patients – which is not always practicable – our approach infers likely mutations using the patient’s full clinical history and a model of drug resistance maintained by a leading HIV research agency. Unlike previous applications of abduction, our approach does not attempt to find the “best” explanations, as we can never be absolutely sure which mutations a patient is carrying. Rather, the intrinsic uncertainty of this domain means that multiple alternative explanations are inevitable and we must seek ways to extract useful information from them. The computational and pragmatic issues raised by this approach have led us to develop a new ALP methodology for handling numerous explanations and for drawing predictions with associated levels of confidence. We present our *in-Silico Sequencing System* (iS3) for reasoning about HIV drug resistance as a concrete example of this approach.

1 Introduction

The World Health Organisation estimates 40 million people worldwide are infected with Human Immunodeficiency Virus (HIV). Since there is no cure for this disease, medical intervention aims to postpone the life-threatening collapse of immune function known as Acquired Immune Deficiency Syndrome (AIDS) [15]. Although potent combinations of drugs can slow its progression, the treatment of HIV is complicated by the propensity of the virus to accrue mutations that confer resistance to known medications. Thus clinicians are often faced with the task of designing *salvage therapies* for patients whose first- or second-line treatments are failing.

To improve the likelihood of finding effective salvage therapies medical guidelines advocate the use of laboratory *resistance tests* to help identify which viral mutations a patient is carrying and predict which drugs they are most likely resistant to [8]. But such tests require expert interpretation as they cannot reliably detect *minority* strains of the virus in a patient’s bloodstream or *archived* strains residing in less accessible tissues which may conceal drug resistant mutations. Thus clinicians must carefully analyse a patient’s medical history in order to infer the presence of other likely mutations not revealed by resistance testing.

This paper presents an experimental logic-based approach that can assist in the interpretation of resistance tests by also reasoning with clinical data summarising the success or failure of previous treatments. In particular, we describe a system called *in-Silico Sequencing System* (iS3) that uses Abductive Logic Programming (ALP) [12] to compute sets of mutations that explain a patient’s treatment history. A unique feature of this system is that it can make recommendations even in the absence of resistance tests – which may not be an option for many patients due to prohibitive costs, restricted access or technical limitations. In brief, iS3 uses the same rules as state-of-the-art HIV resistance test interpretation algorithms, but, instead of using them *forwards* to predict likely drug resistances implied by observed mutations, it uses them *backwards* to explain the observed drug response of a patient in terms of likely mutations.

A notable feature of this application domain is that even when resistance tests are available we can never be absolutely sure which mutations a patient is carrying, and so multiple explanations are unavoidable. Thus, in contrast to existing work on abduction, which is aimed at finding the so-called “best” explanations, we must adopt a more pragmatic approach that accepts the plurality of solutions and seeks to extract useful information from them. To this end we propose a three phase method comprising: (i) the development of a heuristic ALP model based on experimentally determined domain rules and prior knowledge, (ii) the introduction of general purpose and domain specific preference criteria to enable the extraction of ranked abductive hypotheses from the multitude of explanations, and (iii) the use of test data to validate the model and to calibrate the rankings by associating a level of confidence with each hypothesis.

The computational challenge of generating and handling large numbers of abductive explanations is considerable as thousands of explanations are typically generated for a single patient. In fact, such computational considerations required us to develop a new abductive engine, described in [16], simply to return these explanations in a feasible time. But, the sheer number of explanations is still too great to allow the efficient extraction of useful information. This motivates the introduction of minimality criteria to reduce the number of redundant explanations considered. Thus, we also describe an efficient method of computing minimal abductive explanations by explaining the observed data incrementally according to the temporal sequence by which it is generated. To demonstrate the utility of our approach, this paper introduces the iS3 drug resistance system as a concrete instance of our general ALP methodology.

The paper is structured as follows. Section 2 introduces the background material for HIV/AIDS and ALP. Sections 3 and 4 describe the ALP model and iS3 approach. Section 5 evaluates the approach using the clinical histories and genotypic data from 10 HIV-infected patients. We conclude with a discussion of related and future work.

2 Background

2.1 HIV resistance testing

Since its detection in the 1980's, HIV has become a global epidemic. Although several anti-HIV drugs have been developed, they are not very effective in isolation and so infected patients are usually given combination therapies of 3 or 4 drugs to disrupt different stages in the viral life-cycle [15]. Unfortunately, treatment is complicated by the tendency of HIV to develop mutations that confer resistance to these medications [8]. In essence, mutations are copying errors arising in the viral genome that result in amino acid substitutions in the protein sequences coded by those genes. Such changes can reduce the efficacy of certain drugs which target those proteins. For this reason, *resistance tests* are used to help identify which mutations a patient is carrying and predict which drugs they are most likely resistant to. Such tests are of two types [8]: *phenotypic assays* measure the ability of laboratory-cultured clinical isolates to thrive under various concentrations of a particular drug; while *genotypic assays* employ genetic probing or sequencing technologies to identify mutations in the genomes of viruses from infected patients and then apply statistical or rule-based methods to predict levels of drug resistance (based on data from large clinical association studies). However, resistance tests suffer from three limitations [8]. First, they are expensive (250-750\$) and require equipment to which many HIV-infected individuals do not have access. Second, they are ineffective for patients with low blood viral loads ($\leq 500\text{-}900$ copies/ml). Third, they are insensitive to minority strains (comprising $\leq 10\text{-}20\%$ of the viral population) that could lead to the failure of a salvage treatment. Consequently, when they are available, resistance tests require expert interpretation that also takes into account prior clinical history, and, when they are not available, it would be highly desirable to have a means of inferring likely mutations from clinical history alone. To this end, we propose the use of ALP, which is described below.

2.2 ALP Knowledge Representation

Abduction is a form of inference that reasons from effects to causes. Given a goal or observations G and a (logical) theory T , abduction returns explanations Δ that logically entail the goal with respect to the theory. Each explanation is a set of ground atoms whose predicates are specified as *abducible*. Intuitively, the abducibles A are predicates whose extents are incompletely specified by the theory, but which may be subject to further integrity constraints IC .

For computational purposes we use the framework of Abductive Logic Programming (ALP) [12, 6]. Formally, an ALP theory is a triple (T, A, IC) where T is a logic program (the theory), A is a set of predicates (the abducibles) and IC is a set of logical formulae (the integrity constraints). A goal G is a set of literals and an *explanation* of G with respect to (T, A, IC) is a set Δ of ground atoms with predicates in A such that: $T \cup \Delta \models_{LP} G$ and $T \cup \Delta \models_{LP} IC$, where \models_{LP} is some standard entailment relation of logic programming (in this paper we assume the *stable model* semantics).

Each abductive explanation Δ is a hypothesis that together with the model described in T explains how an experimental observable G could hold. The role of the integrity constraints IC , which are modularly stated in the theory, is to augment the basic model in T with any partial information on the abducible predicates or to impose additional validity requirements on the hypotheses Δ .

3 Model of HIV Drug Resistance

Our drug resistance model is automatically extracted from genotypic interpretation rules maintained by the French national AIDS research agency (ANRS) [3]. These rules come from expert analysis of large clinical trials investigating which mutations are associated with resistance to which drugs. We now briefly explain how these associations are represented in our model using the drug *zidovudine* as an example. The ANRS database contains four rules for this drug:

- Z_1 : Mutation Q151M.
- Z_2 : Insertion at codon 69.
- Z_3 : Mutation T215Y/F.
- Z_4 : At least 3 mutations in: M41L, D67N, K70R, L210W, T215A/C/D/E/G/H/I/L/N/S/V, K219Q/E.

Z_1 states that mutation Q151M causes *zidovudine* resistance. The notation Q151M refers to a substitution at codon 151 in the virus where the (wild type) amino acid glutamine, Q, is replaced by (the mutant) methionine, M. In our model, we use atoms of the form *resistant*(P, T, D) to denote that patient P is resistant to drug D at time T , and atoms of the form *mutation*(P, T, M) to denote that patient P is carrying mutation M at time T . Thus we represent Z_1 above by the clause T_1 below. For brevity, we omit the wild types in our formalism – as these are implied by the reference strain – and represent Q151M as 151M. Z_2 states the *insertion* of an amino acid at codon 69 is another indicator of resistance. This is modelled in clause T_2 using "1" to denote an insertion. Z_3 states that either 215Y or 215F will cause resistance. These *alternate* mutations are represented by the term "215YF" in T_3 . Z_4 states that resistance will result if the respective mutations are present at any three of the six codons listed. This is encoded in clause T_4 using the predicate *present*/4 defined in clauses T_5 , T_6 and T_7 to denote the presence in patient P at time T of at least N mutations from the given list. For convenience, the clauses below are all written in standard Prolog notation where variables begin with uppercase letters, the outer universal quantifiers are omitted and commas implicitly denote conjunctions.

- T_1 : *resistant*($P, T, zidovudine$) \leftarrow *mutation*($P, T, "151M"$).
- T_2 : *resistant*($P, T, zidovudine$) \leftarrow *mutation*($P, T, "69i"$).
- T_3 : *resistant*($P, T, zidovudine$) \leftarrow *mutation*($P, T, "215YF"$).
- T_4 : *resistant*($P, T, zidovudine$) \leftarrow *present*($P, T, 3, ["41L", "67N", "70R", "210W", "215ACDEGHILNSV", "219QE"]$).
- T_5 : *present*($P, T, N, [M|Ms]$) \leftarrow *present*(P, T, N, Ms).
- T_6 : *present*($P, T, N, [M|Ms]$) \leftarrow *mutation*(P, T, M), K is $N-1$, *present*(P, T, K, Ms).
- T_7 : *present*($P, T, 0, Ms$).

The ANRS database also contains more complex rules, built from conjunctions of simpler expressions. An example is the rule V_1 for *indinavir*, which is represented in our model by the clause T_8 below.

- V_1 : L90M and at least 2 mutations in: K20M/R, L24I, V32I, M36I, I54V/L/M/T, A71V/T, G73S/A, V77I.
- T_8 : *resistant*($P, T, indinavir$) \leftarrow *mutation*($P, T, "90M"$), *present*($P, T, 2, ["20MR", "24I", "32I", "36I", "54VLMT", "71VT", "73SA", "77I"]$).

For convenience, iS3 automatically downloads the ANRS rules from the Stanford HIV Drug Resistance Database (HIVDB) [19], where they are stored in a more convenient XML format called the Algorithm Specification Interface (ASI) [2]. The XML is parsed by a *document object model* compiler and processed by a *definite clause grammar* in order to extract a logical theory. In this way, we obtain 64 rules for 16 drugs. Currently, we only process rules with in the database which have the highest confidence rating, as these represent the surest indicators of resistance.

Where possible, alternate mutations like 54VLMT are modelled by single terms as this reduces the number of essentially equivalent explanations that need be computed. But, to ensure completeness, it is necessary "break up" alternate mutations that partially overlap with other mutations for the same codon. For example, there are three mutations in the database for codon 54, namely, 54VLMT, 54V and 54AMV, which must be decomposed into the non-overlapping fragments 54V, 54LT, 54M and 54A. For efficiency, alternate mutations are only broken down into the largest possible fragments.

In order to facilitate the computation of minimal abductive explanations some additional equivalence-preserving transformations are applied to the extracted rules such as combining the three rules $T_1 \wedge T_2 \wedge T_3$ into one single rule `resistant(P, T, zidovudine) ← present(P, T, 1, ["151M", "69i", "215YF"])`. As described in the next section, this rewriting is useful because the handling of the predicate `present/4` can be optimised in such a way that reduces the number of non-minimal explanations returned by the abductive proof procedure.

The post-processed theory can be used in two different ways. It can either be used *deductively* to perform standard genotypic test interpretation by asserting known mutations like `mutation(p056, 2, "215YF")` and deriving implied resistances like `resistant(p056, 2, zidovudine)`. More importantly, it can be used *abductively*, for what we call *in-silico* sequencing, by explaining observed resistances in terms of possible mutations. For example, declaring `mutation/3` as the only abducible predicate, there are 23 possible explanations for zidovudine resistance.

This model can now be used to explain the observed ineffectiveness (resp. effectiveness) of a prescribed *set* of drugs by hypothesising the presence (resp. absence) of mutations that imply resistance (resp. non-resistance) to at least one drug in that set. For example, there are 73 explanations for the ineffectiveness of the combination therapy consisting of the three drugs *zidovudine*, *lamivudine* and *indinavir*. Conversely, the effectiveness of a therapy can be explained by the absence of any mutations that would imply resistance to those drugs.

To capture the dynamics of drug resistance, we need an integrity constraint to enforce a key biological assumption in this work: namely, the persistence of mutations. This assumption is motivated by research showing that drug resistant strains of HIV can persist at undetectable levels for long periods (close to the life expectancy of a patient) only to re-emerge when more favourable drugs are prescribed. This constraint, formalised in I_1 below, states that if a patient P carries a mutation M at time T_1 , then he or she will carry that mutation at all later times T_2 .

```
 $I_1: \text{false} \leftarrow \text{mutation}(P, T_1, M), T_2 > T_1,$ 
 $\quad \quad \quad \neg \text{mutation}(P, T_2, M).$ 
```

In summary, our ALP model consists of the rules extracted from the ANRS database, the integrity constraint above and the abducible predicate `mutation/3`. In the next section, we explain how this model is used in iS3 to reason with real patient clinical data.

4 Analysis of Clinical Data

Given a patient's clinical history in the form of facts stating which combinations of drugs were effective or ineffective at given times, iS3 deploys an ALP procedure [16] to infer sets of mutations that explain these observations according to the model in the previous section. The objective is to obtain a set of hypotheses representing different ways of explaining the data which can then be analysed in order derive useful predictions about drug resistance.

As illustrated above, ineffective treatments suggest that certain mutations may have occurred, while effective ones suggest that certain others did not – possibly leading to a violation of integrity that results in the rejection of incorrect explanations. But, for a typical patient – by which we mean one taking 3 different drugs at each of 10 different time points – the computation produces more solutions (many thousands) than can be conveniently analysed.

For this reason, it is necessary to use additional preference criteria to reduce the search space. Assuming that patients adhere to their medications and are regularly monitored to ensure early detection of treatment failure, it is plausible [8] that mutations accrue relatively slowly. We can model this through the notion of *minimality* [12] – which means we only accept explanations from which no smaller explanations can be obtained by removing atoms.

To enforce the minimality of explanations, we optimised the ALP procedure's handling of `present/4` so that, for example, given the subgoal `present(P, T, 1, ["151M", "69i", "215YF"])` it does not consider the first two redundant choices if it has previously established `mutation(P, T, "215YF")`. We also explicitly remove any non-minimal explanations from the solution set obtained after processing each time point. In this way, the number of explanations for the typical patient is cut down to a few hundred.

From this set of explanations explaining a patient's clinical history by the mutations they may or may not be carrying, our task is to analyse these explanations in order to predict for which drugs the patient may be resistant. As a first step, we propose (i) to rank each mutation in the list according to the number and size of explanations it appears in and (ii) to rank each drug in our model according to the number of explanations that imply its resistance.

For task (i), we compute a score for each mutation such that each explanation in which mutation appears contributes a fixed value that decreases with the size of the explanation. (We view this score as simple scalar quantity whose only purpose is to allow the ranking of hypotheses.) The clinical history of a typical patient results in a ranking that contains 30 mutations (out of a possible 60 for which we have rules – or rather 100 if compound mutations are broken up) with scores ranging from 0 to 500, where higher scores indicate a greater likelihood the mutation is present. For example, the top ten ranked mutations for patient p056 are as follows: 215YF (270), 69i (270), 151M (270), 82S (256), 84AV (256), 82T (256), 82AF (256), 46IL (256), 90M (192), 82M (179), etc.

For task (ii), we consider each drug in turn and then count the number of explanations which imply resistance to that drug by essentially using the model in a deductive fashion to perform standard genotypic interpretation on each hypothesised set of mutations. Once again the resulting scores typically range from 0 to 500, with higher scores denoting a greater likelihood of resistance to that drug. For example, the top ten ranked drugs for patient p056 are as follows: efavirenz (252), stavudine (240), zidovudine (230), nevirapine (224), indinavir (81), lamivudine (58), emtricitabine (58), saquinavir (55), ritonavir (53), nelfinavir (49), etc.

5 Calibration and Evaluation

So far we have described a system that, given a patient's clinical history, produces a ranked list of the mutations the patient might be harbouring and the drugs to which they may be resistant. Now we would like to establish some measure of confidence in those lists and identify clinically relevant cut-offs. To do this, we apply the system to data from 10 HIV-infected patients who, over a period of two years, underwent regular medical examinations, routine blood tests, and were genotyped once.³ Some statistics for these patients are shown in the table below. On average, there are six time points for each patient (abstracted in simple way from his treatment history), of which roughly 2 are treatment failures. For reference, the numbers of minimal explanations and ranked mutations are also shown.

patient ID	time points	treatmt. failures	minimal explns.	ranked mutations
p027	9	3	1283	29
p032	5	2	51	32
p056	7	3	333	40
p085	6	3	138	26
p089	9	3	1628	26
p101	7	2	191	32
p113	6	2	1938	38
p114	5	1	73	28
p166	4	1	73	28
p184	6	2	72	27

The only way of assessing whether the mutations predicted by the system are biologically correct is to compare the predicted mutations with the result of the genotype. But this is problematic given that our system is an attempt to overcome the fact genotyping cannot reveal all of the mutations carried by a patient. Thus, while we accept that any mutations detected by the genotype are carried by the patient, we expect that our system will return mutations that are not detected by the genotype but are carried by the patient nonetheless.

Figure 1 (a) plots the percentage of mutations detected by the genotype (on the y-axis) that are contained in the corresponding percentage of top-ranked mutations (on the x-axis). This graph shows that the observed mutations are distributed evenly through the ranking.⁴ In order to obtain a more useful estimate of the system's performance, it is necessary to compensate for selectiveness of the genotype – which is due to the fact that the drugs taken by the patient at the time of genotype reduce non-resistant strains to undetectable levels, while providing the conditions for resistant strains to thrive.

We therefore expect that mutations which are resistant to these drugs will be detected by the genotype with more certainty than those which are not. To account for this, we use our resistance rules to find those mutations that confer no resistance to any of the drugs being taken at the time of the genotype, and we place these mutations further down the ranking while preserving their relative order.

Figure 1 (b) shows the corresponding plot for the adjusted ranking. We see that observed mutations are now ranked much higher, with the majority contained in the top two thirds. While there is insufficient data to draw any significant conclusion⁵, this increases our confidence the system is working correctly, and it suggests a useful

clinical cut-off in the sense that the top 2/3 of the ranked mutations appear to contain most of the useful information.

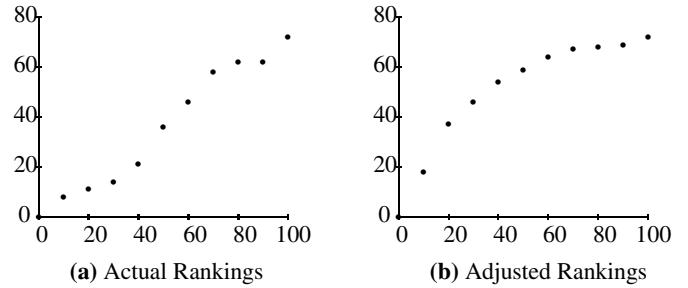

Figure 1. % of genotyped mutations (y) vs. % of top ranked mutations (x)

We would now like to establish whether this 2/3 cut-off also applies to the drug resistances predicted by the system. This is arguably more important since it represents the actual mode of operation for which the system is intended. To do this using the data available to us, we adopted a "leave-one-out" strategy, whereby the system was run on the clinical history of each patient up to *but not including* the last time point with a known (effective or ineffective) outcome at which a new set of drugs was prescribed. We compared the observed effectiveness of the drugs at the next time point with the predicted effectiveness returned by the system.

The results are shown in the table below. For each patient, the 16 drugs are each denoted by one of the symbols '.', '+' or '*' which are distributed in order of decreasing predicted resistance from left to right. A plus denotes a drug contained in the treatment at next time point. Because the prescribed treatments were all found to be effective at the following time point, we would like for the system to give these drugs a low resistance. As shown in the table, they were mostly predicted medium or low resistance, indicating a better than average performance. A star denotes a drug for which resistance can be inferred using the rules of the system and the mutations in the genotype. We would like the system to rank these highly. As shown below, this is generally the case, once again suggesting a better than average performance. All other drugs are denoted by a dot.

Interestingly, half of the patients were prescribed one drug with high predicted resistance. But, in all cases, the other drugs were ranked much lower – which is consistent with the overall success of the treatment. The system performed very well for p166, where resistance to the two top-ranked drugs was independently supported by the genotypic evidence, and two of the drugs found to be effective at the next time point received a low or medium prediction.

Patient ID	Predicted Drug Resistance		
	high	medium	low
p027++..+..
p032	.+.**	+.*..+..
p056	+...+*	+....+
p085	+....	.+....	..+...+
p089	+....	.+....+..
p101	.+...	...++.	+.....
p113+	..++..
p114++..+.*
p166	*+..+	...++.	..+....
p184	..+..	.+....

+ drugs used in effective therapy at next time point

* drugs inferred to be ineffective from genotype data

³ Unfortunately, clinical data from 10 additional patients was considered too unreliable by an HIV specialist to include in this study.

⁴ The graph only rises to 80% as some genotyped mutations are not ranked. These could be given a default score of 0, but this serves no real purpose.

⁵ The genotype only returns results for 33 of 97 mutations in our rules, so that the presence or absence of most ranked mutations is unknown.

6 Discussion and Related Work

Previous work on HIV resistance is aimed at predicting drug resistance from the results of genotypic or phenotypic tests performed on clinical isolates from infected patients [1]. Our work does just the opposite, by explaining previously observed resistance in terms of underlying mutations and using these explanations to predict possible drug resistance. Our model of HIV drug resistance is derived from the ANRS genotypic interpretation algorithm [3]. Other rule-based interpretation algorithms could have been used instead, such as those compared in [23] or those available from the Stanford HIVDB web site [19], but ANRS was selected because it was more amenable to the extraction of logical rules.

Previous applications of abduction, such as natural language understanding [9], planning [20, 11], perception [21] and diagnosis [4, 17, 7], take the approach of inference to the "best explanation" [10] by using domain specific constraints to identify one or more optimal hypotheses. The (often implicit) assumption in these applications is that we have sufficient information to discriminate between alternative explanations. Some applications such as [13] and [5] even combine abduction and constraint solving in order to solve the implicit optimisation problems underlying these domains. When this assumption does not hold it is suggested that we carry out "crucial experiments" [18] to obtain further information that would help home-in on the optimal hypotheses.

Our work offers an alternative approach to real-life applications in which the underlying model does not (and cannot) provide enough information to reliably discriminate between competing hypotheses. In these cases, we suggest the emphasis should be placed on extracting useful information from the multitude of explanations and helping the user to make informed decisions. This view is particularly relevant in applications of abduction to scientific theory formation, such as [24, 14, 22], where the task is to improve a necessarily incomplete model of the problem domain.

7 Conclusions and Future Work

This paper introduced a novel AI approach for abductively inferring mutations carried by HIV-infected patients and predicting likely drug resistance from clinical data. The proposed approach is a concrete instance of a new ALP methodology for addressing the issue of multiple explanations through a process of ranking abductive hypotheses extracted from the multitude of explanations and empirically calibrating the system to obtain a measure of confidence in its results. Our in-silico sequencing system, iS3, is a practical implementation with the potential to assist clinicians in the selection of anti-retroviral drugs – especially in cases where laboratory resistance tests are not available. The system automatically keeps itself updated with the latest drug resistance data provided by a leading HIV research body.

We are currently preparing the system for a trial deployment in an HIV/AIDS clinic where we hope to assess the clinical utility of the system and carry out further tests on another cohort of HIV carriers from a different geographical areas. We are also investigating possible improvements to the system by (i) extending the domain model with additional information about common *pathways* by which some viral mutations are known to occur, by (ii) incorporating information about *antagonistic mutations* that partially reverse the resistance effects of some other mutations, and by (iii) exploiting statistical information associated with the drug resistance rules used in the model. We are also keen to examine how our general ALP approach for handling multiple explanations can be applied to other applications.

ACKNOWLEDGEMENTS

We are grateful to Leondios Kostrikis, who helped with the interpretation of the genotypic tests, and to Bradely Betts for his assistance with the Stanford Algorithm Specification Interface. We also thank the anonymous referees for their helpful suggestions.

Interleaving belief updating and reasoning in abductive logic programming

Fariba Sadri and Francesca Toni¹

Abstract. Most existing work on knowledge representation and reasoning assumes that the updating of beliefs is performed off-line, and that reasoning from the beliefs is performed either before or after the beliefs are changed. This imposes that, if an update occurs while reasoning is performed, reasoning has to be stopped and re-started anew so that the update is taken into account, with an obvious wastage of reasoning effort. In this paper, we tackle the problem of performing belief updating on-line, while reasoning is taking place by means of an abductive proof procedure.

1 INTRODUCTION

Traditionally, the area of knowledge representation and reasoning has focused on identifying techniques for drawing correct conclusions efficiently from beliefs. Beliefs can be held by intelligent agents, for example, and reasoning can aim at identifying plans for the agents' goals or answering queries on the agents' beliefs. Such beliefs can be subject to updates. The updates can be generated by a number of different means, for example by learning, or, in a multi-agent setting, by observation or by communication amongst agents.

If the updating of beliefs takes place while reasoning is performed, the problem arises as to which parts of the already performed reasoning can be "saved", because it has used beliefs which have not been affected by the update. Conventional knowledge representation and reasoning systems assume that no parts of reasoning can be saved, by restarting the reasoning process anew.

In this paper, we show how belief updating and reasoning can be interleaved, so that reasoning with beliefs that are not affected by the updates can be saved and, if necessary, used after the updating. We assume that reasoning is performed by means of the abductive proof procedure IFF [3] and that beliefs are represented by means of abductive logic programs (ALPs) [6]. ALPs consist of logic programs and integrity constraints. We also assume that belief updating amounts to the addition or deletion of rules in the logic program component of the ALP, or to the addition or deletion of integrity constraints in the corresponding component of the ALP.

In this paper, we do not address how the updates are determined. In particular, we do not focus on "belief revision" (e.g. as understood in [1]), but rather on how updates produced by such revision can be interleaved with the reasoning process.

In order to save any reasoning effort not affected by updates, we adopt a labeling technique that maintains dependencies. We define a new variant of the IFF procedure, called *LIFF*, with labels occurring in derivations. We formalise the soundness of LIFF, wrt the semantics

underlying the IFF procedure. We concentrate on the propositional case only for the definition of LIFF and the results.

Our work is closely related to the work of [4, 5], which share our aims. However, we extend an abductive proof procedure (IFF) for beliefs in the form of ALPs whereas [4] extends conventional SLDNF, for ordinary logic programs. Our knowledge representation and reasoning choice paves the way to the use of our techniques for agent applications, following the abductive logic agent approach of [8, 13, 7]. Moreover, we use a labeling technique rather than the (arguably more space consuming) technique based on full data structures associated to atoms as in [4].

Amongst agent applications for which our approach is particularly useful are those where the agents are situated in dynamic environments and need to adjust quickly to the changes in that environment. For example, a situated pro-active agent can plan for its goals while it interleaves the planning with action execution and observations in the environment; such an agent has, for example been described in [10]. The observations that it makes and records from the environment and the success or failure of the actions that it attempts to execute can lead to the agent revising its beliefs. LIFF allows the agent to keep as much of its partial plan as possible and to replan only those parts that are affected by the changes in its beliefs.

Another agent application that would benefit from our work is information integration via a mediator, for example to realise the semantic web. In this application a mediator agent receives the user query specified in some user-oriented high-level language. It then constructs a query plan translating the user query into a form understandable by the sources of information it has at its disposal. It contacts the sources for the necessary information, integrates their answers, and translates the answer into the language of the user. Such an information integration approach based on abductive logic programming and, in particular the IFF proof procedure, has been described in [19]. Now, while the agent is constructing the query plan for the user query, it may receive information about content or availability changes to the information sources. LIFF would allow the agent to accommodate these changes within its reasoning without having to discard all the work it has done in constructing the query plan.

This paper is a revised and extended version of [12].

2 PRELIMINARIES

Abductive logic programming is a general-purpose knowledge representation and reasoning framework that can be used for a number of applications and tasks [6, 8, 11, 14, 13, 17, 18]. It relies upon a logic-based representation of beliefs, for any given domain of application, via *abductive logic programs* (ALPs), and the execution of logic-based reasoning engines, called *abductive proof procedures*,

¹ Department of Computing, Imperial College London, UK,
 email:{fs, ft}@doc.ic.ac.uk

for reasoning with such representations. In this paper we concentrate on the propositional case.

An ALP consists of

- A **logic program**, P , namely a set of if-rules of the form $\text{Head} \leftarrow \text{Body}$, where Head is an atom and Body is either *true* (in which case we write the if-rule simply as Head) or a conjunction of literals. P is understood as a (possibly incomplete) set of beliefs.
- A set of **abducible atoms**, \mathcal{A} , which are assumed not to occur in the Head of any if-rule in P . Abducible atoms can be used to “augment” the (beliefs held within the) logic program, subject to the satisfaction of the integrity constraints (see below).
- A set of **integrity constraints**, I , namely if-then-rules of the form $\text{Condition} \Rightarrow \text{Conclusion}$, where Condition is either *true* (in which case we write the if-then-rule simply as Conclusion) or a conjunction of literals, and Conclusion is *false* or an atom. The integrity constraints are understood as properties that must be “satisfied” by any “acceptable” extension of the logic program by means of abducible atoms.

In the sequel, $\overline{\mathcal{A}}$ will refer to the complement of the set \mathcal{A} wrt the set of all atoms in the vocabulary of P , i.e. $\overline{\mathcal{A}}$ is the set of non-abducible atoms. Both IFF and LIFF rely upon the **completion** [2] of logic programs. The completion of an atom p defined, within a propositional logic program, by the if-rules $p \leftarrow D_1, \dots, p \leftarrow D_k$ is the **iff-definition** $p \leftrightarrow D_1 \vee \dots \vee D_k$. The completion of an atom p not defined in a given logic program is $p \leftrightarrow \text{false}$. The **selective completion** $\text{comp}_{\overline{\mathcal{A}}}(P)$ of a logic program P wrt a set of atoms S in the vocabulary of P is the union of the completions of all the atoms in S . Both IFF and LIFF use $\text{comp}_{\overline{\mathcal{A}}}(P)$, i.e. the selective completion of P wrt $\overline{\mathcal{A}}$.

Abductive proof procedures aim at computing “explanations” (or “abductive answers”) for “queries”, given an ALP representing knowledge about some underlying domain. A **query** is a (possibly empty) conjunction of literals. Given an ALP $\langle P, \mathcal{A}, I \rangle$, an **explanation** (or **abductive answer**) for a query Q is a (possibly empty) set E of abducible atoms such that $P \cup E \text{ entails } Q$ and $P \cup E \text{ satisfies } I$. Various notions of entailment and satisfaction can be adopted, for example entailment and satisfaction could be entailment and consistency, respectively, in first-order, classical logic. In this paper, we adopt truth wrt the 3-valued completion semantics of [9] as the underlying notion of entailment and satisfaction, inherited from IFF [3].

IFF generates a **derivation** consisting of a **sequence of goals**, starting from an **initial goal**, which is the given query conjoined with the integrity constraints in I . IFF computes explanations (referred to as **extracted answers**) for the given query extracting them from disjuncts in a goal in a derivation from the initial goal, when no further inference rule can be applied to these disjuncts.

Goals in a derivation are obtained by applying **inference rules** (see section 5.1). In the simplest case, these goals are disjunctions of **simple goals**, which are conjunctions of the form

$$A_1 \wedge \dots \wedge A_n \wedge I_1 \wedge \dots \wedge I_m \wedge D_1 \wedge \dots \wedge D_k$$

where $n, m, k \geq 0$, $n + m + k > 0$, the A_i are atoms, the I_i are **implications**, with the same syntax as integrity constraints, and the D_i are disjunctions of conjunctions of literals and implications. Implications are obtained by applying the inference rules of the proof procedure to either integrity constraints in the given $\langle P, \mathcal{A}, I \rangle$ or to the result of rewriting negative literals $\text{not } A$ as $A \Rightarrow \text{false}$.

IFF assumes that the inference rules are applied in such a way that every goal in a derivation is a *disjunction of simple goals*. LIFF will make the same assumption.

We omit here the definition of the inference rules of IFF, as they

can be re-constructed from the inference rules of LIFF, given in section 5, by dropping the labels. In section 4 we illustrate the behaviour of IFF and LIFF with an example. The example illustrates the main difference between IFF and LIFF, namely the fact that the latter associates labels to literals and implications in goals, to be exploited when the ALP is updated.

3 ASSIMILATING UPDATES IN THE ABDUCTIVE LOGIC PROGRAM

As mentioned in section 1, the decision of what to revise and how can be done in a number of different ways. However the belief revision is handled, at the end of the process, if-rules or integrity constraints will need to be added or deleted from the ALP. In this section we define how a given ALP $\langle P, \mathcal{A}, I \rangle$ is revised after (any number of) the following kinds of updates:

- the addition to P of if-rules,
- the deletion from P of if-rules,
- the addition to I of integrity constraints,
- the deletion from I of integrity constraints.

Note that *modification* of if-rules and integrity constraints can be achieved by suitable combinations of deletions and additions.

There are a number of different ways that we can accommodate addition and deletion of if-rules in an ALP. For example, we can decide whether or not an atom that is originally abducible will, in effect, remain abducible after any updates. Similarly we can decide whether or not an atom that is originally non-abducible will always be non-abducible, even if all its definitions are deleted from the logic program. LIFF is independent of these choices, and it can deal uniformly with any combinations or variations of these choices. Below, we arbitrarily make the concrete choice where, after any updates, non-abducible atoms remain non-abducible and abducible atoms remain “abducible”, in the sense that they can always be made to hold by abduction, as we will see later. Below, $\langle P, \mathcal{A}, I \rangle$ denotes the ALP before the update.

3.1 Addition of if-rules

Let the update U be the addition of the if-rule $p \leftarrow B$, with $B \neq \text{false}$,² and with B possibly *true*. We will refer to \mathcal{A}_B as the set of atoms occurring in B but not in the vocabulary of $\langle P, \mathcal{A}, I \rangle$.

We refer to the revision of $\langle P, \mathcal{A}, I \rangle$ by U as $U(\langle P, \mathcal{A}, I \rangle) = \langle P', \mathcal{A}', I \rangle$, obtained as follows:

1. if p is an abducible in \mathcal{A} , then
 - $P' = P \cup \{p \leftarrow B\} \cup \{p \leftarrow p^*\}$,
 - $\mathcal{A}' = ((\mathcal{A} \cup \{p^*\}) - \{p\}) \cup \mathcal{A}_B$,

where p^* is an atom not in the vocabulary of $\langle P, \mathcal{A}, I \rangle$;
2. if p is in the vocabulary of $\langle P, \mathcal{A}, I \rangle$ but is not abducible or p is not in the vocabulary of $\langle P, \mathcal{A}, I \rangle$, then
 - $P' = P \cup \{p \leftarrow B\}$,
 - $\mathcal{A}' = \mathcal{A} \cup \mathcal{A}_B$.

Note that, in case 1, the definition of p in P' conforms to our policy that atoms that are abducible in the initial ALP always remain

² The addition of $p \leftarrow \text{false}$ is not allowed directly, but it can be achieved by deleting all if-rules with head p . We assume that p remains in the language of the ALP even after all if-rules for p are deleted from it.

“abducible”, in the sense that they can be assumed to hold by abduction (of atoms p^*). Note also that we assume that any atom in the body of any added rule but not present in the vocabulary of the ALP prior to the update is treated as a new abducible (in \mathcal{A}_B). This choice sees new undefined atoms as “open”. Finally, note that we do not allow the addition of new abducible atoms explicitly, from the outside. However, new abducible atoms are added as a by-product of adding definitions for abducible atoms (case 1 above) or definitions of atoms containing the new abducible atoms in the body, as atoms that did not occur before in the ALP (cases 1-2 above).

3.2 Deletion of if-rules

Let update U be the deletion of $p \leftarrow B \in P$ (B possibly true). We will assume that B is different from a p^* atom, namely an atom introduced in case 1 in section 3.1. Revising $\langle P, \mathcal{A}, I \rangle$ by U gives $U(\langle P, \mathcal{A}, I \rangle) = \langle P', \mathcal{A}, I \rangle$, obtained as follows: $P' = P - \{p \leftarrow B\}$.

3.3 Addition of integrity constraints

Let update U be the addition of $C \Rightarrow D$. Let \mathcal{A}_U be the set of all atoms occurring in C, D but not in the vocabulary of $\langle P, \mathcal{A}, I \rangle$. Revising $\langle P, \mathcal{A}, I \rangle$ by U gives $U(\langle P, \mathcal{A}, I \rangle) = \langle P, \mathcal{A}', I' \rangle$, obtained as follows:

- $I' = I \cup \{C \Rightarrow D\}$;
- $\mathcal{A}' = \mathcal{A} \cup \mathcal{A}_U$.

3.4 Deletion of integrity constraints

Let update U be the deletion of $C \Rightarrow D \in I$. Revising $\langle P, \mathcal{A}, I \rangle$ by U gives $U(\langle P, \mathcal{A}, I \rangle) = \langle P, \mathcal{A}, I' \rangle$, obtained as follows: $I' = I - \{C \Rightarrow D\}$.

3.5 Multiple updates

Here we define the effect of multiple updates upon an initially given ALP $\langle P, \mathcal{A}, I \rangle$. Let the sequence of updates be U_1, \dots, U_n , with $n > 1$. Then, U_1, \dots, U_n applied to $\langle P, \mathcal{A}, I \rangle$ gives

$U_n \circ U_{n-1} \circ \dots \circ U_1(\langle P, \mathcal{A}, I \rangle) = U_n(U_{n-1}(\dots(U_1(\langle P, \mathcal{A}, I \rangle))))$. Later, in section 5.2, we will allow empty updates to occur in sequences of updates. An empty update stands for no update at all.

4 AN ILLUSTRATIVE EXAMPLE

In this section we illustrate the application of LIFF and its relationship to IFF via a concrete example. The example also illustrates the potential saving in re-computation, for example, compared to “backtracking” to an appropriate place in the search space.

Given the ALP $\langle P, \mathcal{A}, I \rangle$ with

$$\begin{aligned} P: p &\leftarrow r, \quad q \leftarrow s, \quad r \leftarrow t, \quad m \leftarrow \neg a \\ \mathcal{A}: a, n, s, t \\ I: s \wedge m &\Rightarrow n \end{aligned}$$

and a query $p \wedge q$, IFF may derive the following sequence of goals (where, with an abuse of notation, I will stand for $s \wedge m \Rightarrow n$):

$$\begin{aligned} p \wedge q &\wedge I \\ \text{by unfolding } p \text{ with } \text{Comp}_{\overline{\mathcal{A}}}(P): \\ r \wedge q &\wedge I \\ \text{by unfolding } q \text{ with } \text{Comp}_{\overline{\mathcal{A}}}(P): \\ r \wedge s \wedge I \\ \text{by unfolding } r \text{ with } \text{Comp}_{\overline{\mathcal{A}}}(P): \end{aligned}$$

$$t \wedge s \wedge I$$

by propagation with $s \wedge m \Rightarrow n \in I$:

$$t \wedge s \wedge (m \Rightarrow n) \wedge I$$

by unfolding m with $\text{Comp}_{\overline{\mathcal{A}}}(P)$:

$$t \wedge s \wedge (\neg a \Rightarrow n) \wedge I$$

by negation elimination and splitting:

$$[t \wedge s \wedge a \wedge I] \vee [t \wedge s \wedge n \wedge I]$$

From the final goal in this derivation, IFF would extract the explanations $\{t, s, a\}$ (from the first disjunct) and $\{t, s, n\}$ (from the second disjunct) for the given query.

Given the same $\langle P, \mathcal{A}, I \rangle$ and query, the analogous LIFF derivation would consist of the following sequence of goals with labels. Labels are formally given in definition 1. A label $\{\langle X_1; Y_1 \rangle, \dots, \langle X_n; Y_n \rangle\}$ associated with a literal conjunct or an implication Z in a goal, intuitively indicates that “if X_i is updated, then Z should be replaced by Y_i ”. In the simplest case, each X_i is an atom or an integrity constraint and each Y_i is an atom or an implication or \emptyset , standing for empty. For ease of reading where the label of a conjunct does not change from one goal to the next in the sequence we do not repeat the label.

$$p : \{\} \wedge q : \{\} \wedge I : \{\langle I; \emptyset \rangle\}$$

by unfolding p with $\text{Comp}_{\overline{\mathcal{A}}}(P)$:

$$r : \{\langle p; p \rangle\} \wedge q \wedge I$$

by unfolding q with $\text{Comp}_{\overline{\mathcal{A}}}(P)$:

$$r \wedge s : \{\langle q; q \rangle\} \wedge I$$

by unfolding r with $\text{Comp}_{\overline{\mathcal{A}}}(P)$:

$$t : \{\langle p; p \rangle, \langle r; r : \{\langle p; p \rangle\} \rangle\} \wedge s \wedge I$$

by propagation (with $s \wedge m \Rightarrow n \in I$):

$$t \wedge s \wedge (m \Rightarrow n) : \{\langle q; \emptyset \rangle, \langle I; \emptyset \rangle\} \wedge I$$

by unfolding m with $\text{Comp}_{\overline{\mathcal{A}}}(P)$:

$$t \wedge s \wedge (\neg a \Rightarrow n) : \text{label} \wedge I$$

where label is $\{\langle q; \emptyset \rangle, \langle I; \emptyset \rangle, \langle m; (m \Rightarrow n) : \{\langle q; \emptyset \rangle, \langle I; \emptyset \rangle\} \rangle\}$

by negation elimination and splitting:

$$[t \wedge s \wedge a : \text{label} \wedge I] \vee [t \wedge s \wedge n : \text{label} \wedge I]$$

Suppose at this stage of the derivation there is an update (addition or deletion) to the definition of p . If we were to simply “backtrack” to where the definition of p was used the first time we would go back to the very first goal of the derivation, namely $p \wedge q \wedge I$ and, effectively, start all over again. But using the labels of LIFF we would simply rewrite the last goal of the derivation as $[p \wedge s \wedge a] \vee [p \wedge s \wedge n]$ (for ease of reading we have dropped the labels here) thus in effect, saving the work done in the application of 4 out of the 6 inferences.

5 THE LIFF PROOF PROCEDURE

Definition 1 A label (for an atom or implication) is a set

$$\{\langle X_1; Y_1 \rangle, \dots, \langle X_n; Y_n \rangle\}$$

$n \geq 0$, with each X_i an atom or an integrity constraint and each Y_i either

- empty: \emptyset , or
- an atom (possibly with a label), or
- an implication (possibly with a label), and $X_i \neq X_j$ for all $i \neq j$.

Note that labels can be empty (i.e. if $n = 0$). Each $\langle X_i; Y_i \rangle$ in a label for Z indicates that Z should be replaced by Y_i if any update is made upon X_i . In effect, this label identifies the components that have contributed to the derivation of Z . We impose that all X_i are different so that there is no ambiguity as to what Z has to be replaced with when X_i is updated.

We will refer to labeled atoms/implications simply as atoms/implications. Moreover, the terminology of goals and simple goals will carry through in the presence of labels.

5.1 LIFF inference rules

Given an ALP $\langle P, \mathcal{A}, I \rangle$ and an initial query Q , we will define *LIFF derivations* for Q in terms of sequences of goals, G_1, \dots, G_n , such that $G_1 = Q : \{\} \wedge I^*$, where $(A_1 \wedge \dots \wedge A_k) : 1$ ($k > 1$) stands for $A_1 : 1 \wedge \dots \wedge A_k : 1$ ³, $I^* = \{i : \langle i; \emptyset \rangle | i \in I\}$, and each G_{i+1} is obtained from the previous goal G_i either by enforcing an update (see section 5.2) or by application of one of the inference rules below.

Unfolding an atomic conjunct: given $p \leftrightarrow D_1 \vee \dots \vee D_n$ in $\text{comp}_{\overline{\mathcal{A}}}(P)$ and an atom $p : 1$ which is a conjunct of a simple goal in G_i ,

then G_{i+1} is G_i with $p : 1$ replaced by $(D_1 \vee \dots \vee D_n) : 1'$, where $1' = 1$ if $\langle p; S \rangle \in 1$, for some S , and $1' = 1 \cup \{\langle p; p : 1 \rangle\}$ otherwise.

Unfolding an atom in the conditions of an implication: given $p \leftrightarrow D_1 \vee \dots \vee D_n$ in $\text{comp}_{\overline{\mathcal{A}}}(P)$ and an implication $[L_1 \wedge \dots \wedge L_i \wedge \dots \wedge L_m \Rightarrow A] : 1$ which is a conjunct of a simple goal of G_i with $L_i = p$,
then G_{i+1} is G_i with the implication replaced by the conjunction $[L_1 \wedge \dots \wedge D_1 \wedge \dots \wedge L_m \Rightarrow A] : 1' \wedge \dots \wedge [L_1 \wedge \dots \wedge D_n \wedge \dots \wedge L_m \Rightarrow A] : 1'$, where $1' = 1$ if $\langle p; S \rangle \in 1$, for some S , and $1' = 1 \cup \{\langle p; L_1 \wedge \dots \wedge L_m \Rightarrow A : 1 \rangle\}$ otherwise.

Propagation: given an atom $p : 1$ and an implication $[L_1 \wedge \dots \wedge L_i \wedge \dots \wedge L_m \Rightarrow A] : 1'$ with $L_i = p$, both conjuncts of the same simple goal in G_i ,
then, if the implication $[L_1 \wedge \dots \wedge L_{i-1} \wedge L_{i+1} \wedge \dots \wedge L_m \Rightarrow A] : \{\langle q; \emptyset \rangle | \langle q; r \rangle \in 1 \cup 1'\}$ is not already a conjunct of the simple goal, then G_{i+1} is G_i with the new implication conjoined to the simple goal.

Negation elimination: given an implication $\text{not } A_1 \wedge \dots \wedge \text{not } A_m \Rightarrow A : 1$ which is a conjunct of a simple goal in G_i , then G_{i+1} is G_i with the implication replaced by the disjunction $[A \vee A_1 \vee \dots \vee A_m] : 1$.⁴

Logical simplification replaces:

- $[B : 1 \vee C : 1'] \wedge E : 1''$ by $[B : 1 \wedge E : 1''] \vee [C : 1' \wedge E : 1'']$ (**splitting**)
- $B : 1 \wedge B : 1$ by $B : 1$
- $B : 1 \vee B : 1$ by $B : 1$
- $\text{not } A : 1$, where A is an atom, by $(A \Rightarrow \text{false}) : 1$

Note that we are not including some simplification steps present in IFF, e.g. $A \wedge \text{false} \equiv \text{false}$ and $A \vee \text{false} \equiv A$. Such simplification steps only affect the “efficiency” of IFF, rather than its correctness. We leave these steps out in LIFF because it simplifies the labels while allowing us to incorporate updates and revise the goals when necessary (e.g. revising $A \wedge \text{false}$, if what led to false is updated). For similar reasons we also do not include a simplification step for “merging” identical conjuncts which have different labels.

Note that for goals in LIFF derivations to be guaranteed to be disjunctions of simple goals, it is sufficient that every step of unfolding and negation elimination is followed by a step of splitting. We will assume this is the case in all derivations.

³ In the sequel, $(D_1 \vee \dots \vee D_n) : 1$ will similarly stand for $D_1 : 1 \vee \dots \vee D_n : 1$.

⁴ In [3], negation elimination is defined as follows: $\text{not } A_1 \wedge \text{Rest} \Rightarrow A$ is replaced by $\text{Rest} \Rightarrow A \vee A_1$. Operationally, our definition (ignoring the labels) is equivalent to the one in [3].

5.2 LIFF derivations

In LIFF derivations, the application of inference rules (as given in section 5.1) is interleaved with the assimilation of updates within the ALP (as given in section 3) and the application of these updates to goals, defined as follows:

Definition 2 Given a goal G and an update U , the **updated goal wrt G and U** is a goal G' obtained as follows:

- if U is the addition or deletion of an if-rule $p \leftarrow B$, then G' is G where every conjunct with $\langle p; Q \rangle$ in its label is replaced by Q ;
- if U is the deletion of an integrity constraint X then G' is G where every conjunct with label containing $\langle X; Q \rangle$ is replaced by Q (Q will be \emptyset in all such cases);
- if U is the addition of an integrity constraint i then G' is G with an added conjunct $i : \{\langle i; \emptyset \rangle\}$.

In all cases, any resulting conjunct which is \emptyset is deleted.

Definition 3 Given a query Q , an ALP $\langle P, \mathcal{A}, I \rangle$, and a sequence of updates U_1, \dots, U_n , $n > 0$, a **LIFF derivation** is a sequence

$$(G_1, U_1, R_1, ALP_1), \dots, (G_n, U_n, R_n, ALP_n)$$

where, for each $1 \leq i \leq n$,

- G_i is a goal
- U_i is an update (possibly empty)
- R_i is empty or (an instance of) an inference rule applied to a simple goal in G_i which does not have false as a conjunct
- exactly one of U_i and R_i is non-empty
- ALP_i is an ALP

and $G_1 = Q : \{\} \wedge I^*$ (where I^* is defined in section 5.1), $ALP_1 = \langle P, \mathcal{A}, I \rangle$, and, for each $1 < i \leq n$,

- if R_{i-1} is non-empty then
 - G_i is obtained from G_{i-1} by applying R_{i-1}
 - $ALP_i = ALP_{i-1}$
- if U_{i-1} is non-empty then
 - G_i is the updated goal wrt G_{i-1} and U_{i-1}
 - $ALP_i = U_{i-1}(ALP_{i-1})$.

The **end goal** and **end ALP** in a LIFF derivation

$$(G_1, U_1, R_1, ALP_1), \dots, (G_n, U_n, R_n, ALP_n)$$

are G and ALP , respectively, such that:

- if R_n is non-empty then
 - G is obtained from G_n by applying R_n
 - $ALP = ALP_n$
- if U_n is non-empty then
 - G is the updated goal wrt G_n and U_n
 - $ALP = U_n(ALP_n)$.

We will refer to a LIFF derivation whose updates are all empty as a **static LIFF derivation**.

5.3 Successful LIFF derivations and extracted answers

Here we formalise the notion of answer extraction for LIFF, by adapting the notion of answer extraction for IFF to take labels into account.

Given a LIFF derivation for a query Q , ALP $\langle P, \mathcal{A}, I \rangle$ and a given sequence of updates, let G be the end goal of the derivation. Let D be a disjunct of G :

- if no inference rule can be applied to D , then D is called **conclusive**;
- if $false : \perp$ is a conjunct in D , then D is called **failed**;
- if D is conclusive and not failed then it is called **successful**.

Then, the derivation is **successful** iff there exists a successful disjunct D in G . An **answer extracted from** a successful LIFF-derivation wrt a query Q , an ALP and a sequence of updates is the set of all abducible atoms, without labels, in a successful disjunct D in the end goal of the derivation.

6 SOUNDNESS OF THE LIFF PROOF PROCEDURE

Theorem 1 (Soundness) *Let E be an answer extracted from a successful LIFF-derivation wrt Q , $\langle P, \mathcal{A}, I \rangle$ and a sequence of updates. Let $\langle P', \mathcal{A}', I' \rangle$ be the ALP resulting after the sequence of updates. Then E is an explanation for Q , wrt $\langle P', \mathcal{A}', I' \rangle$.*

The proof of this theorem relies upon the following lemmas and the correctness of the IFF proof procedure.

Lemma 1 *Every non-static LIFF derivation wrt Q , $\langle P, \mathcal{A}, I \rangle$, U_1, \dots, U_m , with end goal G and end ALP $\langle P', \mathcal{A}', I' \rangle$, can be mapped onto a static LIFF derivation wrt Q , $\langle P', \mathcal{A}', I' \rangle$, ending at (a simplified version of) G .*

Lemma 2 *Every static LIFF derivation wrt Q , $\langle P, \mathcal{A}, I \rangle$, can be mapped onto an IFF derivation wrt Q .*

7 CONCLUSIONS AND FUTURE WORK

In this paper we have proposed a dynamic abductive logic programming proof procedure, called LIFF, which modifies the existing proof procedure IFF by adding labels to goals. The labels keep track of dependencies amongst the atoms and implications in goals and between these and the logic program. By keeping track of these dependencies, after updating the ALP, LIFF can keep parts of the reasoning that have not been affected by the updates and determine how best to replace those parts that have been affected. It thus allows reasoning in dynamic environments and contexts without having to discard earlier reasoning when changes occur. We have considered updates consisting of addition and deletion of if-rules and integrity constraints.

LIFF is particularly good at saving earlier reasoning effort when the definitions of relatively lower level atoms are modified. This kind of update is particularly prominent in the case when we use abductive logic programming and agent-based techniques for information integration [19]. In such an application the higher level atoms are user-level and auxiliary atoms, and the lower level atoms are related to information sources. Changes in various aspects of the information sources, for example content or availability, amount to updating these lower level atoms.

Our work on LIFF shares the same objectives as that of [4]. However whereas we adapt IFF for abductive logic programming, they adapt conventional SLDNF for ordinary logic programs. We also

share some of the objectives of [15, 16]. In their work on speculative computation they allow reasoning to proceed with default values for specific facts and then accommodate updates which replace the default values, attempting to keep some of the earlier computation. They, however, use SLD derivation for Horn theories (no negation in rules and no integrity constraints). They also keep a form of dependency, but it is at a much coarser level compared to ours, as the dependency information is for the whole goal, rather than for the individual conjuncts in goals, thus allowing fewer savings in computations.

We have described LIFF and a soundness result for propositional abductive logic programs. Work is currently in progress for the predicate case, catering for the additional inference rules of factoring, case analysis and equality rewriting. Completeness results are subject of future work. It would also be worth exploring how this work scales up to substantial applications that would require large knowledge bases and frequent updates.

Bridging the Gap between Informal and Formal Guideline Representations

Andreas Seyfang,¹ Silvia Miksch,^{1,2} Mar Marcos,³
Jolanda Wittenberg,⁴ Cristina Polo-Conde,³ Kitty Rosenbrand⁴

Abstract. Clinical guidelines are important means to improve quality of health care while limiting cost and supporting the medical staff. They are written as free text with tables and figures. Transforming them into a formal, computer-processable representation is a difficult task requiring both computer scientist skills and medical knowledge.

To bridge this gap, we designed an intermediate representation (or ontology) which serves as a mediator between the original text and different formal guideline representations. It is easier to use than the latter, structures the original prose and helps to spot missing information and contradictions.

In this paper we describe the representation and a practical evaluation thereof through the modelling of a real-world clinical guideline.

1 Introduction

Clinical guidelines are "systematically developed statements to assist practitioner and patient decisions about appropriate health care for specific clinical circumstances" [2]. A guideline describes the optimal care for patients and therefore, when properly applied, it is assumed that they improve the quality of care. Evidence-based guidelines are becoming an important and indispensable part of quality health care.

Translating guidelines into a computer-processable form brings several advantages. It makes them more accessible to browsing as in DeGeL [8], it allows their execution, i.e., the selection of the appropriate treatment steps based on the patient condition, and it is a precondition to various quality assurance techniques such as those pursued by the Protocure project [1].

While producing a formal model of a guideline is desirable, it is difficult and expensive. In addition, the resulting model is often difficult to compare to the original. If a guideline is revised, the modeling effort is lost and it is not easy to detect which changes in the formal model are required by the changes in the original text.

The main reason for this is that there is a large gap between natural language and the currently available formal representations. To close this gap in a versatile manner we designed an *intermediate representation* called MHB (Many-Headed Bridge). It can be seen as a small and versatile *ontology* of guideline components. It groups the statements in the guideline into chunks with predefined dimensions such as control flow, data flow, temporal aspects and evidence. The aspects of each dimension are described using natural language. Af-

ter building the initial model in MHB, the content of the aspects is reviewed to eliminate deliberate use of synonyms and to describe the knowledge missing to arrive at a model.

As the name suggests, MHB is not designed as a unidirectional bridge from a certain type of natural language guideline to a certain formal representation. Instead it is designed as a versatile device to improve guideline quality. Modeling a guideline in MHB makes important aspects such as control and data flow, resources, and patient aspects explicit. They can easily be grouped in various overview lists. Using the MHB model helps in locating and acquiring knowledge which is missing in the guideline text and inconsistencies such as contradicting definitions or recommendations.

In the next section we describe related work in the field of guideline modelling. In Section 3 we describe MHB in detail. In Section 4 we describe its evaluation. Section 5 concludes the paper.

2 Related Work

There are several guideline representations. Asbru, EON, GLIF, Guide, Prodigy and ProForma have been compared by [4]. Further representation are Glare [11] and GEM [9]. Although the degree of formalization varies between these approaches, the majority of them represents the guideline in a format which is precise enough to execute it (semi-)automatically. In practice, it is very difficult and error-prone to translate the original guideline into such a precise format in one step. Except for GEM and NewGuide, the mentioned languages do not explicitly model the evidence level of the each part of the guideline.

The tool which is used to generate and maintain the guideline's version in MHB forms an important background for the design of the representation itself. This tool is called Document Exploration and Linking Tools with Add-ons (DELT/A) [12]. DELT/A allows for explicit linking between pairs of guideline parts in textual and formal representations. DELT/A supports a multi-step modeling process. E.g., in a first step, the original guideline text is displayed at the left-hand side and the MHB model at the right-hand side. In a second step, the (then complete) MHB model is displayed at the left and a newly created translation of MHB to Asbru, GLIF, or ProForma is shown at the right-hand side. Tools similar to DELT/A are GEM Cutter [9], Degel [8], and Stepper [10]. DELT/A differs from GEM Cutter and Degel in maintaining explicit links between the original text and the formal representation. In contrast to Stepper it does not prescribe a fixed number of modeling steps from the informal text to the formal model.

3 Our Solution: A Many-Headed Bridge

This section describes our solution to the afore described challenges in detail. Several teams try to bridge the gap between different kinds of representation building bridges between pairs of isles. Our vision is to connect all these isles by a single bridge having more than two heads. We therefore call it the *many-headed bridge* (MHB).

The syntax of MHB is based on XML, which allows us to use a range of available tools to create and process it, most importantly DELTA/A.

The overall structure of an MHB file is very flexible. It is a series of *chunks*. Each chunk corresponds to a certain bit of information in the natural language guideline text, e.g., a sentence, part of a sentence, or more than one sentence. Initially, the order of the chunks reflects the order of building blocks in the original version of the guideline. However, they can be moved freely in the MHB file. Such regrouping eases the construction of a more formal representation based on the MHB model.

The information in a chunk is structured in *aspects*. These aspects are grouped in *dimensions*, e.g., control flow, data flow, and evidence. The aspects of different dimensions are independent, i.e., a chunk can have any combination of aspects. However, some are related, e.g., the evidence aspects always refer to the aspects in the other dimensions of the same chunk. In practice, for most chunks only aspects of a few dimensions are given. The reason for this lies in the fact that chunks are a uniform representation for all the heterogeneous parts of the guideline.

In addition to the aspects grouped in dimensions, each chunk has optional fields for the context and the subject of the chunk. All aspects contain link elements which store the connection between each part of the MHB file and the original guideline text. In addition, most aspects contain an attribute *degree-of-certainty* to explicitly show the confidence the original guideline authors expressed in the particular statement, expressed in words like "should", "could", "is advisable", etc. This is completely independent of the evidence dimensions (Section 3.4) which describes the formal rating of the evidence base of a certain conclusion or the importance of a certain recommendation. The subsections below describe the representation of each of these dimensions.

3.1 Dimension: Control Flow

One of the most prominent aspects of a guideline is, *when to do what*. This is often shown (incompletely) by a clinical algorithm. *When* either relates to the condition under which something happens, or to the temporal order of actions relative to each other. *What* generally refers to a task⁵ to be performed under the described condition. A third issue is *decomposition*, i.e., the way in which larger tasks or activities are made up of smaller ones. Furthermore, some tasks are performed *repeatedly* as part of other tasks.

Ordering, decomposition, and repetition imply temporal aspects, e.g., one task being performed after the other. Still, they are included here, while the dimension *temporal aspects* deals with explicit and often quantitative descriptions of the timing of actions and also effects, etc. (see explanations in Section 3.3).

Decisions. From the formal modeling point of view, the main distinction is made between mutually exclusive and non-excluding options. In the first case, clear directives on how to arrive at exactly one

of the given options are specified, be it in a decision tree, a decision table, or simple if-then rules. In the second case, for each of the options there are one or more reasons to take it or not to take it and there is no a-priori safety that exactly one option will be taken.

In MHB the basic structure of a single decision is *if-then*. It consists of a condition, a condition-modifier, a result, a result-modifier, and a degree-of-certainty. All five are attributes formally containing any text. Semantically, the condition is described as precisely as possible based on the guideline text. It should – if possible – contain concepts described in the data dimension (compare Section 3.2). The condition-modifier supports various categories of choices, such as negative recommendations and strong and weak arguments pro and contra a certain option.

The result designates the recommended action, first in the words of the original guideline, later in terms of the more formal representation to which MHB will be translated. If omitted, result-modifier defaults to simply *do* but it can also take values describing the state of the task/plan/action. These depend on the target representation and on the precision of the information in the guideline. E.g., tasks in ProForma have three states (abandoned, terminated, performed) while plans in Asbru only have two (aborted, completed).

The words *should*, *can*, etc. which sometimes are found in a guideline's recommendations as well as phrases like "it seems appropriate" are stored in *degree-of-certainty* alternatively to the above.

Sometimes more than one recommendation or option are described together. In MHB the element *option-group* is used to group several *if-then* elements. The options can exclude each other or not. The attribute *selection-type* has the values *single-choice* or *multiple-choice* to represent this distinction. The additional (optional) attribute *other-selection-specification* can contain more complex constraints on the selection, such as the number of options to select together, e.g., "perform two of the following five tasks".

Ordering and Decomposition. A task can be *decomposed* into subtasks. *Ordering* defines constraints on their execution relative to each other. Both ordering and decomposition are modeled by the same element in MHB named *decomposition*.

It names a task as an attribute and the names of subtasks in separate elements.

The ordering of the children is specified in attribute *ordering* of element *decomposition*. Its values should map to plan orderings available in the targeted formal representation. Binary temporal relations between child tasks are modelled in the temporal dimension (Section 3.3).

Synchronization. When several tasks are performed in parallel or otherwise independent from each other, the question arises when to pursue the rest of the guideline. Several formal guideline representation allow to define those subtasks (*awaited-subtasks* in MHB) which must be completed before the next step is taken in a logical expression, or the number of completed subtasks can be given alternatively.

Repetition. Often one task is performed more than once – either for a certain number of times or at certain times during another task. In any case, there is a task ("envelope task") which lasts during all the repetitions and a subtask ("repeated task") which is performed repeatedly.

⁵ The word *task* is used in this text as a synonym for action, plan, activity, procedure, etc. used by different guideline modelling groups.

Atomic Actions. Some activities or tasks are only described in a sentence without further detailing it. In these cases, they are generally called *atomic actions* which may be too strict if taken literally. Therefore, the MHB element to model such cases is called *clinical-activity*.

3.2 Dimension: Data Flow

Interwoven with control flow is the description of the data processing involved in the diagnosis and treatment of the patient. While the processing of data seems of little importance in the treatment of many diseases, it is often prominently described in the diagnosis part of a guideline. As control flow describes the gathering of information, data flow describes how one piece of information is abstracted from other ones. In MHB, we distinguish the following:

- The definition of a data item is rarely found in the guideline in explicit form. Still, it is necessary for the formal version of the guideline. It consists of a name, a type, and often a range of plausible values and a preferred unit.
- The usage of a data item is made explicit to varying degrees in actions described in the guideline and calculation of other values.
- The input of a data item is sometimes explicitly described in the description of the patient interview or diagnosis.
- abstraction-rules describe the calculation or abstraction of one data item based on others. It is found mostly in descriptions of diagnosis. The time at which the calculation or abstraction is performed may be explicitly stated or not. In the first case, the statement in question has a data flow aspect and a control flow aspect at the same time. In the second case, abstraction is assumed to take place automatically whenever necessary.

3.3 Dimension: Temporal Aspects

Both data and control flow may have temporal aspects. They can be qualitative or quantitative. MHB covers the complexity of Asbru (which has the most complex means to model the temporal dimension) in modeling temporal aspects, but adds more standard concepts such as average or precise duration. For each of start, end, and duration, the minimum, maximum, estimate, and precise value can be given. Of course the precise value excludes others, but the other three values can be combined, i.e., minimum, maximum, and estimate can be given together, if ever found in a guideline. The difference between estimate and precise value lies in the semantic given in the guideline. If start or end are given relative to a certain starting point and it is not obviously the start of the task described, then the reference point must be noted together with the offset in the respective attribute.

In addition to the above, the temporal dimension also models qualitative temporal relations such as "A is started after the end of B". While this could be implemented using the above elements, we provide a distinct element for qualitative relations to improve comprehensibility of the model.

3.4 Dimension: Evidence

An evidence-based guideline builds a bridge from carefully examined pieces of evidence which are obtained for the problem to generally applicable recommendations. While it might be an interesting task to document the foundation of each sentence in the guideline, it will be too tiresome in practice. However, it can be useful for certain parts of the guideline.

Evidence for a statement can appear in explicit and implicit form. For *explicit* references with defined format (summary statement of the evidence, literature references) MHB provides the attributes *grade*, *level*, *importance* and *literature-reference*. They are all optional and can be combined as suitable.

Implicit references in the guideline can be made explicit in the MHB file to help improve the quality of the guideline. To this end, the attribute *is-based-on* contains a reference to another MHB element.

3.5 Dimension: Background Information

Background information describes various aspects of the topic. Their potential to be formally encoded largely varies – some information is aimed at motivating the reader to follow the guideline, while other information complements the statements in the recommendation part.

- *Intentions* of the described actions or recommendations inform and motivate the reader about the reason of certain steps.
- *Effects* are relations between data or phenomena and other phenomena which are not seen as events or actions.
- *Relations* are similar to effects, but do not postulate that one of the two named entities is the cause of the other.
- Other *educational information* can target at the physician or the patient to discuss the recommendations in detail. To some extent, it is related to evidence, as it is an alternative backing for the recommendations in the guideline.
- *Explanations* contain information directly explaining recommendations or other (important) statements in the guideline. When executing a guideline in a computer-based form, it might be useful to show them to the user (patient or physician) – in contrast to the education information above which is not as directly related to the actions resulting from following the guideline.
- *Indicators* are measurable elements of health care that give an indication about the quality. One way to develop indicators is to derive them from key recommendations of a guideline. They are not yet part of many guidelines but will be integrated in the future.

3.6 Dimension: Resources

Each action consumes resources of various nature: *Personnel* resources such as the working time of clinical staff; *Devices*, such as treatment facilities; and *Financial cost*, which can be given independent of qualitative or quantitative information on the above items. It includes also drug cost, etc.

3.7 Dimension: Patient Related Aspects

While the resources dimension mostly represents the view of the care provider, there are several other general issues mentioned in a guideline which see treatment from the patient perspective. *Risk* connected to a certain treatment option or diagnostic action. *Patient discomfort* is often described as free text and refers to undesired side effects of treatments, such as chemotherapy against cancer. *Health prospective* can be seen as a resource which is gained by the treatment process, while it is consumed by waiting.

3.8 Dimension: Document Structure

While the position of a statement in the guideline document could be considered a formal property, its status (narrative, displayed recommendation) certainly forms an important context for its interpretation. This means that a statement found in the recommendations or

control	decomp- osition	parent-task	mastectomy
		child-task(s)	deciding whether to carry out primary or secondary reconstruction
	if-then	condition	higher risk of requiring postoperative radiotherapy
		result	consider the increased risk of complications
	degree-of- certainty	should	
data	usage	name	is there higher risk of postoperative requiring radiotherapy
structure		status	recommendations

Figure 1. Model of a vague recommendation.

the scientific conclusions has more weight than one in the introduction or other parts of the guideline.

Example. Figure 1 shows the MHB model of the statement "*In women who have a higher risk of requiring postoperative radiotherapy, the increased risk of complications should be considered when deciding whether to carry out primary or secondary reconstruction.*" This statement is made in the context of mastectomy interventions. It can be modelled as a decomposition stating that "deciding whether to carry out primary or secondary reconstruction" is a child-task of task "mastectomy". This child-task is performed under the condition of "higher risk of requiring postoperative radiotherapy". There is one data item used here – the information whether there is a higher risk of requiring postoperative radiotherapy.

MHB is intended for the use with various guideline representations. In the first practical evaluation, carried out as part of the Protocure II project, it was used together with Asbru, bridging the gap between this representation and the English text in a real-world guideline of more than 100 pages. This is described in the next section.

4 Evaluation

Evaluation of MHB is performed on a theoretical and on a practical level.

Theoretical evaluation. This consisted of three parts complementing each other:

- The mapping between MHB and various formal representations for clinical guidelines and protocols is analyzed in detail in [7].
- The suitability of MHB to represent guidelines was discussed with domain experts.
- It was shown that MHB can represent the guideline constructs on a list of prototypical patterns developed as another part of the Protocure II project [6].

Each of the three activities led to the conclusion that MHB is sufficiently expressive. The discussion with domain experts also showed that MHB is easier to comprehend than Asbru or other formal guideline representations.

Dimension	Aspect	Chapter						Total
		1	2	3	4	5	6	
control	clinical-activity	13	1	1	1	0	9	25

Figure 2. Usage count for each dimension and aspect.

Practical evaluation. Scientific conclusions, other considerations, and recommendations in the Dutch Guideline for the Treatment of Breast Carcinoma [3] were modeled in MHB in a shared effort by three teams in different countries [5]. Parts of the guideline not relevant for the subsequent formal representation of the guideline were omitted. These parts mostly described background information regarding the disease and the details of the studies which form the evidence for the recommendations. All recommendations were modeled.

Table 2 shows the number of elements used for each of the aspects in the various dimensions.

The greatest count of elements is given for dimension evidence which was expected for an evidence-based guideline such as the modeled one. As assumed from the beginning, the control dimension proved to be the most prominent one. The data dimension is also frequently used.

In the background dimensions, educational information and description of effects were equally frequent while all other aspects of that dimension were rarer.

Some rare aspects were not used at all in the guideline. They are omitted for space consideration, as is the structure dimension which

is trivially present in every chunk.

The evaluation of the data dimensions confirms the assertion that data input is only implied in the guideline. There was not a single bit of information found for any chunk. This is in part due to the fact that the guideline deals with treatment and not with diagnose or screening. Besides this, it is assumed that the reader of the guideline knows about the usual data flow during diagnosis and treatment.

The fact that little information regarding patient aspects and resources were found is in line with the common opinion that future guidelines should focus more on these issues. The fact that they were mostly found in chapter 1 hints at an inter-modeler deviation.

Indicators were not contained in the guideline because they are a future development of guidelines.

Overall, the evaluation confirmed the suitability of the representation. All the necessary information was captured in the modelling process.

Unfortunately, the nature of the chapters proved to be rather dissimilar. Therefore, deviations between chapters or teams can be caused by the nature of the chapter or by the preference of the team. However, when reading chapters from other teams, we found a very large degree of consistency of the modeling. This was also due by a set of written recommendations which directed the modeling process.

5 Conclusions

Our experience has shown that MHB is appropriate to model the statements found in the significant guideline parts. MHB not only provides constructs to express the essential knowledge we intended to model, but also allowed for a modeling with the degree of detail necessary for our purposes. An initial problem was the variation observed across the MHB models obtained initially. To solve this, we elaborated a series of basic MHB modeling recommendations. Thanks to these recommendations, the degree of variation was greatly decreased, regardless of the different background of the modellers.

In the Protocure II project we showed that MHB is easier to understand than Asbru by persons without computer background. However, a significant effort in training was necessary.

It is easier to create an MHB model from the original guideline text than an Asbru model. The main reason for this is that MHB does not demand complete information. Also, MHB can be structured like the guideline, while formal representations such as Asbru and others model a guideline as a hierarchy of tasks which is not easy to detect in the original guideline text.

In addition, it is easier to create an Asbru model based on MHB than based on the original text alone. While missing knowledge and vague information in the guideline text still cause modeling problems, they are more efficiently handled since they are already displayed in the MHB model. Using a cross-reference table of all task and data items mentioned in the guideline, we were able to spot countless instances of slightly deviating names for the same entity used in different places of the guideline.

The major drawback of MHB compared to other, more formal representations such as Asbru or GLIF lies in the fact that the syntax of MHB does not impose strict rule for the usage of each attribute (or aspect). The usage is only described in a guidelines [7] and it is the author's responsibility to follow them. While this is an advantage in the early modeling phase, it takes considerable effort to arrive at a uniform naming scheme for tasks and data items in the guideline. However, this is a known problem shared by all formal guideline representations.

In practical work with non-IT persons such as epidemiologists it showed that MHB when used in an XML editor like DELTA is very difficult to understand for them. Therefore, future work will go into developing a user-friendly editing environment, which guides the user by means of context-sensitive help and shields away the complexity of XML. Also, the integration of knowledge extraction to automatically generate parts of the model is an interesting option. Standard vocabularies such as UMLS can be used together with MHB (including compliance checks), however the editor does not yet include browsing and picking items per mouse click.

Weighing the advantages and limitations of MHB, we conclude that MHB is a suitable solution to bridge the gap between the original guideline text and formal representations such as Asbru.

Boolean Propagation Based on Literals for Quantified Boolean Formulae

Igor Stéphan¹

Abstract. This paper proposes a new set of propagation rules for quantified Boolean formulae based on literals and generated automatically thanks to quantified Boolean formulae certificates. Different decompositions by introduction of existentially quantified variables are discussed in order to construct complete systems. This set of rules is compared with already proposed quantified Boolean propagation rule sets and Stålmarck's method.

1 Introduction

The quantified Boolean formulae validity problem is a generalization of the Boolean formulae satisfiability problem. While the complexity of Boolean satisfiability problem is NP-complete, it is PSPACE-complete for quantified Boolean formulae validity problem. This is the price for more concise representation of many classes of formulae. Many important problems in several search fields have polynomial-time translations to the quantified Boolean formulae validity problem. This is the reason why the implementation of effective tools for deciding the validity of quantified Boolean formulae is an important research issue. Since quantified Boolean formulae may be reduced to (unquantified) Boolean formulae by expansion of the universal quantifiers, the first solution seems to reduce the quantified Boolean formula and then apply a satisfiability algorithm. The main drawback of this approach is that the size of the Boolean propositional formula is in worst-case exponential in the size of the quantified Boolean formula. Most of the recent decision procedures for quantified Boolean formulae validity [23, 22, 17, 13, 19] are extensions of the search-based Davis-Putnam procedure [14] for Boolean satisfiability. Some other decision procedures are based on resolution principle [24] (as Q-resolution [11] which extends the resolution principle for Boolean formulae [15] to quantified Boolean formulae or Quantor [10] which combines efficiently Q-resolution and expansion), quantifier-elimination algorithms [21, 20], or skolemization and SAT solvers [7]. There exists also efficient algorithm for the 2CNF-QBF [3] or useful heuristics for Quantified Renamable Horn Formulas [18], for example.

In [6], a methodology is proposed to construct constraint propagation systems to “constraint satisfaction problems that are based on predefined, explicitly given constraints”. Boolean constraint propagation (see [5] for a small but nice history of it) and Quantified Boolean Constraint Propagation [12] verify this definition. Properties and definitions of these articles are in terms of domain and (Quantified) arc-consistency. Usually constraint propagation systems use implicitly a decomposition by introduction of existentially quantified variables. This decomposition does not allow to capture all the

possible simplifications due to the properties of the connectors in the Boolean lattice. We are more interested by these results in term of propositional logic and logical equivalence as in the Stålmarck's method [25] for tautology checking.

In [8] is introduced the notion of certificate for a QBF. A certificate is a mapping extracted from a QBF which allows to check or generate models. From this certificate we will see in the following that rules for Quantified Boolean Propagation may be extracted automatically.

In this article, after some preliminaries in section 2, we describe in section 3 the core of our contribution: a set of Boolean propagation rules based on literals for QBF. First we introduce the decomposition by introduction of existentially quantified literals ; then we describe the automatic generation, thanks to the certificate, of the Boolean propagation rules based on literals for QBF ; and finally we propose a complete algorithm based on this set of rules and the semantics of the quantifiers. In section 4, we compare our approach with already proposed (quantified) Boolean propagation rule systems and the Stålmarck's method and in section 5, we present some future works.

2 Preliminaries

Quantified boolean formulae. The Boolean values are denoted **true** and **false**. The set of propositional symbols (or variables) is denoted PV . The symbols \perp and \top are the propositional constants. The symbol \wedge is used for conjunction, \vee for disjunction, \neg for negation, \rightarrow for implication and \leftrightarrow for equivalence. A literal is a propositional variable or the negation of a propositional variable. If l is a literal and $l = \neg x$ then $|l| = x$ and $\bar{l} = x$ otherwise $|l| = l$ and $\bar{l} = \neg l$. Propositional satisfaction is denoted \models and logical equivalence is denoted \equiv . The symbol \exists is used for existential quantification and \forall for universal quantification (q is used as a quantification variable). Every Boolean formula is also a quantified Boolean formula (QBF). If F is a QBF and x is a propositional variable then $(\exists x F)$ and $(\forall x F)$ are QBF. If a literal $l = \neg x$ then $q|l|$ stands for qx otherwise it stands for ql . It is assumed that distinct quantifiers bind occurrences of distinct variables. If a variable x is not under the scope of a quantifier qx then it is a free variable. The set of free variables of a QBF F is denoted $FV(F)$. We define $G[x \leftarrow F]$ as the formula obtained from G by replacing occurrences of the propositional variable x by the formula F . A binder Q is a string $q_1x_1 \dots q_nx_n$ with x_1, \dots, x_n distinct variables and $q_1 \dots q_n$ quantifiers. We write $qx_1 \dots x_n$ for any permutation of $qx_1 \dots qx_n$. A QBF QF is in prenex conjunctive normal form if F is a Boolean formula (called the matrix) in conjunctive normal form.

QBF semantics. Semantics of all the Boolean symbols is defined in standard way. In particular, from the structure of the Boolean lat-

¹ LERIA, Université d'Angers, France, email: igor.stephan@info.univ-angers.fr

tice some simplifications on a QBF may be applied (we only present simplifications for disjunction, but a similar presentation may be done for conjunction, implication or any binary Boolean operator):

$$\begin{array}{ll}
 (1) \quad (\perp \vee \perp) \equiv \perp & (2) \quad (\perp \vee \top) \equiv \top \\
 (3) \quad (\top \vee \perp) \equiv \top & (4) \quad (\top \vee \top) \equiv \top \\
 (5) \quad (\perp \vee y) \equiv y & (6) \quad (\top \vee y) \equiv \top \\
 (7) \quad (x \vee \perp) \equiv x & (8) \quad (x \vee \top) \equiv \top \\
 (9) \quad (x \vee x) \equiv x & (10) \quad (x \vee \overline{x}) \equiv \top
 \end{array}$$

These rules may be applied iteratively until the (unique) fix-point is reached. The semantics of QBF is defined as follows: for every Boolean variable y and QBF F , a formula $(\exists y F) = (F[y \leftarrow \top] \vee F[y \leftarrow \perp])$ and $(\forall y F) = (F[y \leftarrow \top] \wedge F[y \leftarrow \perp])$. A QBF F is valid if $F \equiv \top$. If y is an existentially quantified variable preceded by the universally quantified variables x_1, \dots, x_n we denote $\hat{y}_{x_1, \dots, x_n}$ its Skolem function from $\{\text{true}, \text{false}\}^n$ to $\{\text{true}, \text{false}\}$. A model for a QBF F is a sequence s of satisfying Skolem functions for F (denoted $s \models F$). For example, the QBF $\exists y \exists z ((x \vee y) \leftrightarrow z)$ is not valid but the QBF $\forall z \exists y \exists x ((x \vee y) \leftrightarrow z)$ is valid and its possible sequence of satisfying Skolem functions is $\hat{y}_z(v) = v$, $\hat{y}_z(f) = f$, $\hat{x}_z(v) = f$ and $\hat{x}_z(f) = f$. In [27], a new equivalence relation for QBF, denoted \cong is introduced. This equivalence is about preservation of models (and not only preservation of validity). For example, $\forall z \exists y \exists x ((x \vee y) \leftrightarrow z) \equiv \top$ but $\forall z \exists y \exists x ((x \vee y) \leftrightarrow z) \not\cong \top$. A (Boolean) model of an unquantified Boolean formula corresponds exactly to a (QBF) model of its existential closure. A QBF is valid if and only if there exists a sequence of satisfying Skolem functions. According to the theorems $\exists x \exists y F \equiv \exists y \exists x F$, $\forall x \forall y \equiv \forall y \forall x F$ and $\exists x \forall y F \neq \forall y \exists x F$ for any QBF F , the QBF induce an order on the equivalence classes formed by the same adjacent quantifiers. Every QBF may be easily transformed in an equivalent prenex QBF.

Certificates for QBF. In [8] is introduced the notion of certificate for a QBF (this notion is also introduced in [27, 26] but under another name). A certificate is a mapping from the set of the existentially quantified variables of a QBF to couples of Boolean formulae only constituted on the variables which precede the variable in the binder. The certificate may be extracted from a QBF by an extension of the quantifier-elimination algorithm QMRES [20]. From a certificate $\{x \mapsto (\Phi_x^+, \Phi_x^-)\}_{x \in V}$ may be extracted a QBF $\bigwedge_{x \in V} (x \vee \Phi_x^+) \wedge (\neg x \vee \Phi_x^-)$. This QBF is equivalent (i.e. preserves the validity) of the QBF from which the certificate is extracted, but also preserves the set of satisfying Skolem functions (and in other words the models) [27, 26]. This certificate allows model-checking for QBF [8] and also enumeration of models [8, 27, 26]. For example, the mapping $\{y \mapsto (\top, z), x \mapsto ((\neg z \vee y), z)\}$ is the certificate of the QBF $F = \forall z \exists y \exists x ((x \vee y) \leftrightarrow z)$. From this certificate, the QBF $F' = \forall z \exists y \exists x ((y \vee \top) \wedge (\neg y \vee z) \wedge (x \vee (\neg z \vee y)) \wedge (\neg x \vee z))$ may be extracted. This QBF has the two following properties: $F' \equiv F$ and $F' \cong F$.

Decomposition by introduction of existentially quantified variables. The decomposition by introduction of existentially quantified variables (applied usually on prenex formulae) introduces existentially quantified variables to capture the intermediate results of a calculus. This decomposition preserves the validity of the initial QBF. For example, the QBF $\forall z \exists y \exists x \exists u (((x \vee y) \leftrightarrow u) \wedge (\neg z \leftrightarrow v) \wedge ((u \leftrightarrow v) \leftrightarrow \top))$. This QBF

is valid only if the QBF $\forall z \exists v ((\neg z \leftrightarrow v))$, $\exists y \exists x \exists u ((x \vee y) \leftrightarrow u)$ and $\forall z \exists u ((u \leftrightarrow z) \leftrightarrow \top)$ are also valid. This decomposition is the base of Boolean constraint propagation systems [5, 4] and the Stålmarck's algorithm [25] for tautology checking. The simplification rules become simplification propagation rules. In the case of QBF, the binder is important and then added to give what we call an equivalence schema. The simplification rules already introduced are rewritten to integrate the existentially quantified variables and the binder. For example, the simplification rule (9) is rewritten in the equivalence schema $qx \exists z ((x \vee x) \leftrightarrow z)$ with the propagation $[z \leftarrow x]$. Here the order on the quantifiers is very important since $\exists z \forall x ((x \vee x) \leftrightarrow z)$ is not valid. One may notice that rule (10) can not be a rule of Boolean constraint propagation systems based on decomposition by introduction of variables since it does not allow literals in the rules.

3 Boolean Propagation based on literals for Quantified Boolean Formulae

This section describes the core of our contribution: a set of propagation rules for quantified Boolean formulae based on literals and generated thanks to quantified Boolean formulae certificates. First we introduce the decomposition by introduction of existentially quantified literals ; then we describe the automatic generation of the Boolean propagation rules based on literals for QBF ; finally we propose a complete algorithm based on this set of rules and the semantics of quantifiers.

3.1 Decomposition by introduction of existentially quantified literals

The classical decomposition by introduction of existentially quantified variables for Boolean formulae keeps negation as a connector of the generated Boolean formulae. By this way, equivalence schema as $x \vee \overline{x} \equiv \top$ with $[z \leftarrow \top]$ can not be captured. We propose a decomposition based on literals instead of variables to be able to introduce this kind of rules in our propagation system. The negation then disappears form the connectors of the decomposed formula. The following function δ decomposes a Boolean formula by introduction of existentially quantified literals (\circ is a binary connector, functions δ^+ and δ^- return couples (variable, decomposition), $\pi_i(c)$ with $i = 1$ (resp. $i = 2$) stands for the first (resp. second) projection of the couple c).

$$\begin{aligned}
 \delta(F) &= \pi_2(\delta^+(F)) \wedge (\pi_1(\delta^+(F)) \leftrightarrow \top) \\
 \delta^+(x) &= (x, \top), x \in PV \\
 \delta^-(x) &= (\overline{x}, \top), x \in PV \\
 \delta^+(\neg A) &= \delta^-(A), \\
 \delta^-(\neg A) &= \delta^+(A), \\
 \delta^+(A \circ B) &= (z, \pi_2(\delta^+(A)) \wedge \pi_2(\delta^+(B))) \\
 &\quad \wedge ((\pi_1(\delta^+(A)) \circ \pi_1(\delta^+(B))) \leftrightarrow z)) \\
 \delta^-(A \circ B) &= (z, \pi_2(\delta^+(A)) \wedge \pi_2(\delta^+(B))) \\
 &\quad \wedge ((\pi_1(\delta^+(A)) \circ \pi_1(\delta^+(B))) \leftrightarrow \overline{z}))
 \end{aligned}$$

If QF is a prenex QBF, $D = \delta(F)$ the decomposition of F and $X = FV(QD)$ the set of new existentially quantified variables introduce by the function δ then the QBF $Q \exists X D$ is the result of the decomposition by introduction of existentially quantified literals of QF^2 . For example, the QBF $\forall z \exists y \exists x ((x \vee y) \leftrightarrow \neg z)$ is now decomposed in the QBF $\forall z \exists y \exists x \exists u (((x \vee y) \leftrightarrow u) \wedge ((u \leftrightarrow \overline{z}) \leftrightarrow \top))$.

² as in decomposition by introduction of existentially quantified variables the equivalence $z \leftrightarrow \top$ is immediately propagated

According to the theorems $\forall x(F \wedge G) \equiv (\forall xF \wedge \forall xG)$ and $\exists x(F \wedge G) \models (\exists xF \wedge \exists xG)$, if $Q \wedge ((x \circ y) \leftrightarrow z)$ is the decomposition of the QBF F then F is valid only if all the QBF $Q((x \circ y) \leftrightarrow z)$ are also valid.

3.2 The set of Boolean propagation rules based on literals for QBF

The set of Boolean propagation rules based on literals for QBF presented in this article are generated automatically by enumeration of the possible equivalence schemata and by the calculus of the associated certificate as described in the next section³. The set of equivalence schemata is divided in two equal sets: the set of contradictory schemata issued from non valid equivalence schemata and the set of the other schemata. A contradictory rule is generated for every contradictory schema. A contradictory rule must stop the fix-point calculus and return that the QBF is not valid (since one of the conjunction of the decomposed QBF is not valid). The other schemata are of four different types:

- some equivalence schemata are tautological: in that case a tautological simplification rule is generated which only eliminates the equivalence from the decomposition (the number of this rule is superscripted by \models) ;
- some equivalence schemata are only contingent (i.e. it is not tautological and gives no substitution for the variables): in that case no rule is generated (the number of the schema is superscripted by $?$) ;
- some equivalence schemata determine all the variables by substitution: in that case a simplification propagation rule is generated which eliminates the equivalence from the decomposition and propagates the substitutions (the number of this rule is superscripted by \Rightarrow) ;
- some equivalence schemata determine only a part of the variables by substitution and after propagation is still contingent: in that case a propagation rule is generated which propagates the substitutions (the number of this rule is superscripted by $\Rightarrow ?$).

We report only the results for disjunction. We obtain 16 tautological simplification rules (abbreviated in the 10 rules of Figure 2), 58 simplification propagation rules (abbreviated in the 10 rules of the section 2 and the 30 first rules of Figure 1), 2 propagation rules (the last 2 rules of Figure 1), 28 contingent equivalence schemata (cf. Figure 3), and 104 contradictory rules not reported here.

The proof that the fix-point of the iterative application of our rules is always reached and is unique is based on the results of [4]. The argument cannot be based on reduction domain as for constraint propagation systems since not all the rules decrease the number of possible Boolean values of the variables of the rule. Instead we use a usual argument in logic based on the weight of the decomposed formula.

3.3 Automatic generation of the Boolean propagation rules based on literals for QBF

The calculus of a certificate for an equivalence schema (with the literal x (resp. \bar{x}) considers as the variable x (resp. the formula $\neg x$) allows us to deduce automatically its associated rule if exists. During this calculus two cases may appear: the certificate demonstrates that the equivalence is not valid then a contradictory rule is generated or it demonstrates that the equivalence is valid and in that case

	Equivalence schema	Substitutions
(1) \Rightarrow	$\exists y \perp \vee y \leftrightarrow \perp$	$[y \leftarrow \perp]$
(2) \Rightarrow	$\exists y \perp \vee y \leftrightarrow \top$	$[y \leftarrow \top]$
(3) \Rightarrow	$\exists x x \vee \perp \leftrightarrow \perp$	$[x \leftarrow \perp]$
(4) \Rightarrow	$\exists x x \vee \perp \leftrightarrow \top$	$[x \leftarrow \top]$
(5) \Rightarrow	$\exists x x \vee x \leftrightarrow \perp$	$[x \leftarrow \perp]$
(6) \Rightarrow	$\exists x x \vee x \leftrightarrow \top$	$[x \leftarrow \top]$
(7) \Rightarrow	$\exists x x \vee y \leftrightarrow \perp$	$[x \leftarrow \perp]$
(8) \Rightarrow	$\exists x x \vee y \leftrightarrow \top$	$[x \leftarrow \top]$
(9) \Rightarrow	$\exists x y \vee x \leftrightarrow \perp$	$[y \leftarrow \perp]$
(10) \Rightarrow	$\exists x y \vee x \leftrightarrow \top$	$[y \leftarrow \top]$
(11) \Rightarrow	$\exists y \perp \vee y \leftrightarrow \perp$	$[y \leftarrow \perp]$
(12) \Rightarrow	$\exists y \perp \vee y \leftrightarrow \top$	$[y \leftarrow \top]$
(13) \Rightarrow	$\exists x x \vee \perp \leftrightarrow \perp$	$[x \leftarrow \perp]$
(14) \Rightarrow	$\exists x x \vee \perp \leftrightarrow \top$	$[x \leftarrow \top]$
(15) \Rightarrow	$\exists x x \vee x \leftrightarrow \perp$	$[x \leftarrow \perp]$
(16) \Rightarrow	$\exists x x \vee x \leftrightarrow \top$	$[x \leftarrow \top]$
(17) \Rightarrow	$\exists x y x \vee y \leftrightarrow \perp$	$[x \leftarrow \perp], [y \leftarrow \perp]$
(18) \Rightarrow	$\exists x y x \vee y \leftrightarrow \top$	$[x \leftarrow \top]$
(19) \Rightarrow	$\exists y x x \vee y \leftrightarrow \top$	$[y \leftarrow \top]$
(20) \Rightarrow	$\exists x x \vee \top \leftrightarrow x$	$[x \leftarrow \top]$
(21) \Rightarrow	$\exists x x \vee \top \leftrightarrow \bar{x}$	$[x \leftarrow \perp]$
(22) \Rightarrow	$q z \exists y \perp \vee y \leftrightarrow z$	$[y \leftarrow z]$
(23) \Rightarrow	$\exists y \top \vee y \leftrightarrow y$	$[y \leftarrow \top]$
(24) \Rightarrow	$\exists y \top \vee y \leftrightarrow \bar{y}$	$[y \leftarrow \perp]$
(25) \Rightarrow	$\exists z q y \top \vee y \leftrightarrow z$	$[z \leftarrow \top]$
(26) \Rightarrow	$q z \exists x x \vee \perp \leftrightarrow z$	$[z \leftarrow x]$
(27) \Rightarrow	$\exists z q x x \vee \top \leftrightarrow z$	$[z \leftarrow \top]$
(28) \Rightarrow	$q z \exists x x \vee x \leftrightarrow z$	$[x \leftarrow z]$
(29) \Rightarrow	$\exists x x \vee \bar{x} \leftrightarrow x$	$[x \leftarrow \top]$
(30) \Rightarrow	$\exists x x \vee \bar{x} \leftrightarrow \bar{x}$	$[x \leftarrow \perp]$
(31) \Rightarrow	$\exists z q x x \vee \bar{x} \leftrightarrow z$	$[z \leftarrow \top]$
(32) \Rightarrow	$\exists x y x \vee y \leftrightarrow \bar{x}$	$[x \leftarrow \perp][y \leftarrow \top]$
(33) \Rightarrow	$\exists x y x \vee y \leftrightarrow x$	$[x \leftarrow \top]$
(34) \Rightarrow	$\exists y v x x \vee y \leftrightarrow x$	$[y \leftarrow \top]$
(35) \Rightarrow	$\exists x v y x \vee y \leftrightarrow y$	$[x \leftarrow \perp]$
(36) \Rightarrow	$\exists y v x x \vee y \leftrightarrow y$	$[y \leftarrow \top]$
(37) \Rightarrow	$\exists x y x \vee y \leftrightarrow \bar{y}$	$[x \leftarrow \top][y \leftarrow \perp]$
(38) \Rightarrow	$\exists y z v x x \vee y \leftrightarrow z$	$[y \leftarrow \top][z \leftarrow \top]$
(39) \Rightarrow	$\exists y v z \exists x x \vee y \leftrightarrow z$	$[y \leftarrow \top][x \leftarrow z]$
(40) \Rightarrow	$\exists x z v y x \vee y \leftrightarrow z$	$[x \leftarrow \top][z \leftarrow \top]$
(41) \Rightarrow	$\exists x v z \exists y x \vee y \leftrightarrow z$	$[x \leftarrow \perp][y \leftarrow z]$
(1) $\Rightarrow ?$	$\exists z v x \exists y x \vee y \leftrightarrow z$	$[z \leftarrow \top]$
(2) $\Rightarrow ?$	$\exists z v y \exists x x \vee y \leftrightarrow z$	$[z \leftarrow \top]$

Figure 3. Contingent equivalence schemata for disjunction.

the certificate itself allows us to deduce if the rule is a tautological simplification rule, a simplification propagation rule, a propagation rule or that the equivalence is contingent.

- If the certificate is empty or $\{x \mapsto (\top, \top)\}$ then the equivalence is tautological and a tautological simplification rule is generated.
- If the certificate contains the couple $(x \mapsto (\top, \perp))$ then x is equivalent to \perp and a propagation rule which contains the substitution $[x \leftarrow \perp]$ is generated. Conversely, If the certificate contains the couple $(x \mapsto (\perp, \top))$ then x is equivalent to \top and a propagation rule which contains the substitution $[x \leftarrow \top]$ is generated.
- If the certificate contains the couple $(x \mapsto (\overline{y}, y))$ and if $x < y$ then a propagation rule which contains the substitution $[y \leftarrow x]$ is generated otherwise a propagation rule which contains the substitution $[x \leftarrow y]$ is generated. Conversely, if the certificate contains the couple $(x \mapsto (y, \overline{y}))$ and if $x < y$ then a propagation rule which contains the substitution $[y \leftarrow \overline{x}]$ is generated otherwise a propagation rule which contains the substitution $[x \leftarrow \overline{y}]$ is generated.

If all the literals of an equivalence are determined by substitution then the rule is a simplification rule (which can also be a propagation rule). A propagation rule is not necessarily a simplification rule since the equivalence schema can propagate a Boolean value for a literal and be at the same time contingent.

For example, $\{x \mapsto (\top, \top)\}$ is the certificate of the equivalence $\exists x(x \vee \top \leftrightarrow \top)$ and then is a tautological schema and generates a tautological simplification rule ; $\{y \mapsto (\top, \top), z \mapsto (\neg x \wedge \neg y, x \vee y)\}$ is the certificate of the equivalence $\forall x \exists y \exists z(x \vee y \leftrightarrow z)$ and then is a contingent schema and generates no rule ; $\{x \mapsto (\neg z, z)\}$ is the certificate of the equivalence $\forall z \exists x(x \vee x \leftrightarrow z)$ and then generate a simplification propagation rule ; $\{z \mapsto (\perp, \top), y \mapsto (x, \top)\}$ is the certificate of the equivalence $\exists z \forall x \exists y(x \vee y \leftrightarrow z)$ and then generates a propagation rule with the substitution $[z \leftarrow \top]$ since all the variables are not determined by substitution and the equivalence schema $\forall x \exists y(x \vee y \leftrightarrow \top)$ is still contingent⁴.

3.4 An algorithm to reach completeness

It is obvious that only the application of the set of rules described in this article is incomplete to decide if a QBF is valid or not. In Boolean constraint propagation, completeness is reached by a two-steps loop: propagation-enumeration of one of the remaining variables. Since all

⁴ All the certificates are accessible on our web site.

the variables are existentially quantified, the choice of the variable is free and only guided by efficiency. It can not be the same for QBF since the initial quantifiers are ordered and can not be so easily permuted.

In the case of search algorithms, which try to eliminate the outermost quantifiers first, only the quantifiers of the outermost equivalence class induce by the order may be chosen. Let qxD be the decomposition of a QBF F , x a variable of the outermost equivalence class and $z \in \{\top, \perp\}$. By the semantics of universal quantifier, if $q = \forall$ then $F \equiv (D[x \leftarrow \top] \wedge D[x \leftarrow \perp])$. Then F is valid if and only if $D[x \leftarrow \top]$ and $D[x \leftarrow \perp]$ are valid. In particular, if $D[x \leftarrow z]$ is not valid then it is useless to calculate $D[x \leftarrow \bar{z}]$ and F is not valid. Conversely, by the semantics of existential quantifier, if $q = \exists$ then $F \equiv (D[x \leftarrow \top] \vee D[x \leftarrow \perp])$. Then F is valid if and only if $D[x \leftarrow \top]$ or $D[x \leftarrow \perp]$ are valid. In particular, if $D[x \leftarrow z]$ is valid then it is useless to calculate $D[x \leftarrow \bar{z}]$ and F is valid. We recognize here the Dilemma rule of the Stålmarck's method [25].

It does not seem to us easy to use an inside-out quantifier-elimination method like [20] to reach completeness since inner-most quantifiers are existential and the semantics of existential quantifier introduces a disjunction that breaks the decomposition.

It is worth to notice that if the formula is already decomposed as a conjunction of equivalence schemata all the rules are applicable. Otherwise, the decomposition introduce only one occurrence of each new existentially quantified literals in the right hand side of the equivalences. Then this occurrence can never be universally quantified. This means that some of the rules (mainly contradictory rules) can not be applied.

4 Comparisons

Quantified Boolean propagation. In [12] an extension of arc-consistency to quantified constraints (quantified arc-consistency) is proposed. This extension is applied to QBF and a set of propagation rules is described. This set is the counterpart in constraint propagation of the rules $(1)^{\Rightarrow} - (8)^{\Rightarrow}$, $(11)^{\Rightarrow} - (14)^{\Rightarrow}$, $(17)^{\Rightarrow} - (19)^{\Rightarrow}$, $(22)^{\Rightarrow} - (25)^{\Rightarrow}$, $(38)^{\Rightarrow} - (41)^{\Rightarrow}$, $(1)^{\Rightarrow?}$ and $(2)^{\Rightarrow?}$. The other simplification propagation rules are out of the scope of quantified arc-consistency. So our set of rules is more powerful than the one proposed in [12].

Stålmarck's method. In [25] is described the Stålmarck's method of tautology checking. Tautology checking is co-NP complete and thus corresponds to a prenex QBF with only universally quantified variables. Stålmarck's method tries to prove that the matrix of the QBF can not be equivalent to \perp . Stålmarck's method first uses the same decomposition principal as described in preliminaries and then applies a set of rules. This method translates $(\neg x)$ in $(x \rightarrow \perp)$ and only covers the $\{\rightarrow, \perp\}$ -Boolean formulae. So, initial Stålmarck's rules are for the implication, we translate them (cf. Figure 4) to compare with ours. We do not detail the comparison of the two sets of rules. Just some remarks: rule $(32)^{\Rightarrow}$ covers rule r_6 but is finer since it also substitutes the y variable ; rules $(9)^{\Rightarrow}$, $(16)^{\Rightarrow}$, $(28)^{\Rightarrow}$ and $(37)^{\Rightarrow}$ are not covered by any rules of Stålmarck's method and would be added in a Stålmarck's method based on literals. Stålmarck's method also includes contradictory equivalence schemata (called “terminal triplets”), they are also expressed with implication and given in Figure 4 for comparison. Due to the lack of space we cannot present all our contradictory equivalence schemata. These schemata cover more than the Stålmarck's set of contradictory equivalence schemata and the following ones may be added in a Stål-

marck's method based on literals: $\exists|x| \ x \vee \bar{x} \leftrightarrow \perp$, $\exists|y| \ \perp \vee y \leftrightarrow \bar{y}$, $\exists|x| \ x \vee x \leftrightarrow \bar{x}$ and $\exists|x| \ x \vee \perp \leftrightarrow \bar{x}$.

Stålmarck's set of rules		
	Schema	Substitutions
r_1	$\exists xy \ x \vee y \leftrightarrow \perp$	$[x \leftarrow \perp][y \leftarrow \perp]$
r_2	$\exists xz \ x \vee \top \leftrightarrow z$	$[z \leftarrow \top]$
r_3	$\exists yz \ \top \vee y \leftrightarrow z$	$[z \leftarrow \top]$
r_4	$\exists yz \ \perp \vee y \leftrightarrow z$	$[z \leftarrow y]$
r_5	$\exists xz \ x \vee \perp \leftrightarrow z$	$[z \leftarrow x]$
r_6	$\exists xy \ x \vee y \leftrightarrow \bar{x}$	$[x \leftarrow \top]$
r_7	$\exists xz \ x \vee \bar{x} \leftrightarrow z$	$[z \leftarrow \top]$

Terminal schemata	
	$\perp \vee \perp \leftrightarrow \top$
$\exists y$	$\top \vee y \leftrightarrow \perp$
$\exists x$	$x \vee \top \leftrightarrow \perp$

Figure 4. Stålmarck's set of rules and terminal schemata

Stålmarck's method proves that a propositional formula is a tautology by proving that it is impossible to falsify it. We can not do the same since there exists QBF with no models such that the matrix in prenex normal form has (Boolean) models (for example, the equivalence $\forall x \forall y \forall z (x \vee y \leftrightarrow z)$).

5 Future Works

The RuleMiner algorithm [1] is an algorithm for generating propagation rules for constraints over finite domains defined extensionally. It seems to be able to generate a set of rules more compact and more powerful than the methodology described in [6] thanks to an order over the rules and a more powerful set of possible rules. So we will study the impact of RuleMiner on our set of rules.

We develop a C++ version of a complete algorithm based on our set of rules. This implementation will work on non CNF formulae since during CNF transformation many useful pieces of information are lost. Non CNF benchmarks are rare but in [2] new difficult ones in non CNF format are proposed. One may also use to reduce the scope of quantifiers tools like qTree [9].

The Constraint Handling Rule (CHR) language [16] is used straightforwardly to implement Boolean constraint propagation system. We are interested in implementing our set of rules in CHR in side a dialect of Prolog.

6 Conclusion

In this article we have proposed a new set of Boolean propagation rules based on a decomposition by introduction of existentially quantified literals instead of variables. This new set of rules has been generated automatically thanks to QBF certificate calculated for equivalence schemata. This set of rules has been proven to cover the already proposed set of rules in [12] and to extend the propositional rules of the Stålmarck's method.

General Concept Inclusions in Fuzzy Description Logics

Giorgos Stoislos¹ and **Umberto Straccia²** and **Giorgos Stamou³** and **Jeff Z. Pan⁴**

Abstract. *Fuzzy Description Logics* (fuzzy DLs) have been proposed as a language to describe structured knowledge with vague concepts. A major theoretical and computational limitation so far is the inability to deal with *General Concept Inclusions* (GCIs), which is an important feature of classical DLs. In this paper, we address this issue and develop a calculus for fuzzy DLs with GCIs.

1 INTRODUCTION

Description Logics (DLs) [2] are a logical reconstruction of the so-called frame-based knowledge representation languages, with the aim of providing a simple well-established Tarski-style declarative semantics to capture the meaning of the most popular features of structured representation of knowledge. Nowadays, DLs have gained even more popularity due to their application in the context of the *Semantic Web*, as the theoretical counterpart of OWL DL (the W3C standard for specifying ontologies, see [9] for details).

Fuzzy DLs [15, 18, 23, 24] extend classical DLs by allowing to deal with *fuzzy/vague/imprecise concepts* such as “Candia is a creamy white rose with dark pink edges to the petals”, “Jacaranda is a hot pink rose”, and “Calla is a very large, long white flower on thick stalks”. Such concepts involve so-called *fuzzy or vague concepts*, like “creamy”, “dark”, “hot”, “large” and “thick”, for which a clear and precise definition is not possible.

The problem to deal with imprecise concepts has been addressed several decades ago by Zadeh [25], which gave birth in the meanwhile to the so-called *fuzzy set and fuzzy logic theory* and a huge number of real life applications exists. Despite the popularity of fuzzy set theory, relative little work has been carried out in extending DLs towards the representation of imprecise concepts, notwithstanding DLs can be considered as a quite natural candidate for such an extension [1, 3, 4, 5, 6, 11, 12, 14, 15, 16, 17, 18, 20, 21, 22, 23, 24, 26].

A major theoretical and computational limitation so far of fuzzy DLs is the inability to deal with *General Concept Inclusions* (GCIs), which is an important feature of classical DLs; e.g., GCIs are necessary to represent domain and range constraints. In this paper, we address this issue and develop a calculus for fuzzy DLs with GCIs.

In the next section, we briefly recall basic concepts of DLs and fuzzy DLs, while in Section 3 we present a sound and complete calculus dealing with GCIs. Section 4 concludes.

2 PRELIMINARIES

DLs basics. DLs [2] are a family of logics for representing structured knowledge. Each logic is identified by a name made of labels,

which identify the operators allowed in that logic. Major DLs are the so-called logic *ALC* [13] and is used as a reference language whenever new concepts are introduced in DLs, *SHOIN(D)*, which is the logic behind the ontology description language OWL DL and *SHIF(D)*, which is the logic behind OWL LITE, a slightly less expressive language than OWL DL (see [9]). A DL can be seen as a restricted First Order Language with unary and binary predicates. For the sake of our purpose we deal here with *ALC*, whose syntax and semantics is described in Table 1, (an *interpretation* $\mathcal{I} = (\Delta^{\mathcal{I}}, \cdot^{\mathcal{I}})$ has domain $\Delta^{\mathcal{I}}$ and maps concepts into subsets of $\Delta^{\mathcal{I}}$, maps roles into subsets of $\Delta^{\mathcal{I}} \times \Delta^{\mathcal{I}}$ and maps individuals into elements of $\Delta^{\mathcal{I}}$). An *ALC knowledge base* is defined as a pair $\Sigma = \langle \mathcal{T}, \mathcal{A} \rangle$, where \mathcal{T} is called a *TBox* and \mathcal{A} an *ABox*. \mathcal{T} is a finite set of *general inclusion axioms* (GCIs for short) of the form, $C \sqsubseteq D$ and \mathcal{A} is a finite set of *concept and role assertions* of the form $a : C$ and $(a, b) : R$, respectively. For example \mathcal{T} could contain an axioms of the form *HappyFather* $\sqsubseteq \exists \text{hasChild}.\text{Female}$, and \mathcal{A} an assertion of the form *Tom* : *HappyFather*. An interpretation \mathcal{I} satisfies \mathcal{T} if $C^{\mathcal{I}} \sqsubseteq D^{\mathcal{I}}$ for all GCIs in \mathcal{T} , then \mathcal{I} is called a *model* of \mathcal{T} , and it satisfies \mathcal{A} if $a^{\mathcal{I}} \in C^{\mathcal{I}} \wedge (a^{\mathcal{I}}, b^{\mathcal{I}}) \in R^{\mathcal{I}}$ for all concept (role) assertions in \mathcal{A} . Then \mathcal{I} is called a model of \mathcal{A} . An interpretation satisfies an *ALC KB* $\Sigma = \langle \mathcal{T}, \mathcal{A} \rangle$ if it satisfies both \mathcal{A} and \mathcal{T} ; then \mathcal{I} is called a *model* of Σ . A concept C is *subsumed* by a concept D , written $C \sqsubseteq D$, with respect to (w.r.t.) \mathcal{T} , if for all models \mathcal{I} of \mathcal{T} , it holds that $C^{\mathcal{I}} \sqsubseteq D^{\mathcal{I}}$. An ABox \mathcal{A} is *consistent* (*inconsistent*) w.r.t. a TBox \mathcal{T} if there exists (does not exist) a model \mathcal{I} of \mathcal{T} , that is also a model of \mathcal{A} . Finally, Σ *entails* an *ALC* assertion ϕ , written $\Sigma \models \phi$, if each model of Σ is a model of ϕ .

Fuzzy DLs basics. Fuzzy DLs [18] extend classical DLs by allowing to deal with *fuzzy/imprecise concepts*. The main idea underlying fuzzy DLs is that an assertion $a:C$, stating that the constant a is an instance of concept C , rather being interpreted as either true or false, will be mapped to a truth value $n \in [0, 1]_{\mathbb{Q}}$ (the rationals in the unit interval $[0, 1]$). The intended meaning is that n indicates to which extent ‘ a is a C ’. From a syntax point of view, concepts, roles, individuals and concept inclusion axioms are as for *ALC*. In place of assertions, we have *fuzzy assertions* [18], which are of the form $\langle \alpha \bowtie n \rangle$, where α is an assertion, $n \in [0, 1]_{\mathbb{Q}}$ and \bowtie is one of $\geq, \leq, >, <$. For instance, $\langle a:C \geq n \rangle$ allows to state that individual a is an instance of concept C at least to degree n . Similarly for role assertions. A *Fuzzy Knowledge Base*, $\Sigma = \langle \mathcal{T}, \mathcal{A} \rangle$, is as for the crisp case, except that now \mathcal{A} is a set of fuzzy assertions rather than assertions only. From a semantics point of view, a *fuzzy interpretation* $\mathcal{I} = (\Delta^{\mathcal{I}}, \cdot^{\mathcal{I}})$ has domain $\Delta^{\mathcal{I}}$, but now maps a concept C into a function $C^{\mathcal{I}}: \Delta^{\mathcal{I}} \rightarrow [0, 1]_{\mathbb{Q}}$ and a role R into a function $R^{\mathcal{I}}: \Delta^{\mathcal{I}} \times \Delta^{\mathcal{I}} \rightarrow [0, 1]_{\mathbb{Q}}$. For $d \in \Delta^{\mathcal{I}}$, $C^{\mathcal{I}}(d)$ gives us the degree of d being an instance of the concept C (similarly for roles). The semantics is summarized in Table 1. A fuzzy interpretation \mathcal{I} satisfies a fuzzy TBox \mathcal{T} if $\forall x \in \Delta^{\mathcal{I}}. C^{\mathcal{I}}(x) \leq D^{\mathcal{I}}(x)$ for all

Table 1. \mathcal{ALC} and fuzzy \mathcal{ALC} .

Syntax		Concepts		Examples
		Classical Semantics	Fuzzy Semantics	
$C, D \rightarrow$	\top (top concept)	$\top^{\mathcal{I}}$	$= \Delta^{\mathcal{I}}$	
	\perp (bottom concept)	$\perp^{\mathcal{I}}$	$= \emptyset$	
	A (atomic concept)	$A^{\mathcal{I}}$	$\subseteq \Delta^{\mathcal{I}}$	
$C \sqcap D$	(concept conjunction)	$(C_1 \sqcap C_2)^{\mathcal{I}} = C_1^{\mathcal{I}} \sqcap C_2^{\mathcal{I}}$	$(\bar{C}_1 \sqcup \bar{C}_2)^{\mathcal{I}} = \max(C_1^{\mathcal{I}}, C_2^{\mathcal{I}})$	Human
$C \sqcup D$	(concept disjunction)	$(C_1 \sqcup C_2)^{\mathcal{I}} = C_1^{\mathcal{I}} \sqcup C_2^{\mathcal{I}}$	$(\bar{C}_1 \sqcap \bar{C}_2)^{\mathcal{I}} = \min(C_1^{\mathcal{I}}, C_2^{\mathcal{I}})$	Human \sqcap Male
	$\neg C$ (concept negation)	$(\neg C)^{\mathcal{I}} = \Delta^{\mathcal{I}} \setminus C^{\mathcal{I}}$	$(\neg C)^{\mathcal{I}} = \inf_{y \in \Delta^{\mathcal{I}}} \{1 - R^{\mathcal{I}}(x, y)\}$	Nice \sqcup Rich
$\exists R.C$	(existential quantification)	$(\exists R.C)^{\mathcal{I}} = \{x \mid \exists y. \langle x, y, \in \rangle R^{\mathcal{I}} \wedge y \in C^{\mathcal{I}}\}$	$(\exists R.C)^{\mathcal{I}} = \{x \mid \exists y. \langle x, y, \in \rangle R^{\mathcal{I}} \Rightarrow y \in C^{\mathcal{I}}\}$	\neg Male
$\forall R.C$	(universal quantification)	$(\forall R.C)^{\mathcal{I}} = \{x \mid \forall y. \langle x, y, \in \rangle R^{\mathcal{I}} \Rightarrow y \in C^{\mathcal{I}}\}$	$(\forall R.C)^{\mathcal{I}} = \{x \mid \forall y. \langle x, y, \in \rangle R^{\mathcal{I}} \Rightarrow y \in C^{\mathcal{I}}\}$	\exists has.child.Blonde
				\forall has.child.Human

$C \sqsubseteq D \in \mathcal{T}$, then \mathcal{I} is called a *model* of \mathcal{T} , and it satisfies a fuzzy ABox \mathcal{A} if $C^{\mathcal{I}}(a^{\mathcal{I}}) \bowtie n (R^{\mathcal{I}}(a^{\mathcal{I}}, b^{\mathcal{I}}) \bowtie n)$, for each $\langle a : C \bowtie n \rangle (\langle a, b : R \bowtie n \rangle)$ in \mathcal{A} . Then \mathcal{I} is called a *model* of \mathcal{A} . A fuzzy \mathcal{ALC} KB $\Sigma = \langle \mathcal{T}, \mathcal{A} \rangle$ is consistent if there exists a model \mathcal{I} of \mathcal{A} and \mathcal{T} .

Given a fuzzy KB Σ , and a fuzzy assertion ψ (resp. a GCI $C \sqsubseteq D$), we say that Σ *entails* ψ (resp. $C \sqsubseteq D$), denoted $\Sigma \models \psi$ (resp. $\Sigma \models C \sqsubseteq D$), if each model of Σ is a model of ψ (resp. $C \sqsubseteq D$). Finally, given Σ and a fuzzy assertion α , it is of interest to compute α 's best lower and upper truth value bounds. The *greatest lower bound* of α w.r.t. Σ (denoted $glb(\Sigma, \alpha)$) is $glb(\Sigma, \alpha) = \sup\{n \mid \Sigma \models \langle \alpha \geq n \rangle\}$ where $\sup \emptyset = 0$. Similarly, the *least upper bound* of α w.r.t. Σ (denoted $lub(\Sigma, \alpha)$) is $lub(\Sigma, \alpha) = \inf\{n \mid \Sigma \models \langle \alpha \leq n \rangle\}$ where $\inf \emptyset = 1$. Determining the *glb* is called the *Best Truth Value Bound* (BTVB) problem. Basic inference problems are: (i) Check if a fuzzy KB is *consistent*, i.e. has a model. (ii) Check if D *subsumes* C w.r.t. Σ , i.e. $\Sigma \models C \sqsubseteq D$. (iii) Check if a is instance of C to degree $\geq n$, i.e. $\Sigma \models \langle a:C \geq n \rangle$ (Similarly for the other relations $\leq, >$ and $<$). (iv) Determine $glb(\Sigma, a:C)$.

We recall that all the inference problems can be reduced to the consistency problem [18]: (i) Concerning the entailment problem, it can be verified that it can be reduced to the inconsistency problem: $\langle \mathcal{T}, \mathcal{A} \rangle \models \langle \alpha \geq n \rangle$ iff $\langle \mathcal{T}, \mathcal{A} \cup \{\langle \alpha < n \rangle\} \rangle$ is inconsistent, and similarly for the other relations $\leq, >$ and $<$; (ii) Concerning the BTVB problem, it holds that $lub(\Sigma, a:C) = 1 - glb(\Sigma, a:\neg C)$, i.e. the *lub* can be determined through the *glb* (and vice-versa). Furthermore, the computation of the *glb* can be determined by relying on a finite number of entailment tests. First, for $\Sigma = \langle \mathcal{T}, \mathcal{A} \rangle$, we define $X^{\mathcal{A}} = \{0, 0.5, 1\} \cup \{n \mid \langle \alpha \bowtie n \rangle \in \mathcal{A}\}$ and $N^{\mathcal{A}} = X^{\mathcal{A}} \cup \{1 - n \mid n \in X^{\mathcal{A}}\}$. Then $glb(\Sigma, a:C) = \max\{n \mid n \in N^{\mathcal{A}} \text{ and } \Sigma \models \langle \alpha \geq n \rangle\}$. (iii) Concerning the subsumption problem, we have that $\Sigma \models C \sqsubseteq D$ iff $\Sigma = \langle \mathcal{T}, \{\langle a:C \geq n \rangle, \langle a:D < n \rangle\} \rangle$, with $n \in \{n_1, n_2\}$, $n_1 \in (0, 0.5]$ and $n_2 \in (0.5, 1]$ (e.g., we may choose $n_1 = 0.25, n_2 = 0.75$), is not consistent. So, the subsumption problem can be reduced to the consistency problem as well.

In all previous approaches to fuzzy DLs [18, 6, 14] decision procedures for the consistency, the entailment and the BTVB problem are given for various DL languages, but with restrictions on the form of concept inclusion axioms in a TBox \mathcal{T} . More precisely, \mathcal{T} was considered to be *simple*, i.e. cyclic axioms are not allowed, while concept inclusions were restricted to those of the form $A \sqsubseteq D$, where A is an *atomic* concept. Both GCIs and cyclic axioms are considered important for the classical case and, thus, should be provided in the fuzzy variant as well. For instance, cyclic definitions allow us to consider definitions such as

$$\begin{aligned} \text{Human} &\sqsubseteq \exists \text{hasParent}. \text{Human} \\ \text{GeometricElement} &\sqsubseteq \forall \text{hasPart}. \text{GeometricElement} . \end{aligned}$$

It is also well known that GCIs are used to express important features like: (i) The *domain* of a role R is concept C . This can be expressed by means of the GCI, $\exists R. \top \sqsubseteq C$. (ii) The *range* of a role R is concept C . This can be expressed by means of the GCI, $\top \sqsubseteq \forall R. C$ ⁵. (iii) Concept C_1 and concept C_2 are *disjoint*. This can be expressed by means of the GCI, $C_1 \sqcap C_2 \sqsubseteq \perp$.⁶ Such features appear in the OWL DL [9] and hence also in the fuzzy OWL DL language [16]. In the following we will present a calculus for fuzzy \mathcal{ALC} with both GCIs and cyclic axioms.

3 DEALING WITH GCIs IN FUZZY DLs

Suppose that we have an individual a and a concept C . Then, for any fuzzy interpretation \mathcal{I} , $\forall n \in [0, 1]_{\mathbb{Q}}$ either $C^{\mathcal{I}}(a^{\mathcal{I}}) < n$ or $C^{\mathcal{I}}(a^{\mathcal{I}}) \geq n$ holds⁷. Furthermore, if $\mathcal{I} \models C \sqsubseteq D$, then either $C^{\mathcal{I}}(a^{\mathcal{I}}) < n$ or $D^{\mathcal{I}}(a^{\mathcal{I}}) \geq n$. From this observation, the following can be shown.

Proposition 1 $\mathcal{I} \models C \sqsubseteq D$ iff for all $n \in [0, 1]_{\mathbb{Q}}$, either $\mathcal{I} \models \langle a : C < n \rangle$ or $\mathcal{I} \models \langle a : D \geq n \rangle$, for all a .

This suggests that the models of a TBox \mathcal{T} can be captured in the form of mutually exclusive ABoxes. For example, if $\mathcal{T} = \{C_1 \sqsubseteq D_1, C_2 \sqsubseteq D_2\}$, then for any n , the four alternatives are (i) $\{\langle a:C_1 < n \rangle, \langle a:C_2 < n \rangle\}$; (ii) $\{\langle a:C_1 < n \rangle, \langle a:D_2 \geq n \rangle\}$; (iii) $\{\langle a:D_1 \geq n \rangle, \langle a:C_2 < n \rangle\}$; and (iv) $\{\langle a:D_1 \geq n \rangle, \langle a:D_2 \geq n \rangle\}$. Note that this is a generalisation of crisp DLs where for any crisp model $\mathcal{I} = (\Delta^{\mathcal{I}}, \cdot^{\mathcal{I}})$ of \mathcal{T} , we have that $\forall d \in \Delta^{\mathcal{I}}. d \in ((\neg C_1 \sqcup D_1) \sqcap (\neg C_2 \sqcup D_2))^{\mathcal{I}}$. Please note that this *internalized* [2] concept cannot be used in fuzzy DLs since a GCI of the form $C \sqsubseteq D$ is not equivalent to the concept $\neg C \sqcup D$. Hence, in order to decide the consistency of a $\Sigma = \langle \mathcal{T}, \mathcal{A} \rangle$, for each individual a that exists in \mathcal{A} , or might be created by the reasoning algorithm, we have to create 2^k ABoxes, where k is the number of GCIs that exist in \mathcal{T} .

However, it is practically impossible to devise a terminating reasoning algorithm that uses Proposition 1 to handle GCIs and cyclic axioms as we cannot realistically apply it to all $n \in [0, 1]_{\mathbb{Q}}$. Fortunately, we can restrict these n to a *finite* set of values. Indeed, from the previous section, it turns out that the good candidate is the set $N^{\mathcal{A}}$. In [18, 19] it is shown that if a fuzzy \mathcal{ALC} ABox is consistent, then there exists a model where the membership degrees used to build the model are restricted to those that exist in the ABox. For instance,

⁵ Note that the top concept (\top) is not an atomic concept, hence range restrictions indeed are GCIs.

⁶ Note that $C \sqsubseteq \neg D$ is not a proper disjoint axiom in fuzzy \mathcal{ALC} .

⁷ Similarly, either $C^{\mathcal{I}}(a^{\mathcal{I}}) \leq n$ or $C^{\mathcal{I}}(a^{\mathcal{I}}) > n$.

in order to satisfy $\{\langle a:C \geq n \rangle\}$, we set $C^{\mathcal{I}}(a^{\mathcal{I}}) = n$, while to satisfy $\{\langle a:C > n \rangle\}$, we set $C^{\mathcal{I}}(a^{\mathcal{I}}) = n + \epsilon$, for a sufficiently small $\epsilon \in [0, 1]_{\mathbb{Q}}$.

In the following, we assume that an ABox \mathcal{A} has been *normalized*, i.e. fuzzy assertions of the form $\langle a:C > n \rangle$ are replaced by $\langle a:C \geq n + \epsilon \rangle$ and those of the form $\langle a:C < n \rangle$, by $\langle a:C \leq n - \epsilon \rangle$. Please note that in a normalized fuzzy KB we allow the degree to range in $[-\epsilon, 1 + \epsilon]_{\mathbb{Q}}$ in place of $[0, 1]_{\mathbb{Q}}$. It can be proved that the process of normalization is satisfiability preserving.

Proposition 2 Let $\Sigma = \langle \mathcal{T}, \mathcal{A} \rangle$ be a fuzzy knowledge base. Then Σ is satisfiable if and only if its normalized variant is satisfiable.

3.1 A fuzzy tableau for fuzzy \mathcal{ALC}

We have seen that the inference problems in fuzzy DLs can be reduced to the consistency checking problem. Similar to crisp DLs, our tableau algorithm checks the consistency of a fuzzy KB by trying to build a fuzzy tableau, from which it is immediate either to build a model in case KB is consistent or to detect that the KB is inconsistent. The fuzzy tableau we present here can be seen as an extension of the tableau presented in [8], and is inspired by the one presented in [14]. Without loss of generality, we assume that all concepts C are in *negation normal form* (NNF) [7], i.e. negations occur in front of atomic concepts only.⁸ In the following, $\bowtie \in \{\geq, \leq\}$, while we also use \bowtie^- to denote the *reflection* of \bowtie , e.g. if $\bowtie = \leq$, then $\bowtie^- = \geq$.

Definition 1 Given $\Sigma = \langle \mathcal{T}, \mathcal{A} \rangle$, let \mathbf{R}_{Σ} be the set of roles occurring in Σ and let $\text{sub}(\Sigma)$ be the set of named concepts appearing in Σ . A fuzzy tableau T for Σ is a quadruple $(\mathbf{S}, \mathcal{L}, \mathcal{E}, \mathcal{V})$ such that: \mathbf{S} is a set of elements, $\mathcal{L} : \mathbf{S} \times \text{sub}(\Sigma) \rightarrow [0, 1]_{\mathbb{Q}}$ maps each element and concept, to a membership degree (the degree of the element being an instance of the concept), and $\mathcal{E} : \mathbf{R}_{\Sigma} \times 2^{\mathbf{S} \times \mathbf{S}} \rightarrow [0, 1]_{\mathbb{Q}}$ maps each role of \mathbf{R}_{Σ} and pair of elements to the membership degree of the pair being an instance of the role, and $\mathcal{V} : \mathbf{I}_{\mathcal{A}} \rightarrow \mathbf{S}$ maps individuals occurring in \mathcal{A} to elements in \mathbf{S} . For all $s, t \in \mathbf{S}$, $C, E \in \text{sub}(\Sigma)$, and $R \in \mathbf{R}_{\Sigma}$, T has to satisfy:

1. $\mathcal{L}(s, \perp) = 0$ and $\mathcal{L}(s, \top) = 1$ for all $s \in \mathbf{S}$,
2. If $\mathcal{L}(s, \neg C) \bowtie n$, then $\mathcal{L}(s, C) \bowtie^- 1 - n$.
3. If $\mathcal{L}(s, C \sqcap E) \geq n$, then $\mathcal{L}(s, C) \geq n$ and $\mathcal{L}(s, E) \geq n$.
4. If $\mathcal{L}(s, C \sqcup E) \leq n$, then $\mathcal{L}(s, C) \leq n$ and $\mathcal{L}(s, E) \leq n$.
5. If $\mathcal{L}(s, C \sqcup E) \geq n$, then $\mathcal{L}(s, C) \geq n$ or $\mathcal{L}(s, E) \geq n$.
6. If $\mathcal{L}(s, C \sqcap E) \leq n$, then $\mathcal{L}(s, C) \leq n$ or $\mathcal{L}(s, E) \leq n$.
7. If $\mathcal{L}(s, \forall R.C) \geq n$, then $\mathcal{E}(R, \langle s, t \rangle) \leq 1 - n$ or $\mathcal{L}(t, C) \geq n$ for all $t \in \mathbf{S}$.
8. If $\mathcal{L}(s, \exists R.C) \leq n$, then $\mathcal{E}(R, \langle s, t \rangle) \leq n$ or $\mathcal{L}(t, C) \leq n$ for all $t \in \mathbf{S}$.
9. If $\mathcal{L}(s, \exists R.C) \geq n$, then there exists $t \in \mathbf{S}$ such that $\mathcal{E}(R, \langle s, t \rangle) \geq n$ and $\mathcal{L}(t, C) \geq n$.
10. If $\mathcal{L}(s, \forall R.C) \leq n$, then there exists $t \in \mathbf{S}$ such that $\mathcal{E}(R, \langle s, t \rangle) \geq 1 - n$ and $\mathcal{L}(t, C) \leq n$.
11. If $C \sqsubseteq D \in \mathcal{A}$, then either $\mathcal{L}(s, C) \leq n - \epsilon$ or $\mathcal{L}(s, D) \geq n$, for all $s \in \mathbf{S}$ and $n \in N^{\mathcal{A}}$.
12. If $\langle a:C \bowtie n \rangle \in \mathcal{A}$, then $\mathcal{L}(\mathcal{V}(a), C) \bowtie n$.
13. If $\langle (a, b):R \bowtie n \rangle \in \mathcal{A}$, then $\mathcal{E}(R, \langle \mathcal{V}(a), \mathcal{V}(b) \rangle) \bowtie n$.

Proposition 3 $\Sigma = \langle \mathcal{T}, \mathcal{A} \rangle$ is consistent iff there exists a fuzzy tableau for Σ .

⁸ A fuzzy \mathcal{ALC} concept can be transformed into an equivalent one in NNF by pushing negations inwards using a combination of the De Morgan laws and the equivalences $\neg \exists R.C \equiv \forall R.\neg C$, $\neg \forall R.C \equiv \exists R.\neg C$.

Proof: [Sketch] For the *if* direction if $T = (\mathbf{S}, \mathcal{L}, \mathcal{E}, \mathcal{V})$ is a fuzzy tableau for Σ , we can construct a fuzzy interpretation $\mathcal{I} = (\Delta^{\mathcal{I}}, \cdot^{\mathcal{I}})$ that is a model of \mathcal{A} and \mathcal{T} as follows:

$$\begin{aligned} \Delta^{\mathcal{I}} = \mathbf{S} \quad a^{\mathcal{I}} = \mathcal{V}(a), a \text{ occurs in } \mathcal{A} \quad A^{\mathcal{I}}(s) = \mathcal{L}(s, A) \text{ for all } s \in \mathbf{S} \\ \top^{\mathcal{I}}(s) = \mathcal{L}(s, \top), \perp^{\mathcal{I}}(s) = \mathcal{L}(s, \perp), \text{ for all } s \in \mathbf{S} \\ R^{\mathcal{I}}(s, t) = \mathcal{E}(R, \langle s, t \rangle) \text{ for all } \langle s, t \rangle \in \mathbf{S} \times \mathbf{S} \end{aligned}$$

To prove that \mathcal{I} is a model of \mathcal{A} and \mathcal{T} , we can show by induction on the structure of concepts that $\mathcal{L}(s, C) \bowtie n$ implies $C^{\mathcal{I}}(s) \bowtie n$ for all $s \in \mathbf{S}$. Together with properties 12, 13, Proposition 1, the fact that we can restrict our attention to the degrees in $N^{\mathcal{A}}$ and the interpretation of individuals and roles, this implies that \mathcal{I} is a model of \mathcal{T} , and that it satisfies each fuzzy assertion in \mathcal{A} .

For the converse, if $\mathcal{I} = (\Delta^{\mathcal{I}}, \cdot^{\mathcal{I}})$ is a model of Σ , then a fuzzy tableau $T = (\mathbf{S}, \mathcal{L}, \mathcal{E}, \mathcal{V})$ for Σ can be defined as follows:

$$\mathbf{S} = \Delta^{\mathcal{I}} \quad \mathcal{E}(R, \langle s, t \rangle) = R^{\mathcal{I}}(s, t) \quad \mathcal{L}(s, C) = C^{\mathcal{I}}(s) \quad \mathcal{V}(a) = a^{\mathcal{I}}$$

It is easy to show that T is a fuzzy tableau for Σ . \square

3.2 An algorithm for constructing a fuzzy tableau

In order to decide the consistency of $\Sigma = \langle \mathcal{T}, \mathcal{A} \rangle$ a procedure that constructs a fuzzy tableau T for Σ has to be determined. Like the tableau algorithm presented in [8], our algorithm works on *completion-forests* since an ABox might contain several individuals with arbitrary roles connecting them. Due to the presence of general or cyclic terminologies, the termination of the algorithm is ensured by the use of *blocking*, where an expansion is terminated when individuals on the same path are asserted to belong to the same concepts.

Definition 2 Let $\Sigma = \langle \mathcal{T}, \mathcal{A} \rangle$ be a fuzzy KB. A completion-forest \mathcal{F} for Σ is a collection of trees whose distinguished roots are arbitrarily connected by edges. Each node x is labelled with a set $\mathcal{L}(x) = \{\langle C, \bowtie, n \rangle\}$, where $C \in \text{sub}(\Sigma)$, $\bowtie \in \{\geq, \leq\}$ and $n \in [-\epsilon, 1 + \epsilon]$. Each edge $\langle x, y \rangle$ is labelled with a set $\mathcal{L}(\langle x, y \rangle) = \{\langle R, \bowtie, n \rangle\}$, where $R \in \mathbf{R}_{\Sigma}$ are roles occurring in Σ . Two triples $\langle C, \geq, n \rangle$ ($\langle R, \geq, n \rangle$) and $\langle C, \leq, m \rangle$ ($\langle R, \leq, m \rangle$) are conjugated if $n > m$.

If nodes x and y are connected by an edge $\langle x, y \rangle$ with $\langle R, \bowtie, n \rangle \in \mathcal{L}(\langle x, y \rangle)$, then y is called an $R_{\bowtie n}$ -successor of x and x is called an $R_{\bowtie n}$ -predecessor of y . Let y be an $R_{\geq n}$ -successor of x , the edge $\langle x, y \rangle$ is conjugated with triples $\langle R, \leq, m \rangle$ if $n > m$. Similarly, we can extend it to the cases of $R_{\leq n}$ -successor. A node x is an R -successor (resp. R -predecessor) of y if it is an $R_{\bowtie n}$ -successor (resp. $R_{\bowtie n}$ -predecessor) of y for some role R . As usual, ancestor is the transitive closure of predecessor.

A node x is directly blocked iff none of its ancestors are blocked, it is not a root node, and it has an ancestor y such that $\mathcal{L}(x) \subseteq \mathcal{L}(y)$. In this case, we say y directly blocks x . A node x is blocked iff it is directly blocked or if one of its predecessor is blocked.

A node x is said to contain a clash iff there exist two conjugated triples in $\mathcal{L}(x)$ or one of the following triples exists within $\mathcal{L}(x)$: (i) $\langle \perp, \geq, n \rangle$, for $n > 0$; (ii) $\langle \top, \leq, n \rangle$, for $n < 1$; (iii) $\langle C, \leq, -\epsilon \rangle$; (iv) $\langle C, \geq, 1 + \epsilon \rangle$. The notion of ' $\mathcal{L}(\langle x, y \rangle)$ contains a clash' is defined similarly.

The algorithm initializes a forest \mathcal{F} to contain (i) a root node x_0^i , for each individual a_i occurring in \mathcal{A} , labelled with $\mathcal{L}(x_0^i)$ such that $\{\langle C_i, \bowtie, n \rangle\} \subseteq \mathcal{L}(x_0^i)$ for each fuzzy assertion $\langle a_i:C_i \bowtie n \rangle \in \mathcal{A}$, and (ii) an edge $\langle x_0^i, x_0^j \rangle$, for each fuzzy assertion $\langle (a_i, a_j):R_i \bowtie n \rangle \in \mathcal{A}$, labelled with $\mathcal{L}(\langle x_0^i, x_0^j \rangle)$ such that $\{\langle R_i, \bowtie, n \rangle\} \subseteq \mathcal{L}(\langle x_0^i, x_0^j \rangle)$. \mathcal{F} is then expanded by repeatedly

Table 2. Tableaux expansion rules

Rule	Description	Rule	Description
(\neg)	if 1. $\langle \neg C, \bowtie, n \rangle \in \mathcal{L}(x)$, and 2. $\langle C, \bowtie^-, 1-n \rangle \notin \mathcal{L}(x)$ then $\mathcal{L}(x) \rightarrow \mathcal{L}(x) \cup \{\langle C, \bowtie^-, 1-n \rangle\}$	(\exists_{\geq})	if 1. $\langle \exists R.C, \geq, n \rangle \in \mathcal{L}(x)$, x is not blocked, 2. x has no $R_{\geq n}$ -successor y with $\langle C, \geq, n \rangle \in \mathcal{L}(y)$ then create a new node y with $\mathcal{L}(\langle x, y \rangle) = \{\langle R, \geq, n \rangle\}$, $\mathcal{L}(y) = \{\langle C, \geq, n \rangle\}$,
(\sqcap_{\geq})	if 1. $\langle C_1 \sqcap C_2, \geq, n \rangle \in \mathcal{L}(x)$ and 2. $\{\langle C_1, \geq, n \rangle, \langle C_2, \geq, n \rangle\} \not\subseteq \mathcal{L}(x)$ then $\mathcal{L}(x) \rightarrow \mathcal{L}(x) \cup \{\langle C_1, \geq, n \rangle, \langle C_2, \geq, n \rangle\}$	(\forall_{\leq})	if 1. $\langle \forall R.C, \leq, n \rangle \in \mathcal{L}(x)$, x is not blocked, 2. x has no $R_{\geq 1-n}$ -successor y with $\langle C, \leq, n \rangle \in \mathcal{L}(y)$ then create a new node y with $\mathcal{L}(\langle x, y \rangle) = \{\langle R, \geq, 1-n \rangle\}$, $\mathcal{L}(y) = \{\langle C, \leq, n \rangle\}$,
(\sqcup_{\leq})	if 1. $\langle C_1 \sqcup C_2, \leq, n \rangle \in \mathcal{L}(x)$ and 2. $\{\langle C_1, \leq, n \rangle, \langle C_2, \leq, n \rangle\} \not\subseteq \mathcal{L}(x)$ then $\mathcal{L}(x) \rightarrow \mathcal{L}(x) \cup \{\langle C_1, \leq, n \rangle, \langle C_2, \leq, n \rangle\}$	(\forall_{\geq})	if 1. $\langle \forall R.C, \geq, n \rangle \in \mathcal{L}(x)$, 2. x has an R -successor y with $\langle C, \geq, n \rangle \notin \mathcal{L}(y)$ and 3. $\langle R, \leq, 1-n \rangle$ is conjugated with the edge $\langle x, y \rangle$ then $\mathcal{L}(y) \rightarrow \mathcal{L}(y) \cup \{\langle C, \geq, n \rangle\}$,
(\sqcup_{\geq})	if 1. $\langle C_1 \sqcup C_2, \geq, n \rangle \in \mathcal{L}(x)$ and 2. $\{\langle C_1, \geq, n \rangle, \langle C_2, \geq, n \rangle\} \cap \mathcal{L}(x) = \emptyset$ then $\mathcal{L}(x) \rightarrow \mathcal{L}(x) \cup \{C\}$ for some $C \in \{\langle C_1, \geq, n \rangle, \langle C_2, \geq, n \rangle\}$	(\exists_{\leq})	if 1. $\langle \exists R.C, \leq, n \rangle \in \mathcal{L}(x)$, 2. x has an R -successor y with $\langle C, \leq, n \rangle \notin \mathcal{L}(y)$ and 3. $\langle R, \leq, n \rangle$ is conjugated with the edge $\langle x, y \rangle$ then $\mathcal{L}(y) \rightarrow \mathcal{L}(y) \cup \{\langle C, \leq, n \rangle\}$,
(\sqcap_{\leq})	if 1. $\langle C_1 \sqcap C_2, \leq, n \rangle \in \mathcal{L}(x)$ and 2. $\{\langle C_1, \leq, n \rangle, \langle C_2, \leq, n \rangle\} \cap \mathcal{L}(x) = \emptyset$ then $\mathcal{L}(x) \rightarrow \mathcal{L}(x) \cup \{C\}$ for some $C \in \{\langle C_1, \leq, n \rangle, \langle C_2, \leq, n \rangle\}$	(\sqsubseteq)	if 1. $C \sqsubseteq D \in \mathcal{T}$ and 2. $\{\langle C, \leq, n-\epsilon \rangle, \langle D, \geq, n \rangle\} \cap \mathcal{L}(x) = \emptyset$ for $n \in N^A$ then $\mathcal{L}(x) \rightarrow \mathcal{L}(x) \cup \{E\}$ for some $E \in \{\langle C, \leq, n-\epsilon \rangle, \langle D, \geq, n \rangle\}$

applying the completion rules from Table 2. The completion forest is complete when, for some node x (edge $\langle x, y \rangle$), $\mathcal{L}(x)$ ($\mathcal{L}(\langle x, y \rangle)$) contains a clash, or none of the completion rules in Table 2 are applicable. The algorithm stops when a clash occurs; it answers ‘ Σ is consistent’ iff the completion rules can be applied in such a way that they yield a complete and clash-free completion forest, and ‘ Σ is inconsistent’ otherwise.

From Table 2, we can see that for an arbitrary fuzzy assertion of the form $\langle a:D \bowtie n \rangle$ either value n or its complement $1-n$ appear in the expansion of a node x where $D \in \mathcal{L}(x)$. The finite property of the membership degrees makes blocking possible in our algorithm.

Example 1 Let us show how the blocking condition works on the cyclic fuzzy KB, $\Sigma = \{\langle \text{HotPinkRose} \sqsubseteq \exists \text{nextGen.HotPinkRose} \rangle, \{\langle a:\text{HotPinkRose} \geq 0.6 \rangle\}\}$. Σ is satisfiable and $N^A = \{0, 0.5, 1\} \cup \{0.4, 0.6\}$. We start with a root node x^a , with label $\mathcal{L}(x^a) = \{\langle \text{HotPinkRose}, \geq, 0.6 \rangle\}$. By applying rule (\sqsubseteq) to node x^a , to $\text{HotPinkRose} \sqsubseteq \exists \text{nextGen.HotPinkRose}$ with, e.g., $n = 0.6$, and $E = \langle \exists \text{nextGen.HotPinkRose}, \geq, n \rangle$, we update the label $\mathcal{L}(x^a)$ with $\mathcal{L}(x^a) = \{\langle \text{HotPinkRose}, \geq, 0.6 \rangle, \langle \exists \text{nextGen.HotPinkRose}, \geq, 0.6 \rangle\}$. Continuing with node x^a , we apply rule (\exists_{\geq}) to $\langle \exists \text{nextGen.HotPinkRose}, \geq, 0.6 \rangle$, create a new edge $\langle x^a, y_1 \rangle$ with $\mathcal{L}(\langle x^a, y_1 \rangle) = \{\langle \text{nextGen}, \geq, 0.6 \rangle\}$ and $\mathcal{L}(y_1) = \{\langle \text{HotPinkRose}, \geq, 0.6 \rangle\}$. By continuing with node y_1 exactly as for node x^a , after applying rule (\sqsubseteq) , we update the label $\mathcal{L}(y_1)$ with $\mathcal{L}(y_1) = \{\langle \text{HotPinkRose}, \geq, 0.6 \rangle, \langle \exists \text{nextGen.HotPinkRose}, \geq, 0.6 \rangle\}$. Now, y_1 is an nextGen -successor of x^a and $\mathcal{L}(y_1) = \mathcal{L}(x^a)$ and, thus, y_1 is directly blocked.

Example 2 We show that $\Sigma = \{\{C \sqsubseteq D\}, \{\langle a:C > 0.3 \rangle, \langle a:D \leq 0.3 \rangle\}\}$ is inconsistent. We first normalize Σ into $\Sigma = \{\{C \sqsubseteq D\}, \{\langle a:C \geq 0.3 + \epsilon \rangle, \langle a:D \leq 0.3 \rangle\}\}$, for a small $\epsilon > 0$, e.g. $\epsilon = 0.01$. $N^A = \{0, 0.5, 1\} \cup \{0.3, 0.3 + \epsilon, 0.7 - \epsilon, 0.7\}$. We start with a root node x^a and $\mathcal{L}(x^a) = \{\langle C, \geq, 0.3 + \epsilon \rangle, \langle D, \leq, 0.3 \rangle\}$. By applying rule (\sqsubseteq) to node x^a , to $C \sqsubseteq D$ with, e.g., $n = 0.3 + \epsilon$ we get two branches, depending on the ‘choice of $E \in \{\langle C, \leq, 0.3 + \epsilon \rangle, \langle D, \geq, 0.3 + \epsilon \rangle\}$ ’. In the former case, we update the label $\mathcal{L}(x^a)$ with $\mathcal{L}(x^a) = \{\langle C, \geq, 0.3 + \epsilon \rangle, \langle D, \leq, 0.3 \rangle, \langle C, \leq, 0.3 \rangle\}$

which contains a clash, while in the latter case we update the label $\mathcal{L}(x^a)$ with $\mathcal{L}(x^a) = \{\langle C, \geq, 0.3 + \epsilon \rangle, \langle D, \leq, 0.3 \rangle, \langle D, \geq, 0.3 + \epsilon \rangle\}$ which also contains a clash. No complete, clash-free forest can be obtained, thus the algorithm answers with ‘inconsistent’.

Proposition 4 (Termination) For each fuzzy ALC KB Σ , the tableau algorithm terminates.

Proof: [Sketch] Termination is a result of the properties of the expansion rules, as in the classical case [8]. More precisely we have the following observations. (i) The expansion rules never remove nodes from the tree or concepts from node labels or change the edge labels. (ii) Successors are only generated by the rules \exists_{\geq} and \forall_{\leq} . For any node and for each concept these rules are applied at-most once. (iii) Since nodes are labelled with nonempty subsets of $\text{sub}(\Sigma)$, obviously there is a finite number of possible labellings for a pair of nodes. Thus, the condition of blocking will be applied in any path of the tree and consequently any path will have a finite length. \square

Proposition 5 (Soundness) If the expansion rules can be applied to an fuzzy ALC KB Σ such that they yield a complete and clash-free completion-forest, then Σ has a fuzzy tableau for Σ .

Proof: [Sketch] Let \mathcal{F} be a complete and clash-free completion-forest constructed by the tableaux algorithm for Σ . A fuzzy tableau $T = (\mathbf{S}, \mathcal{L}, \mathcal{E}, \mathcal{V})$ can be defined as follows:

$$\begin{aligned}
 \mathbf{S} &= \{x \mid x \text{ is a node in } \mathcal{F}, \text{ and } x \text{ is not blocked}\}, \\
 \mathcal{L}(x, \perp) &= 0, \text{ for all } x \in \mathbf{S}, \\
 \mathcal{L}(x, \top) &= 1, \text{ for all } x \in \mathbf{S}, \\
 \mathcal{L}(x, C) &= \max[\langle C, \geq, n_i \rangle], \text{ for all } x \in \mathcal{F} \text{ not blocked}, \\
 \mathcal{L}(x, \neg A) &= 1 - \mathcal{L}(x, A), \text{ for all } x \in \mathcal{F} \text{ not blocked}, \\
 &\quad \text{with } \langle \neg A, \geq, n \rangle \in \mathcal{L}(x), \\
 \mathcal{E}(R, \langle x, y \rangle) &= \{\max[\langle R, \geq, n_i \rangle] \mid \\
 &\quad 1. y \text{ is an } R_{\geq n_i} \text{-successor of } x \text{ or} \\
 &\quad 2. \langle R, \geq, n_i \rangle \in \mathcal{L}(\langle x, z \rangle) \text{ and } y \text{ blocks } z\}, \\
 \mathcal{V}(a_i) &= x_0^i, \text{ where } x_0^i \text{ is a root node}
 \end{aligned}$$

where \max returns the maximum degree n out of the set of triples of the form $\langle A, \geq, n_i \rangle$, or 0 if no such triple exists. It can be shown that T is a fuzzy tableau for Σ . \square

Proposition 6 (Completeness) Consider a fuzzy ALC KB Σ . If Σ has a fuzzy tableau, then the expansion rules can be applied in such a way that the tableaux algorithm yields a complete and clash-free completion-forest for Σ .

Proof: [Sketch] Let $T = (\mathbf{S}, \mathcal{L}, \mathcal{E}, \mathcal{V})$ be a fuzzy tableau for Σ . Using T , we trigger the application of the expansion rules such that they yield a completion-forest \mathcal{F} that is both complete and clash-free. Similarly to [8] we can define a mapping π which maps nodes of \mathcal{F} to elements of \mathbf{S} , and guide the application of the non-deterministic rules \sqsubseteq , \sqcup_{\geq} and \sqcap_{\leq} . Our method slightly differs from the one used in crisp DLs [8] in the following way. Using the membership degree of a node to a concept, found in the fuzzy tableau, we create artificial triples that are tested against conjugation with the candidate triples that the non-deterministic rule can insert in the completion-forest. The triples that don't cause a conjugation can be added. The modified rules, which are used to guide such an expansion, are presented in Table 3. The modified rules together with the termination property ensure the completeness of the algorithm. \square

Table 3. The \sqsubseteq' , \sqcup'_{\geq} and \sqcap'_{\leq} rules

(\sqsubseteq')	if 1. $C \sqsubseteq D \in \mathcal{T}$, x is not indirectly blocked and 2. $\{\langle C, \leq, n - \epsilon \rangle, \langle D, \geq, n \rangle\} \cap \mathcal{L}(x) = \emptyset$ for $n \in N^A$ then $\mathcal{L}(x) \rightarrow \mathcal{L}(x) \cup \{E\}$ for some $E \in \{\langle C, \leq, n - \epsilon \rangle, \langle D, \geq, n \rangle\}$, not conjugated with $\langle C, \geq, \mathcal{L}(\pi(x), C) \rangle$ or $\langle D, \leq, \mathcal{L}(\pi(x), D) \rangle$
(\sqcup'_{\geq})	if 1. $\langle C_1 \sqcup C_2, \geq, n \rangle \in \mathcal{L}(x)$, x is not indirectly blocked, and 2. $\{\langle C_1, \geq, n \rangle, \langle C_2, \geq, n \rangle\} \cap \mathcal{L}(x) = \emptyset$ then $\mathcal{L}(x) \rightarrow \mathcal{L}(x) \cup \{C\}$ for some $C \in \{\langle C_1, \geq, n \rangle, \langle C_2, \geq, n \rangle\}$ not conjugated with $\langle C_1, \leq, \mathcal{L}(\pi(x), C_1) \rangle$ or $\langle C_2, \leq, \mathcal{L}(\pi(x), C_2) \rangle$
(\sqcap'_{\leq})	if 1. $\langle C_1 \sqcap C_2, \leq, n \rangle \in \mathcal{L}(x)$, x is not indirectly blocked, and 2. $\{\langle C_1, \leq, n \rangle, \langle C_2, \leq, n \rangle\} \cap \mathcal{L}(x) = \emptyset$ then $\mathcal{L}(x) \rightarrow \mathcal{L}(x) \cup \{C\}$ for some $C \in \{\langle C_1, \leq, n \rangle, \langle C_2, \leq, n \rangle\}$ not conjugated with $\langle C_1, \geq, \mathcal{L}(\pi(x), C_1) \rangle$ or $\langle C_2, \geq, \mathcal{L}(\pi(x), C_2) \rangle$

4 CONCLUSIONS

Fuzzy DLs extend crisp DLs to deal with vague concepts. None of the work on fuzzy DLs so far presented a correct and complete calculus for cyclic TBoxes and general concept inclusions, which are important features of current crisp DL systems. We overcome to this limitation by providing a tableau for fuzzy ALC with GCIs.

Major topics for future research are indeed the extension of the fuzzy tableau algorithm to expressive DL languages such as fuzzy SHIF(D) or SHOIN(D) [21] and the development of a system supporting this language. In the former case, such algorithm can be based directly on the ones presented for the fuzzy ST and SHIN DLs [14, 15] and the rules for nominals, for SHOIN [10] and for fuzzy SHOIN [16].

Approximating Extended Answer Sets

Davy Van Nieuwenborgh¹ and Stijn Heymans² and Dirk Vermeir³

Abstract. We present an approximation theory for the extended answer set semantics, using the concept of an approximation constraint. Intuitively, an approximation constraint, while satisfied by a “perfect” solution, may be left unsatisfied in an approximate extended answer set. Approximations improve as the number of unsatisfied constraints decreases. We show how the framework can also capture the classical answer set semantics, thus providing an approximative version of the latter.

1 Introduction

The idea behind the answer set semantics for logic programs is both intuitive and elegant. Given a program P and a candidate answer set M , one computes a reduct program P_M of a simpler type for which a semantics P_M^* is known. The reduct P_M is obtained from P by taking into account the consequences of accepting the proposed truth values of the literals in M . The candidate set M is then an answer set just when $P_M^* = M$, i.e. M is “self-producible”.

In [17], the same reduction technique is applied to define the extended answer set semantics for simple logic programs, i.e. programs containing only classical negation. In contrast with the classical answer set semantics, extended answer sets are able to handle contradictory programs by allowing rules to be defeated, i.e. to leave certain rules unsatisfied.

The answer set semantics has been implemented in state-of-the-art solvers such as DLV[11] or SMODELS[14]. While these solvers perform well in many cases, they implement an “all or nothing” strategy, i.e. they do not provide the user with “partial” or “approximate” answer sets if there are insufficient resources for computing an exact solution. Clearly, given the inherent complexity of the problems tackled by such solvers, it would be desirable to have such an approximation facility, e.g. in cases where the available resources are limited. Furthermore, for many application areas obtaining such a “good enough” solution within a certain time limit, may be attractive, e.g. in diagnostic reasoning [18].

In this paper, we propose to provide an approximation theory for the extended answer set semantics, based on so-called approximation constraints. Intuitively, an approximation constraint is a constraint that should be satisfied by a perfect solution to a problem, but which may be left unsatisfied by an approximate solution. The more approximation constraints an approximate extended answer set satisfies, the “better” it approximates an exact solution. We will show that the proposed framework can also be used to approximate classical answer

sets⁴, which may lead to the development of “anytime” approximate answer set solvers.

The computation of extended answer sets for programs without constraints is very efficient, i.e. it takes quadratic time in the size of the program to compute an extended answer set for such programs, which implies that a first approximation can be computed very quickly. Although grounding adds an exponential⁵ factor [6] to the computation in the worst case, the extended answer set semantics should perform much better in the average case. Moreover, the semantics allows for a “ground when needed” implementation, in contrast to solvers such as DLV [11] or SMODELS [14] which first completely ground the program, before computing a solution.

The above mentioned efficiency implies that the basic extended answer set semantics is not able to handle problems located above \mathcal{P} . However, adding approximation constraints to the semantics lifts the complexity up to include \mathcal{NP} -complete problems, placing the proposed semantics at the same level as the classical answer set semantics.

The remainder of the paper is organized as follows: Section 2 introduces the extended answer set semantics, while Section 3 presents the framework of approximation constraints. In Section 4 the relationship with classical answer programming is explored, while we briefly discuss some related work in Section 5. Finally, we conclude and give some directions for future research in Section 6. Due to space restrictions, all proofs are omitted, they can be found in the technical report [16].

2 Extended Answer Set Semantics

In this section, we introduce the extended answer set semantics for simple logic programs, i.e. logic programs with only classical negation, no disjunction in the head of rules and no constraints.

A *term* is a constant or a variable, where the former will be written lower-case and the latter upper-case. An *atom* is of the form $p(t_1, \dots, t_n)$, $0 \leq n < \infty$, where p is an n -ary⁶ predicate name and t_i , $1 \leq i \leq n$, are terms. A *literal* is an atom a or a classically negated atom $\neg a$.

Definition 1 A *simple logic program (SLP)* is a countable set P of rules of the form $a \leftarrow \alpha$ where $\{a\} \cup \alpha$ is a finite set of literals⁷.

⁴ Conversely, Theorem 4 in [17] shows that classical answer set programming can be used to compute extended answer set semantics.

⁵ If we restrict the arities of predicates to small numbers, e.g. binary or ternary, it is shown in [8] that the additional complexity of grounding only adds one level of the polynomial hierarchy in contrast to the exponential factor in general.

⁶ We thus allow for 0-ary predicates, i.e., *propositions*.

⁷ Note that constraints, i.e. rules with empty heads, are not allowed for the moment.

A *ground* atom, literal, rule, or SLP does not contain variables. Substituting every variable in a SLP P with every possible constant in P yields the ground SLP $gr(P)$.

Example 1 Grounding the SLP

$$\neg p(c, a) \leftarrow \quad p(X) \leftarrow \neg q(X, b) \quad q(X) \leftarrow \neg p(X, a)$$

yields the SLP⁸.

$$\begin{array}{lll} p(a) \leftarrow \neg q(a, b) & p(b) \leftarrow \neg q(b, b) & p(c) \leftarrow \neg q(c, b) \\ q(a) \leftarrow \neg p(a, a) & q(b) \leftarrow \neg p(b, a) & q(c) \leftarrow \neg p(c, a) \\ \neg p(c, a) \leftarrow & & \end{array}$$

In the rest of the paper we always assume ground SLPs and ground literals; to obtain the definitions for ungrounded SLPs, replace every occurrence of a SLP P by $gr(P)$, e.g., an extended answer set of an ungrounded SLP P is an extended answer set of $gr(P)$.

For a set of literals X , we use $\neg X$ to denote the set $\{\neg p \mid p \in X\}$ where $\neg\neg a \equiv a$. Further, X is said to be *consistent* if $X \cap \neg X = \emptyset$, i.e. X does not contain contradictory literals a and $\neg a$.

Definition 2 The *Herbrand base* \mathcal{B}_P of a SLP P is the set of all ground atoms that can be formed using the language of P . The set of all literals that can be formed with P , i.e. $\mathcal{B}_P \cup \neg \mathcal{B}_P$, is denoted by \mathcal{L}_P . An *interpretation* I of P is any consistent subset of \mathcal{L}_P .

A rule $r = a \leftarrow \alpha$ is **satisfied** by an interpretation I , denoted $I \models r$, if $a \in I$ whenever $\alpha \subseteq I$, i.e., if r is **applicable** ($\alpha \subseteq I$) then it must be **applied** ($\alpha \cup \{a\} \subseteq I$). The rule r is **defeated** w.r.t. I iff there exists an applied competing rule $\neg a \leftarrow \alpha'$ in P , such a rule is said to **defeat** r .

Intuitively, in an extended answer set (see below), a rule $r: a \leftarrow \alpha$ may not be left unsatisfied, unless one accepts the opposite conclusion $\neg a$ which must itself be motivated by a competing applied rule $\neg a \leftarrow \alpha'$ that defeats r .

Example 2 Consider the SLP P_1 containing the rules $\neg a \leftarrow$, $\neg b \leftarrow$, $a \leftarrow \neg b$, and $b \leftarrow \neg a$. For the interpretation $I = \{\neg a, b\}$ we have that I satisfies all rules in P_1 but one: $\neg a \leftarrow$ and $b \leftarrow \neg a$ are applied while $a \leftarrow \neg b$ is not applicable. The unsatisfied rule $\neg b \leftarrow$ is defeated by $b \leftarrow \neg a$.

For a set of rules P , we use P^* to denote the unique minimal [15] model of the positive logic program consisting of the rules in P , where negative literals $\neg a$ are considered as fresh atoms. We can compute P^* using the immediate consequence operator $T_P(X) = \{l \in \mathcal{L}_P \mid l \leftarrow \beta \in P \wedge \beta \subseteq X\}$. Clearly, the operator T_P is monotonic, and $T_P^\infty(\emptyset) = P^*$.

For the program of Example 2, we have that $P_1^* = \{a, b, \neg a, \neg b\}$ is inconsistent. The following definition allows us to not apply certain rules when computing a consistent interpretation for programs such as P_1 .

Definition 3 The *reduct* $P_I \subseteq P$ of a SLP P w.r.t. a set of literals I contains just the rules satisfied by I , i.e. $P_I = \{r \in P \mid I \models r\}$.

An interpretation S is an **extended answer set** of P iff $P_S^* = S$, i.e., S is **founded**, and all rules in $P \setminus P_S$ are defeated w.r.t. S .

We use $\mathcal{ES}(P)$ to denote the set of all extended answer sets of P .

⁸ Note that a variable X in a rule should be grounded with the same constant in that rule (either with a , b or c), while it may be grounded with other constants in other rules, i.e., the variables in a rule are considered local to the rule. One can, e.g., replace the above SLP by the equivalent program

$$\neg p(c, a) \leftarrow \quad p(X) \leftarrow \neg q(X, b) \quad q(Y) \leftarrow \neg p(Y, a)$$

Thus, the extended answer set semantics deals with inconsistencies in a simple yet intuitive way: when faced with contradictory applicable rules, just select one for application and ignore (defeat) the other. In the absence of extra information (e.g., a preference relation for satisfying certain rules at the expense of others [17]; or the approximation constraints introduced in this paper), this seems a reasonable strategy for extracting a consistent semantics out of inconsistent programs.

Reconsidering Example 2, it is easy to verify that P_1 has three extended answer sets, i.e. $M_1 = \{\neg a, b\}$, $M_2 = \{a, \neg b\}$ and $M_3 = \{\neg a, \neg b\}$. Note that e.g. $P_{M_1} = P_1 \setminus \{\neg b \leftarrow\}$, i.e. $\neg b \leftarrow$ is defeated w.r.t. M_1 .

While Definition 3 allows P_M , with M an extended answer set, to be a strict subset of P , it still maximizes the set of satisfied rules w.r.t. an extended answer set.

Theorem 1 Let P be a SLP and let M be an extended answer set for P . Then P_M is maximal w.r.t. set inclusion among the reducts of founded interpretations of P .

The reverse of the above theorem does not hold in general, as witnessed by the following example.

Example 3 Consider the program P_2 containing the following rules.

$$\neg a \leftarrow \quad b \leftarrow \quad \neg b \leftarrow \neg a$$

The interpretation $N = \{b\}$ is founded with $P_{2N} = \{b \leftarrow, \neg b \leftarrow \neg a\}$ which is clearly maximal since P_2^* is inconsistent. Still, N is not an extended answer set because $\neg a \leftarrow$ is not defeated.

The extended answer set semantics is universal.

Theorem 2 Every SLP has extended answer sets.

Moreover, the extended answer sets can be efficiently computed using an immediate consequence operator:

$$T_P^e(S) = \begin{cases} S \cup \{l\} & \text{if } r : l \leftarrow \alpha \in P \text{ and } \alpha \subseteq S \text{ and } \neg l \notin S, \\ S & \text{otherwise.} \end{cases}$$

Clearly, the above operator is non-deterministic as the result depends on the order in which rules are applied. However, it can be shown that $T_P^e(\emptyset)$ always results in an extended answer set of P . The non-deterministic behavior of T_P^e greatly influences the complexity of its implementation. In the worst case an algorithm for T_P^e will run in time quadratic⁹ in the size of the program, but on average, depending on the order in which rules get applied, the running time will be much better¹⁰.

Finally, note that the above implies that an implementation that uses T_P^e does not need a fully grounded version of the input program but may instead operate on a “ground (a rule) as needed” basis, as illustrated by the following example.

⁹ Note that, by a well-known result [6], grounding of the program may add an exponential (worst-case) factor to the total cost of computing an extended answer set for an ungrounded program. However, if the arities of the predicates are bounded by a small number, [8] shows that this exponential factor reduces to one level of the polynomial hierarchy.

¹⁰ Also in the non-grounded case the average complexity will be much better than the exponential worst-case scenario as, depending on the sequence in which rules get applied, certain parts of the program need not to be (fully) grounded.

Example 4 Consider the following non-grounded program.

$$\begin{array}{ll} p(a) \leftarrow & q(a) \leftarrow \\ p(b) \leftarrow & q(b) \leftarrow \\ \neg q(X) \leftarrow p(X) & \neg p(X) \leftarrow q(X) \end{array}$$

A possible computation of $T_P^{e\infty}(\emptyset)$ could result in the extended answer set $\{p(a), p(b), \neg q(a), \neg q(b)\}$, e.g. by starting the computation with applying the fact rule $p(a) \leftarrow$, i.e. $T_P^e(\emptyset) = \{p(a)\}$. As a consequence, we can make a ground instantiation $\neg q(a) \leftarrow p(a)$ of the rule $\neg q(X) \leftarrow p(X)$, which an implementation can choose to apply in computing $T_P^e(\{p(a)\}) = \{p(a), \neg q(a)\}$. If we now do a similar reasoning for the fact $p(b) \leftarrow$ to obtain $T_P^e(\{p(a), \neg q(a)\}) = \{p(a), \neg q(a), p(b)\}$ and $T_P^e(\{p(a), \neg q(a), p(b)\}) = T_P^{e\infty}(\emptyset) = \{p(a), p(b), \neg q(a), \neg q(b)\}$, it is easy to see that an implementation does not need any grounded version of the rule $\neg p(X) \leftarrow q(X)$, while classical implementations that first ground everything will obtain two grounded versions $\neg p(a) \leftarrow q(a)$ and $\neg p(b) \leftarrow q(b)$.

Note that we do not conjecture that our approach is better in the worst-case scenario. We only argue that by interleaving the grounding and computation process, one can get better results, both in time and space, in the average case.

3 Approximation Constraints

Because of Theorem 2, checking whether a SLP has an extended answer set can be done in constant time, and thus the semantics is not very expressive when compared to e.g. classical answer set semantics (for which the problem is \mathcal{NP} -complete). In this section, we increase the expressiveness by allowing for constraints to appear in programs.

Intuitively, an *approximation constraint* is like a traditional constraint, i.e. a condition that a solution of a program should satisfy. However, approximation constraints may be left unsatisfied, e.g. due to lack of computation time. This induces a partial order on such “approximate” solutions, where better approximations satisfy more constraints. Combined with the results from Section 2, it then becomes possible to devise an incremental extended answer set solver that combines both the grounding process and the computation, i.e. a “ground when needed” computation¹¹.

Definition 4 A simple approximation logic program (SALP) is a tuple (P, C) , where P is a SLP and C is a set of **approximation constraints**, i.e. rules of the form $\leftarrow \alpha$, with α a finite set of literals¹².

For an interpretation I of P , an approximation constraint $c \in C$ is said to be **satisfied**, denoted $I \models c$, if $\alpha \not\subseteq I$; otherwise it is said to be **violated**, denoted $I \not\models c$. We use I_v^C to denote the set of approximation constraints in C that are violated w.r.t. I , i.e. $I_v^C = \{c \in C \mid I \not\models c\}$.

Extended answer sets of P are **approximate extended answer sets** of (P, C) . An approximate extended answer set S of (P, C) is an **extended answer set** of (P, C) iff $S_v^C = \emptyset$, i.e. all approximation constraints are satisfied w.r.t. S .

In the rest of this paper, we will use $\mathcal{E}\mathcal{S}_n(P, C)$, with $0 \leq n \leq |C|$, to denote the set containing the approximate extended answer

sets of (P, C) that violate less than $n + 1$ approximation constraints in C , i.e. $\mathcal{E}\mathcal{S}_n(P, C) = \{S \in \mathcal{E}\mathcal{S}(P) \mid |S_v^C| \leq n\}$. Clearly, we have that $\mathcal{E}\mathcal{S}_0(P, C)$ corresponds to the extended answer sets of (P, C) ; and $\mathcal{E}\mathcal{S}_0(P, C) \subseteq \mathcal{E}\mathcal{S}_1(P, C) \subseteq \dots \subseteq \mathcal{E}\mathcal{S}_{|C|}(P, C) = \mathcal{E}\mathcal{S}(P)$.

Example 5 Consider the following SALP (P, C) with P

$$\begin{array}{lll} \neg a \leftarrow & \neg b \leftarrow & \neg c \leftarrow \\ b \leftarrow \neg a & a \leftarrow \neg b & c \leftarrow a \end{array}$$

and the following approximation constraints C

$$\leftarrow \neg a, \neg b \quad \leftarrow a \quad \leftarrow c$$

We have four extended answer sets for P , i.e. $\mathcal{E}\mathcal{S}(P) = \{S_1, S_2, S_3, S_4\}$, with $S_1 = \{\neg a, \neg b, \neg c\}$, $S_2 = \{\neg a, b, \neg c\}$, $S_3 = \{a, \neg b, \neg c\}$ and $S_4 = \{a, \neg b, c\}$. One can verify that $\mathcal{E}\mathcal{S}_2(P, Q) = \{S_1, S_2, S_3, S_4\}$, $\mathcal{E}\mathcal{S}_1(P, C) = \{S_1, S_2, S_3\}$ and $\mathcal{E}\mathcal{S}_0(P, C) = \{S_2\}$. Thus S_2 is the only extended answer set of the above SALP (P, C) .

In general, we may consider a partial order \preceq on extended answer set approximations which is such that better approximations are smaller. i.e. $S_1 \prec S_2$ ¹³ iff S_1 is a better approximation of an extended answer set than is S_2 . It seems reasonable to demand that any such preference order satisfies $S_1 \preceq S_2 \Rightarrow |S_1^C| \leq |S_2^C|$, i.e. better approximations satisfy more approximation constraints; and that “full” extended answer sets correspond to \prec -minimal approximations.

Two obvious (others are possible) candidates that satisfy this requirement are:

- cardinality, i.e. $S_1 \preceq S_2$ iff $|S_1^C| \leq |S_2^C|$; and
- subset, i.e. $S_1 \preceq S_2$ iff $S_1^C \subseteq S_2^C$

which are also used in other problem areas, such as diagnostic systems [13], that deal with preference on candidate solutions.

Note that, if $\mathcal{E}\mathcal{S}_0(P, C) = \emptyset$, i.e. there are no extended answer sets, and depending on the preference relation used, a \prec -minimal approximate extended answer set S may be useful, e.g. to provide insight, via the set of violated constraints S_v^C , about possible problems with the program. In this way a semantical debugging scheme for (extended) answer set programming can be defined, a concept which has already been explored in the context of prolog [3, 7, 12], but still needs better exploration in the former setting.

The following result sheds some light on the complexity of reasoning with approximation constraints. As $\mathcal{E}\mathcal{S}_{|C|}(P, C) = \mathcal{E}\mathcal{S}(P)$, we will only consider the cases $\mathcal{E}\mathcal{S}_i(P, C)$ with $0 \leq i < |C|$ (note that this implies that $|C| \geq 1$).

Theorem 3 Let (P, C) be a grounded SALP and take i such that $0 \leq i < |C|$. Deciding whether there exists an approximate extended answer set $S \in \mathcal{E}\mathcal{S}_i(P, C)$ is \mathcal{NP} -complete.

Again an exponential factor [6] or, in case of small bounded predicate arities, an additional level of the polynomial hierarchy [8] has to be added in the case of non-ground SALPs, i.e. either NEXPTIME-complete or Σ_2^P -complete respectively.

The above theorem implies that the semantics already gets its full computational complexity with a single constraint, which is not a surprise as we can replace each constraint $\leftarrow \alpha \in C$ with a rule $\text{inconsistent} \leftarrow \alpha$ in P and take $C = \{\leftarrow \text{inconsistent}\}$. However, the above complexity result is a worst-case scenario (just as

¹¹ Note that current answer set solvers lack this support for “ground when needed” (see Section 4) and compute first the complete grounding, instead.

¹² Note that we allow non-ground constraints. However, grounding a SALP can be done by computing $gr(P \cup C)$ and splitting up the result in two sets, i.e. the ground rules and the ground constraints. Again, we assume grounded SALPs in the rest of the paper.

¹³ As usual, $S_1 \prec S_2$ iff $S_1 \preceq S_2$ and not $S_2 \preceq S_1$.

with grounding), i.e. in an implementation we may expect, in the average case, that more constraints require more computation time.

Finally, the framework developed above can be used to implement an incremental extended answer set solver, i.e. a solver that produces an approximate solution and then, as long as resources permit, produces successively better approximations. Given enough resources, this approach will eventually result in an extended answer set, i.e. an approximation that satisfies all constraints.

Intuitively, such an implementation will start by computing an extended answer set S along the lines of the immediate consequence operator presented in Section 2. Afterwards, a backtracking algorithm will try to improve the approximation by selecting a constraint to satisfy, while maintaining the partial ordering defined on approximations.

4 Classical Answer Set Approximation

Theorem 3 indicates that the semantics presented in Section 3 is computationally equivalent to the classical answer set semantics [9] for non-disjunctive programs containing negation as failure in the body of rules. Here we show how the classical answer set semantics can be effectively translated to approximate extended answer sets, thus making it possible to compute classical answer sets via successive approximations.

We briefly introduce the answer set semantics for semi-negative programs. Such programs are build using atoms and naf-atoms, i.e. for an atom a , we use $\text{not } a$ to denote its negation-as-failure (naf) version, which intuitively means that $\text{not } a$ is true when a is not true. A semi-negative logic program P is a countable set of rules of the form $a \leftarrow \beta$ where a is an atom and β is a finite set of (naf-)atoms. An interpretation I for a semi-negative program P is a subset $I \subseteq \mathcal{B}_P$. An atom a is satisfied w.r.t. I , denoted $I \models a$ if $a \in I$; while a naf-atom $\text{not } a$ is satisfied w.r.t. I , i.e. $I \models \text{not } a$, when $I \not\models a$. The answer set semantics for semi-negative programs is defined in two steps.

First, consider programs without naf-atoms. For such a naf-free program P , an interpretation I is an answer set iff $P^* = I$. Next, for semi-negative programs, we use the Gelfond-Lifschitz transformation [9]. The idea behind this transformation is, for a given program P and a candidate solution S , to remove all naf constructs w.r.t. S and then check if the candidate solution is supported by the reduct program. Formally, for a semi-negative program P and a candidate solution S , the GL-reduct of P w.r.t. S , denoted P^S , is obtained from P by (a) removing each rule $a \leftarrow \beta$ with $\text{not } b \in \beta$ and $b \in S$, and (b) remove all naf-atoms from the remaining rules. Clearly, the program P^S is free from negation as failure. An interpretation S is an answer set of a semi-negative program P iff S is an answer set of P^S , i.e. $P^{S^*} = S$. We use $\mathcal{AS}(P)$ to denote the set containing all answer sets of P .

Example 6 Consider the following semi-negative program.

$$\begin{array}{ll} a \leftarrow \text{not } b & b \leftarrow \text{not } a \\ c \leftarrow a & d \leftarrow b \end{array}$$

Intuitively, the above program represents an exclusive choice between a or b and depending on this choice, the program derives an additional atom c or d resp. Indeed, one can verify that the above program has two answer sets, i.e. $S_1 = \{a, c\}$ and $S_2 = \{b, d\}$. E.g., the reduct P^{S_1} contains the rules $\{a \leftarrow \text{not } c \leftarrow a \quad d \leftarrow b\}$, for which $P^{S_1*} = \{a, c\} = S_1$.

We construct, for a semi-negative logic program P , a SALP $L(P) = (Q, C)$ such that the extended answer sets of $L(P)$, i.e. elements of $\mathcal{ES}_0(Q, C)$, are in one-to-one correspondence with the answer sets of P .

In the following definition we use α' to denote the set of literals obtained from a set α where each naf-atom $\text{not } a$ from α is replaced by $\neg a$. The notation is further extended to rules and programs.

Definition 5 Let P be a semi-negative program. The SALP $L(P) = (Q, C)$ is defined by $Q = P' \cup \{\neg a \leftarrow \text{not } a \mid a \in \mathcal{B}_P\}$ and $C = \{\leftarrow \beta', \neg a \mid a \leftarrow \beta \in P\}$.

Intuitively, we simulate negation as failure in two steps. First, we introduce negation as failure explicitly in Q using classical negation by introducing a fact $\neg a$ for each atom $a \in \mathcal{B}_P$. Secondly, we assert approximation constraints in C to enforce the satisfaction of the original rules in the program P : a rule $a \leftarrow \beta' \in Q$ (i.e. $a \leftarrow \beta \in P$) is only satisfied by an interpretation iff the approximation constraint $\leftarrow \beta', \neg a \in C$ is satisfied w.r.t. that interpretation.

Example 7 Reconsider the program from Example 6. Its SALP version $L(P) = (Q, C)$ is defined by the SLP Q

$$\begin{array}{llll} \neg a \leftarrow & \neg b \leftarrow & \neg c \leftarrow & \neg d \leftarrow \\ a \leftarrow \neg b & b \leftarrow \neg a & c \leftarrow a & d \leftarrow b \end{array}$$

and the set of constraints C

$$\begin{array}{llll} \leftarrow \neg b, \neg a & \leftarrow \neg a, \neg b & \leftarrow a, \neg c & \leftarrow b, \neg d \end{array}$$

Consider the following extended answer sets of Q , i.e. $S'_1 = \{a, \neg b, c, \neg d\}$, $S'_2 = \{\neg a, b, \neg c, \neg d\}$ and $S'_3 = \{a, \neg b, \neg c, \neg d\}$. One can check that $\mathcal{ES}_0(Q, C) = \{S'_1, S'_2\}$ and clearly $S_1 = S'_1 \cap \mathcal{B}_P$ and $S_2 = S'_2 \cap \mathcal{B}_P$. On the other hand, $S'_3 \in \mathcal{ES}_1(Q, C)$, as $c \leftarrow a \in C$ is violated. However, one can easily see that $S_3 = S'_3 \cap \mathcal{B}_P$ is an answer set of the program $P \setminus \{c \leftarrow a\}$.

The behavior outlined in the previous example is confirmed in general by the following theorem.

Theorem 4 Let P be a semi-negative logic program and consider $L(P) = (Q, C)$ as defined in Definition 5. Then, for $S \subseteq \mathcal{B}_P$,

$$S \cup \{\neg l \mid l \in \mathcal{B}_P \setminus S\} \in \mathcal{ES}_0(Q, C) \iff S \in \mathcal{AS}(P)$$

i.e. the answer sets of P are in one-to-one correspondence with the extended answer sets of $L(P)$.

Further, for i , with $0 < i \leq |C|$, we have, with

$S \cup \{\neg l \mid l \in \mathcal{B}_P \setminus S\} \in (\mathcal{ES}_i(Q, C) \setminus \mathcal{ES}_{i-1}(Q, C)) \iff S \in \mathcal{AS}(P \setminus S_v^C)$, where, abusing notation, $P \setminus S_v^C$ denotes the subset of rules in P for which the corresponding approximation constraint in C is satisfied w.r.t. S .

The above result shows that the approximation framework for extended answer sets is able to handle the classical answer set semantics in the sense that, each time a better approximation for $L(P)$ is computed, it is also an answer set for a larger subset of the program P . Interestingly, the algorithm does not rely on negation as failure, but uses only classical negation and the ability to leave rules unsatisfied, i.e. defeated.

Finally, the above results may help to resolve another issue regarding current answer set solvers such as DLV [11] and SMODELS [14]. Indeed, these solvers require that a program first be completely grounded before the actual answer set computation starts. With approximations based on extended answer sets, this is probably not necessary, since the computation of an extended answer set may operate on a “ground (a rule) as needed” basis (Section 2).

5 Related Work

The idea of an approximation theory in logic and logic programming is not new. A good example of this is the “anytime” family of reasoners for propositional logic [4]. Intuitively, such a system consists of a sequence $\vdash_0, \vdash_1, \dots, \vdash_c$ of inference relations such that each \vdash_i is at least as good¹⁴ as \vdash_{i-1} and there exists a complete inference relation \vdash_c for the problem. Using such an anytime reasoner, one starts the computation with the inference relation \vdash_0 and as long as there is computation time left, the inference relations $\vdash_1, \vdash_2, \dots$ are applied to obtain better approximations. When the complete reasoner \vdash_c is reached during the computation, one had enough resources available to compute a completely correct solution.

This idea is e.g. applied in [5] to obtain an anytime reasoner for Boolean Constraint Propagation, which is used in [18] to obtain an approximation theory for diagnostic reasoning.

In [1] a first attempt is made to devise a framework for interactive answer set programming. The idea is to find which part of a program needs to be recomputed in order to find a new answer set in case a single rule is added to the program. Using this framework, one can obtain a similar approximative version of answer set programming as the one presented in Section 4 by starting the computation with a single rule and then subsequently adding new rules. However, the framework presented in this paper is more suitable in the sense that we can start the computation with the whole program, not just a single rule, and obtain a first approximation that in the average case will satisfy more than one rule in the program under consideration.

Weak constraints were introduced in [2] as a relaxation of the concept of a constraint. Intuitively, a weak constraint is allowed to be violated, but only as a last resort, meaning that one tries to minimize the set of violated constraints (e.g. using either subset minimality or cardinality minimality). The main difference of this approach with ours, is that we use approximation constraints to find better approximations, as long as we have resources available, of a final solution that satisfies all approximation constraints (and which will be reached if we have enough time); while the weak constraints in [2] serve to differentiate between the answer sets of the program without weak constraints, by posing additional conditions on those answer sets that do not necessarily have to be satisfied. Also note that the weak constraints from [2] have a much higher complexity than the framework presented in this paper, i.e. Δ_2^P for non-disjunctive programs, or the second level of the polynomial hierarchy.

6 Conclusions and Directions for Further Research

We presented a first attempt at an approximation theory, by means of approximation constraints, for the extended answer set semantics of programs containing only classical negation. Further, we showed how classical answer sets can be approximated using the proposed framework.

In future work, we will implement an approximate extended answer set solver that “grounds when needed”. In our implementation, we will try to incorporate some of the ideas developed in the Platypus system [10], i.e. a system to compute answer sets in a distributed environment, to obtain an implementation that can be used in a distributed setting. One topic for further research in this context is e.g. how on the fly rule instantiations (which result from the “ground when needed” process) have to be propagated to the other participants in the distributed computation process.

Furthermore, we also plan to look into the related problems of profiling (finding out which parts of a program are hard to compute) and debugging (finding out which parts of a program are wrong) for (extended) answer set programming. Finally, the present approach could be generalized to support user-defined preference relations (“hints”) on approximation constraints which could be used to influence the approximation process.

An Axiomatic Approach to Qualitative Decision Theory with Binary Possibilistic Utility

Paul Weng¹

Abstract. Binary possibilistic utility unifies two previously proposed qualitative decision models: optimistic and pessimistic utilities. All these decision models have been axiomatized in a von Neumann-Morgenstern setting. These axiomatizations have shown the formal similarity of these qualitative utilities and expected utility. Unfortunately in this framework, the representation of uncertainty has to be clearly assumed to be given. In a more general setting, without this restriction, optimistic and pessimistic utilities have been axiomatized à la Savage. This paper proposes a study of the axioms of binary possibilistic utility in a Savagean framework.

1 INTRODUCTION

Decision making under uncertainty is an important topic in AI research, whether in the process of building autonomous agents or in modeling the behavior of other agents (human or not) in the course of a multi-agent interaction, since any artificial agent can be viewed as an automated decision maker [21]. Decision theory has been first studied in economics, which explains why quantitative decision models are the most common ones and have been the most investigated. Among those is the classic model of expected utility (EU). The axiomatic works of von Neumann and Morgenstern (vNM) [26] and Savage [22] highlighted the properties of this criterion and described the situations where it should be employed. This model is known to make some strong hypotheses: uncertainty has to be represented by probability and a numeric value (utility) is assigned to each consequence of an action. These assumptions are not suitable to all kinds of problems. Indeed, in the situations where data are imprecise and/or scarce, the use of probability is sometimes debatable. Even when probability is appropriate, the assessment of the parameters of the model (probabilities and utilities) is a difficult and information demanding task.

For these reasons, it is of interest to study other decision models. In the situations where probability is not suitable, many alternatives have been proposed: theory of evidence [24], possibility theory [8], kappa rankings [25] or plausibility measures [13]. In each of these frameworks, decision models have been proposed [18, 9, 14, 4].

In AI, with its long standing tradition of symbolic problem modeling and solving, qualitative decision models ([2], [3], [19],...) have received much attention. They are very appealing as they are not information demanding (only qualitative information is required) and lead to faster computations. In this paper, we restrict ourself to qualitative decision models based on possibility theory and more specifically to binary possibilistic utility (PU) that was introduced by Giang and Shenoy [15]. This qualitative model has many interesting properties. It unifies two previously proposed qualitative utilities: optimistic

and pessimistic utilities [9, 6] and can model decision behavior that neither optimistic nor pessimistic utilities can model. Moreover it is dynamically consistent and therefore can be applied in sequential decision making, especially in Markov Decision Processes [20]. Finally it can be considered the qualitative counterpart of EU. Indeed, Weng [27] has shown that a same set of axioms (complete preorder, independence, continuity and non triviality) leads to either EU or PU depending on whether uncertainty is represented by respectively a probability or a possibility distribution.

Axiomatizing a decision criterion is essential as it reveals its properties and its limits. The axiomatization of EU highlighted its restrictions [1, 12]. Such work has to be done in the qualitative setting, which encompasses logic-formalized decision problems [9]. Axiomatization can be lead in two different frameworks: in a vNM setting where the nature of uncertainty is assumed to be given here of possibilistic nature or in a Savagean setting where no such prior assumption is made. The axiomatic studies of this criterion have all been lead in a vNM framework [15, 16]. Dubois et al. [10] axiomatized optimistic and pessimistic utilities in a Savagean context. These works give new insights about the two qualitative utilities in a very general framework. Following their works, we propose here to give a Savagean axiomatization of PU. Interestingly, such works allow the nature of uncertainty as perceived by the decision maker to be revealed: possibility for optimistic utility, necessity for pessimistic utility and as shown in this paper a pair consisting of possibility and necessity for PU. Consequently, this gives some justifications for the use of non probabilistic uncertainty representation.

This paper is organized as follows. In Section 2, we recall all the necessary notions for the presentation of our results. Due to lack of space, we do not present the Savagean axiomatics for EU and its comparison with that of qualitative utilities. We refer the interested reader to [10]. Then, in Section 3, we present some properties of PU for a better understanding of this decision model. In Section 4, we present our axiomatization. Finally we conclude in Section 5.

2 POSSIBILISTIC UTILITIES

2.1 Some Definitions and Notations

In decision under uncertainty, a decision maker has to choose an action, named act, whose consequence is not known precisely. The decision problem can be described by the following elements:

- S a finite set of states.
- $X = \{x_1, \dots, x_n\}$ a finite set of consequences. Elements 0_X and 1_X denote respectively the worst and the best consequences.
- \mathcal{F} a finite set of acts, i.e. functions from the set of states to the set of consequences ($\mathcal{F} = X^S$).

¹ LIP6, France, email: paul.weng@lip6.fr

A state (or state of nature) describes a possible configuration of the environment. The decision maker has to choose an act, which is a function from the set of states to the set of consequences. The decision maker's preference relation (which is simply a binary relation) over acts is denoted by $\succsim_{\mathcal{F}}$, which reads "at least as good as".

Uncertainty follows from the fact that the decision maker does not know precisely in which state he is. Uncertainty is then defined as uncertainty about the actual state of nature. Events are simply sets of states. The set of all events is denoted 2^S . For two events A and B , $A \succsim_S B$ means that A is judged at least as plausible than B by the decision maker. The complement of an event $A \in 2^S$ is denoted \overline{A} .

For two acts f and g , an event A , fAg denotes the act consisting in doing f if event A and doing g otherwise, i.e. $\forall s \in A, fAg(s) = f(s)$ and $\forall s \in \overline{A}, fAg(s) = g(s)$. The constant act equal to $x \in X$ everywhere is denoted \mathbf{x} . Relation $\succsim_{\mathcal{F}}$ restricted to constant acts induces a preference relation over consequences, denoted \succsim_X .

For any relation \succsim , \succ and \sim denote respectively the asymmetric and the symmetric part of \succsim .

A finite qualitative scale L on which consequences and uncertainty can be measured is defined. Its lowest and its greatest elements are written respectively by 0_L and 1_L . The order on L is denoted by \geq_L . Operators max and min on scale L are respectively written \vee and \wedge . The order reversing involution in L is denoted by n , i.e. $n(0_L) = 1_L, n(1_L) = 0_L$ and $\forall \lambda, \lambda' \in L, \lambda \geq_L \lambda' \Rightarrow n(\lambda) \leq_L n(\lambda')$. By abuse of notation, in the paper, n will denote any such one-to-one mapping that reverses a preordered scale.

A *basic utility assignment* is a mapping that associates a value in a scale to each consequence in X . A *capacity* $\sigma : 2^S \rightarrow L$ is a very general measure of uncertainty that satisfies:

- $\sigma(\emptyset) = 0_L$
- $\sigma(S) = 1_L$
- $\forall A, B \in 2^S, A \subseteq B \Rightarrow \sigma(A) \leq_L \sigma(B)$

As examples, probability, possibility, belief functions, kappa rankings and plausibility measures are all capacities. We recall the definitions of a possibility distribution. A capacity is a possibility distribution (denoted π) iff it additionally satisfies $\forall A \in 2^S, \pi(A) = \bigvee_{s \in A} \pi(s)$. Distribution π can be viewed as an encoding of the ranking of the states in terms of plausibility. It can be interpreted as follows: $\pi(s) = 0_L$ means that state s is impossible, $\pi(s) = 1_L$ means that s is totally possible, when $0_L <_L \pi(s) <_L 1_L$, s is only possible to some extent, i.e. there are states more possible than s . We assume that there exists at least one state of possibility 1_L and of course, there could be several ones.

We introduce a few axioms on the preorder over events.

A1 Relation \succsim_S over 2^S is a total preorder

A2 $S \succsim_S \emptyset$

A3 $\forall A \in 2^S, A \succsim_S \emptyset$

These axioms corresponds to the properties of a capacity. The following theorem can then be stated [11]:

Theorem 1. If \succsim_S , a preorder over states, satisfies axioms **A1**, **A2** and **A3** then it exists a finite qualitative scale (L, \geq_L) and a capacity $\sigma : 2^S \rightarrow L$ such that $A \succsim_S B \Leftrightarrow \sigma(A) \geq_L \sigma(B)$.

Adding the following axiom, the capacity becomes a possibility distribution [5].

POS $\forall A, B, C \in 2^S, A \succsim_S B \Rightarrow A \cup C \succsim_S B \cup C$.

Dually the following axiom characterizes a necessity distribution.

NES $\forall A, B, C \in 2^S, A \succsim_S B \Rightarrow A \cap C \succsim_S B \cap C$.

2.2 Sugeno Integral

Before introducing the qualitative utilities, we present the Sugeno integral, which is a very general decision criterion. It can be seen as the qualitative counterpart of Choquet expected utility (CEU) [17, 23]. Here, the basic utility assignment is written $\mu : X \rightarrow L$.

The utility of an act defined as a Sugeno integral is defined:

$$U_S(f) = \bigvee_{x \in X} (\mu(x) \wedge \sigma(F_x)) \quad (1)$$

where $F_x = \{s \in S : f(s) \succsim_X x\}$.

To understand this formula, Dubois and Prade [7] showed that $U_S(f)$ is the median of the utilities and uncertainty values in the following set: $\{\mu(x) : x \in X\} \cup \{\sigma(F_x) : x \in X, x \succsim_X 0_X\}$. This highlights the similarity with the quantitative models (CEU or EU), which computes a weighted average.

The axioms used for the axiomatization of Sugeno integrals are:

Sav1 Preference relation $\succsim_{\mathcal{F}}$ over \mathcal{F} is a total preorder.

WS3 $\forall x, y \in X, x \succsim_{\mathcal{F}} y \Rightarrow \forall A \in 2^S, \forall h \in \mathcal{F}, xAh \succsim_{\mathcal{F}} yAh$

Sav5 $\exists x, x' \in X, x \succsim_{\mathcal{F}} x'$

RCD $\forall f, g \in \mathcal{F}, \forall x \in X, g \succsim_{\mathcal{F}} f$ and $x \succsim_{\mathcal{F}} f \Rightarrow g \wedge x \succsim_{\mathcal{F}} f$

RDD $\forall f, g \in \mathcal{F}, \forall x \in X, f \succsim_{\mathcal{F}} g$ and $f \succsim_{\mathcal{F}} x \Rightarrow f \succsim_{\mathcal{F}} g \vee x$

Axiom **Sav1** states that any two acts can be compared and the preference relation is transitive. Axiom **WS3** declares that when there is a preference between two consequences, this preference can not reverse if considering two acts giving these consequences on a certain event and the same consequences on the complementary event. Axiom **Sav5** is enforced in order to avoid triviality. Axiom **RCD** states that lowering the consequences of an act f , which is preferred to an act g , to a constant consequence that is also preferred to g still yields a better act than g . Finally axiom **RDD** is the dual of **RCD**. It says that an act f is preferred to an act g even if the worst consequences of g are improved to a constant consequence that is less preferred than f . By way of information, EU verifies neither **RCD** nor **RDD** [10].

Sugeno integrals [10] are characterized by:

Theorem 2. If $\succsim_{\mathcal{F}}$, a preorder over \mathcal{F} , satisfies **Sav1**, **WS3**, **Sav5**, **RCD** and **RDD** then there is a finite qualitative scale (L, \geq_L) , a basic utility assignment $\mu : X \rightarrow L$ and a capacity $\sigma : 2^S \rightarrow L$ such that $f \succsim_{\mathcal{F}} f' \Leftrightarrow U_S(f) \geq_L U_S(f')$.

2.3 Optimistic and Pessimistic Utilities

We now present optimistic and pessimistic utilities, axiomatized in a von Neumann-Morgenstern [6] and a Savagean [10] settings. In this framework, the basic utility assignment is denoted $v : X \rightarrow L$.

Then optimistic and pessimistic utilities are functions from \mathcal{F} to L . Optimistic utility writes:

$$U^+(f) = \bigvee_{s \in S} (\pi(s) \wedge v(f(s))) \quad (2)$$

and pessimistic utility writes:

$$U^-(f) = \bigwedge_{s \in S} (n(\pi(s)) \vee v(f(s))) \quad (3)$$

Optimistic utility is a Sugeno integral with the capacity taken as a possibility distribution. It is a generalization of the maximax criterion axiomatized by Brafman and Tennenholz [3]. And pessimistic utility is a Sugeno integral when the capacity is a necessity distribution. It is a generalization of the maximin criterion [3].

To enforce this utility, axiom **RDD** needs to be replaced by a stronger axiom:

$$\text{OPT } \forall f, g \in \mathcal{F}, \forall A \in 2^S, f \succ_{\mathcal{F}} f A g \Rightarrow g A f \sim_{\mathcal{F}} f$$

This axiom says that if in a certain event, changing the consequences of an act yields a strictly less preferred one then in the complementary event, changing its consequences cannot yield a strictly less preferred act. It reveals a particular property of optimistic utility. If an act can be strictly downgraded in a certain event, this event is judged plausible enough to attract all the attention of the decision maker and what happens on the complementary event is not relevant.

The representation theorem for the optimistic utility [10] states:

Theorem 3. *If $\sim_{\mathcal{F}}$, a preorder over \mathcal{F} , satisfies **Sav1**, **WS3**, **Sav5**, **RCD** and **OPT** then there is a finite qualitative scale (L, \geq_L) , a basic utility assignment $v : X \rightarrow L$ and a possibility distribution $\pi : 2^S \rightarrow L$ such that $f \sim_{\mathcal{F}} f' \Leftrightarrow U^+(f) \geq_L U^+(f')$.*

For the pessimistic utility, axiom **RCD** is to be replaced by:

$$\text{PES } \forall f, g \in \mathcal{F}, \forall A \in 2^S, f A g \succ_{\mathcal{F}} f \Rightarrow f \sim_{\mathcal{F}} g A f$$

This axiom, which is the dual of **OPT** states that if an act is strictly improved in a certain event then it can not be strictly improved in the complementary event.

And the pessimistic utility [10] is characterized by:

Theorem 4. *If $\sim_{\mathcal{F}}$, a preorder over \mathcal{F} , satisfies **Sav1**, **WS3**, **Sav5**, **RDD** and **PES** then there is a finite qualitative scale (L, \geq_L) , a basic utility assignment $v : X \rightarrow L$ and a possibility distribution $\pi : 2^S \rightarrow L$ such that $f \sim_{\mathcal{F}} f' \Leftrightarrow U^-(f) \geq_L U^-(f')$.*

2.4 Binary Possibilistic Utility

Binary possibilistic utility (PU) introduced by Giang and Shenoy [15] unifies the two previous qualitative decision models. It takes values in a particular scale L_2 , which is a binary scale defined by the following set of pairs:

$$L_2 = \{(\lambda, \mu) : \lambda, \mu \in L, \lambda \vee \mu = 1_L\}.$$

Due to constraint $\lambda \vee \mu = 1_L$, scale L_2 is in fact monodimensional (see fig. 1). A pair in L_2 can be interpreted as a binary possibility

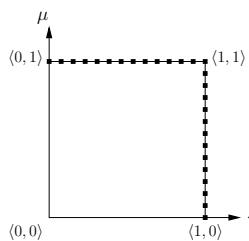

Figure 1. Binary utility scale L_2 .

distribution over two consequences : the best and the worst ones. The first element of the pair would be the possibility to get the best consequence and the second would be the possibility to get the worst consequence. Then a natural order relation² can be defined on L_2 :

$$(\lambda, \mu) \geq_{L_2} (\lambda', \mu') \iff (\lambda \geq_L \lambda' \text{ and } \mu \leq_L \mu').$$

² This order is expressed in a simpler form than in [15, 16]. It can be easily checked that the two forms are equivalent.

Indeed, the decision maker naturally prefers the highest possibility of getting the best outcome and the lowest possibility of getting the worst one.

Here, the basic utility assignment is denoted $u : X \rightarrow L_2$. Remark that it takes values in the binary scale. Uncertainty represented by a possibility distribution is still measured on L .

Operator \vee is extended as an operator on $L_2 \times L_2$ as follows:

$$\langle \lambda, \mu \rangle \vee \langle \lambda', \mu' \rangle = \langle \lambda \vee \lambda', \mu \vee \mu' \rangle.$$

Remark that this operator is not operator max on L_2 , which would be computed as $\max(\langle \lambda, \mu \rangle, \langle \lambda', \mu' \rangle) = \langle \lambda \vee \lambda', \mu \wedge \mu' \rangle$.

Operator \wedge is extended as an operator on $L \times L_2$:

$$\lambda' \wedge \langle \lambda, \mu \rangle = \langle \lambda' \wedge \lambda, \lambda' \wedge \mu \rangle.$$

In the same way as operator max, operator min on L_2 is given by $\min(\langle \lambda, \mu \rangle, \langle \lambda', \mu' \rangle) = \langle \lambda \wedge \lambda', \mu \vee \mu' \rangle$.

PU is then defined as a function from \mathcal{F} to L_2 :

$$PU(f) = \bigvee_{s \in S} (\pi(s) \wedge u(f(s))). \quad (4)$$

As noted in [15], when the basic utility has the following restricted form: $\forall x \in X, \exists \lambda \in L, u(x) = \langle \lambda, 1_X \rangle$ then PU is an optimistic utility. Dually when we have $\forall x \in X, \exists \mu \in L, u(x) = \langle 1_X, \mu \rangle$, PU is a pessimistic utility. Finally we remark that compared to PU, optimistic and pessimistic utilities exploit only half of scale L_2 .

3 STUDY OF THE PU MODEL

3.1 Properties of PU

We assume here that no two consequences in X are equivalent. This is not a restrictive condition as if it were not the case, one could work on the equivalence classes of X instead of X . This condition entails that X is a preordered scale. Let $n \circ f$ be the act that is defined by $\forall s \in S, (n \circ f)(s) = n(f(s))$. Then the *dual* of a preference relation $\sim_{\mathcal{F}}$ over \mathcal{F} , denoted $\sim_{\mathcal{F}}^T$, is defined by $f \sim_{\mathcal{F}}^T g \Leftrightarrow n \circ g \sim_{\mathcal{F}} n \circ f$. Obviously the dual of the dual of a preference relation is the relation itself. By extension, we say that a decision model is the dual of another one if the preference relation defined by the former decision model is the dual of the relation defined by the latter. Pessimistic utility is the dual of optimistic utility.

A preference relation is said to be *autodual* if and only if $\sim_{\mathcal{F}}^T = \sim_{\mathcal{F}}$. This means that for two acts f and g , $f \sim_{\mathcal{F}} g \Leftrightarrow n \circ g \sim_{\mathcal{F}} n \circ f$. Again, by extension, a decision model is said to be autodual if the induced preference relation is autodual. Intuitively, it means that the decision model when stating a preference between two acts looks at how well and how bad these two acts do. Any decision model that is not autodual does not use all the information at its disposal since it could be possible to exploit the dual of the decision model to yield a refined criterion. In this sense a rational decision maker would rather use an autodual decision model.

As the first and second part of PU are respectively of the form of an optimistic utility and a pessimistic one, PU induces an autodual preference relation over acts. EU is another example of such an autodual decision model. Once again, similarities between the two criteria can be emphasized.

When the basic utility assignment is valued in L_2 and uncertainty is measured by a possibility distribution, Eqs. 1 and 4 are equivalent.

Proposition 1. $PU(f) = U_S(f)$

Proof. We prove the result recursively on n the number of different consequences of f . Let $f = x_1 A_1 x_2 A_2 \dots x_n A_n$ where $x_1 \succ_X x_2 \succ_X \dots \succ_X x_n$. We want to prove that $PU(f) = U_S(f)$. Assume for $n = 2$ that $f = x A y$ with $x \succ_X y$. Then $PU(f) = \langle (u_1(x) \wedge \pi(A)) \vee (u_1(y) \wedge \pi(\bar{A})), (u_2(x) \wedge \pi(A)) \vee (u_2(y) \wedge \pi(\bar{A})) \rangle$.

$$\begin{aligned} U_S(f) &= \max(\langle u_1(y), u_2(y) \rangle, \\ &\quad \min(\langle u_1(x), u_2(x) \rangle, \langle \pi(A), \pi(\bar{A}) \rangle)) \\ &= \max(\langle u_1(y), u_2(y) \rangle, \langle u_1(x) \wedge \pi(A), u_2(x) \vee \pi(\bar{A}) \rangle) \\ &= \langle u_1(y) \vee (u_1(x) \wedge \pi(A)), u_2(y) \wedge (u_2(x) \vee \pi(\bar{A})) \rangle \\ &= \langle u_1(y) \vee (u_1(x) \wedge \pi(A)), u_2(x) \vee (u_2(y) \wedge \pi(\bar{A})) \rangle \end{aligned}$$

Now if $\pi(A) = 1_L$ then $PU(f) = \langle u_1(x) \vee (u_1(y) \wedge \pi(\bar{A})), u_2(x) \vee (u_2(y) \wedge \pi(\bar{A})) \rangle = \langle u_1(x), u_2(x) \vee (u_2(y) \wedge \pi(\bar{A})) \rangle$ and $U_S(f) = \langle u_1(y) \vee u_1(x), u_2(x) \vee (u_2(y) \wedge \pi(\bar{A})) \rangle = PU(f)$. In the same way, we can check that if $\pi(\bar{A}) = 1_L$ then $PU(f) = U_S(f)$. Now assume the property is true for n and prove that it is true for $n + 1$. We have $f = x_1 A_1 x_2 A_2 \dots x_{n+1} A_{n+1}$ where $x_1 \succ_X x_2 \succ_X \dots \succ_X x_{n+1}$. If $\pi(A_1) < 1_L$ apply the recursion assumption on $g = x_2 A_2 \dots x_{n+1} A_{n+1}$. Otherwise, apply the recursion assumption on $g = x_1 A_1 \dots x_n A_n \cup A_{n+1}$. We get $PU(g) = U_S(g)$. Then apply the case $n = 2$ to get the result. \square

The previous result is not surprising. Being the unification of optimistic and pessimistic utilities, which are two Sugeno integrals, PU is naturally also a Sugeno integral. Indeed PU satisfies all the required conditions of Theorem 2.

Proposition 2. PU satisfies **Sav1**, **WS3**, **Sav5**, **RCD** and **RDD**.

Consequently, in the PU model, uncertainty is not measured by a possibility distribution, as it could be at first thought, but by the pair of a possibility distribution and its associated necessity distribution. Indeed as noted in Proposition 1, uncertainty is measured by the pair $\langle \pi(A), \pi(\bar{A}) \rangle$. We recall that the necessity distribution that is associated to a possibility distribution is defined by $N(A) = n(\pi(\bar{A}))$.

Before going on with the properties of the underlying uncertainty measure, we introduce the axiom of weak independence. This is a weakening of the axiom of the sure thing principle used by Savage for EU.

$$\textbf{WI} \quad \forall f, g, h, h' \in \mathcal{F} \quad \left\{ \begin{array}{l} f A h \succ_{\mathcal{F}} g A h \\ \forall A \in 2^S \end{array} \right\} f A h' \succ_{\mathcal{F}} g A h'$$

This axiom is crucial in dynamic decision making and ensures that dynamic consistency holds. EU of course fulfills the sure thing principle and **WI**. Axiom **WI** is satisfied by PU guaranteeing that this criterion is dynamically consistent.

3.2 Properties of the Underlying Uncertainty Measure in PU

The properties of duality and autoduality can be also stated on the preorder over events. The *dual* of \succ_S is the relation \succ_S^T defined by $\forall A, B \in 2^S, A \succ_S^T B$ iff $\bar{B} \succ_S \bar{A}$. Preorder \succ_S is said to be *autodual* iff for two events A and B , $A \succ_S B \Leftrightarrow \bar{B} \succ_S \bar{A}$. This means that when A is more plausible than B , the complement of B is more plausible than that of A . Duality and autoduality can be naturally extended to uncertainty measures. As previously an uncertainty measure that is not autodual does not use all the information since it could be refined with its dual uncertainty measure. Therefore autodual uncertainty measure should be exploited when possible. A probability distribution is an example of such a measure.

The underlying uncertainty measure σ used in PU is said to be *autodual possibilistic*. It is defined by $\sigma : 2^S \rightarrow L_2, \forall A \in 2^S, \sigma(A) = \langle \pi(A), \pi(\bar{A}) \rangle$, which is obviously an autodual measure.

Some definitions are needed in order to characterize such capacities. For any event D , we write D^{\prec_S} for the set of events: $\{A \in 2^S : A \prec_S D\}$ and D^{\succ_S} for the set of events: $\{A \in 2^S : A \succ_S D\}$. They are respectively the set of events that are less plausible than D and its complement.

Now we introduce two axioms entailing that the capacity is an autodual possibilistic capacity.

AD^S Relation \succ_S over 2^S is autodual.

POS' $\exists D, S \succ_S D \succ_S \emptyset$ such that

$$\forall A, B, C \in D^{\prec_S}, A \succ_S B \Rightarrow A \cup C \succ_S B \cup C$$

Obviously axiom **AD^S** is required if we want an autodual capacity. Axiom **POS'** roughly states that the set of events can be divided into two parts such that on the less plausible side, \succ_S satisfies axiom **POS**. Together axioms **POS'** and **AD^S** give the dual property:

NES' $\exists D, S \succ_S D \succ_S \emptyset$ such that

$$\forall A, B, C \in D^{\succ_S}, A \succ_S B \Rightarrow A \cup C \succ_S B \cup C$$

Axioms **POS'** and **NES'** are of course fulfilled by autodual possibilistic capacities. If there are two states s, s' that have possibility 1_L then event D is such that its uncertainty value equals $\langle 1_L, 1_L \rangle$ (with $s \in D$ and $s' \in \bar{D}$). Otherwise, let s be the state of possibility 1_L and s' the most plausible state after s . Then D is such that $\sigma(D)$ equals $\langle 1_L, \pi(s') \rangle$.

Now autodual possibilistic capacities can be characterized:

Theorem 5. A capacity σ satisfies axioms **POS'** and **AD^S** if and only if it is an autodual possibilistic capacity.

Proof. First take D from axiom **POS'**. In the following, we write s for the set consisting only of state s . Remark that at least one event s is more plausible than \emptyset . Otherwise, if for all state s , $s \sim_S \emptyset$, by **POS'**, set S would be equivalent to \emptyset .

Choose a member in each equivalence class of S . We have $s_1 \succ_S s_2 \succ_S \dots \succ_S s_n$. Now each equivalence class of $2^S \cap D^{\prec_S}$ is equivalent to one of the s_i by **POS'**.

We have $s_1 \succ_S D$. Otherwise, by **POS'**, set S would be less plausible than D . By contradiction, assume that $s_1 \succ_S D$. Then s_1 is not in D by monotony of σ . Applying **AD^S** with **POS'**, we get **NES'**. Then with $A = s_1, B = D, C = D, A \succ_S B$ implies $A \cap C = \emptyset \succ_S D = B \cap C$, which is a contradiction. Then $s_1 \sim_S D$.

A possibility distribution $\pi : D^{\prec_S} \rightarrow L \setminus \{1_L\}$ can be constructed by **POS'**. Define $\sigma : D^{\prec_S} \rightarrow L_2$ by $\forall A \in D^{\prec_S}, \sigma(A) = \langle \pi(A), 1_L \rangle$.

Consider the case where there is another state $s \neq s_1$ such that $s \sim_S s_1$. Let A be an event containing s_1 but not s . By monotony of σ , $s_1 \succ_S A$. By contradiction, assume $s \sim_S s_1 \prec_S A$. Applying **NES'** with $A, B = s, C = s$, we get $s \prec_S A \cap s = \emptyset$, which is a contradiction. Then any event containing some states equivalent to s_1 but not all those states is equivalent to s_1 . Consider the event B containing all those states. The complement of B is the event containing all the states that are less plausible than s_1 . Then by **AD**, $B \succ_S s_1$. Assume there is k equivalence classes in D^{\prec_S} . Then 2^S has $2k + 1$ equivalence classes. Let $\sigma(D) = \langle 1_L, 1_L \rangle$.

Now consider the opposite case where there is only one state s_1 . The complement of s_1 is the event containing all the states that are less plausible than s_1 . Then 2^S has $2k$ equivalence classes. In both cases, by **AD**, σ is extended on D^{\succ_S} . \square

Remark that the previous theorem could have been stated with axiom **NES'** in place of **POS'**.

4 Axiomatics

For a Sugeno integral to be a binary possibilistic utility, the only condition is to ensure that the capacity is an autodual possibilistic capacity.

For any act $h \in \mathcal{F}$, we write $h^{\prec\mathcal{F}}$ for the set of acts $\{f \in \mathcal{F} : f \prec_{\mathcal{F}} h\}$ and $h^{\succ\mathcal{F}}$ for $\{f \in \mathcal{F} : f \succ_{\mathcal{F}} h\}$. They are respectively the set of acts that are less preferred than h and its complement.

The following axioms are required to state our theorem:

$$\begin{aligned} \textbf{AD } & \forall A, B \in 2^S, 1_X A 0_X \succ_{\mathcal{F}} 1_X B 0_X \Leftrightarrow 1_X \bar{B} 0_X \succ_{\mathcal{F}} 1_X \bar{A} 0_X \\ \textbf{OPT' } & \exists h \in \mathcal{F}, 1_X \succ_{\mathcal{F}} h \succ_S 0_X \text{ such that } \forall f, g \in h^{\succ\mathcal{F}}, \forall A \in 2^S, f \succ_{\mathcal{F}} f A g \Rightarrow g A f \succ_{\mathcal{F}} f \end{aligned}$$

Axiom **AD** is a reformulation of axiom **AD**^S in the context of acts. Axiom **OPT'** states that the set of acts can be divided into two parts, where the set of less preferred acts satisfies axiom **OPT**.

The following representation theorem for PU can be stated.

Theorem 6. If $\succ_{\mathcal{F}}$ is a preorder over \mathcal{F} , satisfies **Sav1**, **WS3**, **Sav5**, **RCD**, **RDD**, **OPT'** and **AD** then there is a finite qualitative scale (L, \geq_L) , a basic utility assignment $u : X \rightarrow L_2$ and a possibilistic distribution $\pi : 2^S \rightarrow L$ such that $f \succ_{\mathcal{F}} f' \Leftrightarrow P_U(f) \geq_{L_2} P_U(f')$.

Proof. Axioms **Sav1**, **WS3**, **Sav5** and **OPT'** implies axiom **POS'**. See Theorem 4 of [11]. Then the result follows from Proposition 1 and Theorems 2 and 5. \square

What is remarkable in this result is that although PU is an autodual criterion, the initial preference relation over acts does not have to be autodual. Indeed only the autoduality for the representation of uncertainty is required and no structure is assumed over the set of consequences X . This shows that PU could be applied even when the consequences are not completely symmetrical around a middle point.

With the following axiom of autoduality of the preference relation over acts, a simplified theorem can be formulated:

AD+ Preference relation $\succ_{\mathcal{F}}$ over \mathcal{F} is autodual

Theorem 7. If $\succ_{\mathcal{F}}$ is a preorder over \mathcal{F} , satisfies **Sav1**, **WS3**, **Sav5**, **RCD**, **OPT'** and **AD+** then there is a finite qualitative scale (L, \geq_L) , a basic utility assignment $u : X \rightarrow L_2$ and a possibilistic distribution $\pi : 2^S \rightarrow L$ such that $f \succ_{\mathcal{F}} f' \Leftrightarrow P_U(f) \geq_{L_2} P_U(f')$.

Proof. Axiom **RDD** follows from **RCD** and **AD+**. Axiom **AD+** implies **AD**. Then the previous theorem can be applied. \square

Compared to Theorem 6, this theorem gives a better picture of the properties of PU. Thanks to the autoduality of PU, in the two previous theorem, axiom **OPT'** could be replaced by **PES'**.

5 CONCLUSION

In this paper we gave an axiomatization à la Savage for the binary possibilistic utility, which is the qualitative counterpart of expected utility. This criterion enjoys many properties similar to its quantitative counterpart: autoduality of the underlying uncertainty measure, autoduality of the decision criterion and dynamic consistency. Moreover being the unification of optimistic and pessimistic utilities, PU

can model different decision attitudes (by shifting utilities of consequences) as can be expected with convex and concave utilities.

However as a qualitative model, it sometimes lacks decisiveness. In [27], a new qualitative model, refined binary possibilistic utility, which is an improvement over PU has been proposed. As a future work, a Savagean axiomatic study could be carried on with this refined decision model in order to unveil its properties.

An Efficient Upper Approximation for Conditional Preference

Nic Wilson¹

Abstract. The fundamental operation of dominance testing, i.e., determining if one alternative is preferred to another, is in general very hard for methods of reasoning with qualitative conditional preferences such as CP-nets and conditional preference theories (CP-theories). It is therefore natural to consider approximations of preference, and upper approximations are of particular interest, since they can be used within a constraint optimisation algorithm to find some of the optimal solutions. Upper approximations for preference in CP-theories have previously been suggested, but they require consistency, as well as strong acyclicity conditions on the variables. We define an upper approximation of conditional preference for which dominance checking is efficient, and which can be applied very generally for CP-theories.

1 Introduction

A basic operation for a preference formalism is testing dominance, i.e., checking if one alternative is preferred to another. Unfortunately this has been shown to be very hard (PSPACE-complete) [7] in general for CP-nets [1, 2] and conditional preference theories (CP-theories) [13, 12], two formalisms for reasoning with qualitative and comparative conditional preferences; the cases where it is known to be feasible are of a very simple form [6, 2].

Dominance testing has particular importance for constrained optimisation; the algorithm for constrained optimisation given in [3] involves dominance testing if one requires more than one undominated solution of a set of constraints, and can involve a great many dominance checks; similar problems apply to the approach in [11]. This problem can be side-stepped by using dominance checking with respect to an upper approximation of preference (see e.g., [13]). If a solution is undominated with respect to the upper approximation it ensures that it will be undominated with respect to the preference relation; the algorithm of [3] amended in this way then generates *some* undominated solutions, but usually not all of them. Dominance testing with respect to such an upper approximation needs to be fast, since many such tests will typically be required. However, it is often not essential that the upper approximation be a close approximation, since we can usually afford to lose undominated solutions—in many situations there will be huge numbers of them, and so we would not be able to explicitly list them all even if we could find them.

Efficient upper approximations have been defined in [13, 12], but they require restrictive conditions on the CP-theory: consistency and strong acyclicity properties on the variables used in the conditional preference statements. However there are many natural situations when these conditions are not satisfied, even for simple examples,

see e.g., [5, 10, 11, 7]. For larger problems, it will be inconvenient and often impractical to have to restrict a user's preference statements so that the CP-theory is of such a special form, firstly, because this may very well mean they cannot express the preferences they wish to, and, secondly, because checking consistency of a CP-net or a CP-theory can be very hard [7].

The main contribution of this paper is to define an upper approximation of conditional preference, for which dominance testing is efficient, and which can be applied very widely for CP-theories; i.e., without the strong acyclicity properties on variables, and without assuming consistency. The approximation is also a closer one than previous upper approximations.

Section 2 describes conditional preference theories, as defined in [13, 12] which is an approach for reasoning with conditional preferences generalising CP-nets and TCP-nets [4]; a new semantics in terms of total pre-orders is also given. Section 3 describes *pre-ordered search trees* with their associated total pre-orders. Our new upper approximation is defined as the intersection of all those total pre-orders satisfying the CP-theory which arise from a pre-ordered search tree. Section 4 presents a number of technical results giving equivalent forms of these definitions; this leads to a simple and efficient algorithm for testing dominance with respect to the upper approximation. Section 5 discusses comparisons with other upper approximations and constrained optimisation.

2 Conditional Preference Theories

Let V be a set of n variables. For each $X \in V$ let \underline{X} be the set of possible values of X ; we assume \underline{X} has at least two elements. For subset of variables $U \subseteq V$ let $\underline{U} = \prod_{X \in U} \underline{X}$ be the set of possible assignments to set of variables U . The assignment to the empty set of variables is written \top . An *outcome* is an element of \underline{V} , i.e., an assignment to all the variables. For partial tuples $a \in \underline{A}$ and $u \in \underline{U}$, we may write $a \models u$, or say a extends u , if $A \supseteq U$ and $a(U) = u$, i.e., a projected to U gives u . More generally, we say that a is compatible with u if there exists outcome $\alpha \in \underline{V}$ extending both a and u , i.e., such that $\alpha(A) = a$ and $\alpha(U) = u$.

The language \mathcal{L}_V (abbreviated to \mathcal{L}) consists of statements of the form $u : x > x' [W]$ where u is an assignment to set of variables $U \subseteq V$ (i.e., $u \in \underline{U}$), x, x' are different values of variable X , and $\{X\}, U$ and W are pairwise disjoint. Let $T = V - (\{X\} \cup U \cup W)$. Such a conditional preference statement φ is intended to represent that given u and any assignment to T , x is preferred to x' irrespective of the values of W . This informal meaning is captured by the set φ^* of pairs of outcomes $\{(tuxw, tux'w') : t \in \underline{T}, w, w' \in \underline{W}\}$, (with $(tuxw, tux'w')$ meaning that $tuxw$ is preferred to $tux'w'$) since u is satisfied in both outcomes $tuxw$ and $tux'w'$, and variable X has the value x in the first, and x' in the second, and they differ at most on

¹ Cork Constraint Computation Centre, Department of Computer Science, University College Cork, Cork, Ireland, n.wilson@4c.ucc.ie

$\{X\} \cup W$. We also say that $tux'w'$ is a *worsening swap from tuxw* (with respect to φ). So, pairs (α, β) in φ^* are intended to represent a preference for α over β , and statement φ is intended as a compact representation of the preference information φ^* .

Subsets Γ of the language \mathcal{L} are called *conditional preference theories (CP-theories)* [13]. For CP-theory Γ , define Γ^* to be $\bigcup_{\varphi \in \Gamma} \varphi^*$, which represents a set of preferences. We suppose here that preferences should be transitive, so it is then natural to define the associated order \succ_Γ , induced on \underline{V} by Γ , to be the transitive closure of Γ^* . So α is preferred to β , i.e., $\alpha \succ_\Gamma \beta$, if and only if there is a sequence of worsening swaps from α to β (each with respect to some element of Γ ; see [13]). Relation \succeq_Γ is defined by $\alpha \succeq_\Gamma \beta$ if and only if either $\alpha = \beta$ or $\alpha \succ_\Gamma \beta$. If φ is the statement $u : x > x' [W]$ and $u \in \underline{U}$ we may write $u_\varphi = u$, $U_\varphi = U$, $x_\varphi = x$, $x'_\varphi = x'$, $W_\varphi = W$. If W is empty we may omit $[W]$, writing just $u : x > x'$.

We say that outcome β *dominates* α (with respect to \succ_Γ) if $\beta \succ_\Gamma \alpha$. Outcome α is said to be *undominated* (w.r.t. \succ_Γ) if there exists no outcome that dominates it. (Although in this paper we focus on this strong sense of *undominated*, of interest also are outcomes α which are dominated only by outcomes which α dominates.) Finding an undominated outcome of a CP-theory amounts to finding a solution of a CSP [12] (so checking if there exists an undominated outcome is an NP-complete problem). Solution α to a set of constraints C (involving variables V) is said to be undominated if it is not dominated by any other solution of C . Finding undominated solutions seems to be a harder problem.

This is a relatively expressive language of conditional preferences: CP-nets [1, 2] can be represented by a set of statements of the form $u : x > x' [W]$ with $W = \emptyset$ [13], and TCP-nets [4] can be represented in terms of such statements with $W = \emptyset$ or $|W| = 1$ [12]. Lexicographic orders can also be represented [13]. Other related languages for conditional preferences include those in [8, 9].

Example. Let V be the set of variables $\{X, Y, Z\}$ with domains as follows: $\underline{X} = \{\bar{x}, \bar{\bar{x}}\}$, $\underline{Y} = \{\bar{y}, \bar{\bar{y}}\}$ and $\underline{Z} = \{\bar{z}, \bar{\bar{z}}\}$. Let $\varphi_1 = \top : x > \bar{x}$, let $\varphi_2 = x : y > \bar{y}$, let $\varphi_3 = y : z > \bar{z}$, and let $\varphi_4 = \bar{x} : \bar{z} > z$. Let CP-theory Γ be $\{\varphi_1, \varphi_2, \varphi_3, \varphi_4\}$. This gives rise to the following preferences, where e.g., $xyz \succ^3 \bar{x}\bar{y}\bar{z}$ means that xyz is a worsening swap from $\bar{x}\bar{y}\bar{z}$ with respect to φ_3 (in other words, $(xyz, \bar{x}\bar{y}\bar{z}) \in \varphi_3^*$): $xyz \succ^3 xyz \succ^2 \bar{x}\bar{y}\bar{z} \succ^1 \bar{x}\bar{y}\bar{z} \succ^4 \bar{x}yz$. We also have $xyz \succ^2 \bar{x}yz \succ^1 \bar{x}\bar{y}z$; and $xyz \succ^1 \bar{x}yz$, and $xyz \succ^1 \bar{x}\bar{y}\bar{z}$. In addition there is the cycle $\bar{x}\bar{y}\bar{z} \succ^4 \bar{x}yz \succ^3 \bar{x}\bar{y}\bar{z}$. The relation \succ_Γ is the transitive closure of these orderings. The cycle shows that Γ is inconsistent (see below). But, despite this “localised” inconsistency (which only involves two outcomes), useful things can be said. In particular, there is a single undominated outcome: xyz . Furthermore, if we add the constraint $(Y = \bar{y}) \vee (Z = \bar{z})$ then there are two undominated solutions: $\bar{x}\bar{y}\bar{z}$ and $\bar{x}\bar{y}z$. In this case the constraint also “removes the inconsistency” in the following sense: \succ_Γ restricted to solutions is acyclic.

Some general properties of relations

A relation \succcurlyeq on a set A is formally defined to be a set of pairs, i.e., a subset of $A \times A$. We will often write $a \succcurlyeq b$ to mean $(a, b) \in \succcurlyeq$. Relation \succ on set A is irreflexive if and only if for all $a \in A$, it is not the case that $a \succ a$. A pre-order \succcurlyeq on A is a reflexive and transitive relation, i.e., such that $a \succcurlyeq a$ for all $a \in A$, and such that $a \succcurlyeq b$ and $b \succcurlyeq c$ implies $a \succcurlyeq c$. Elements a and b are said to be \succcurlyeq -equivalent if $a \succcurlyeq b$ and $b \succcurlyeq a$. We may write \succ for the *strict part of* \succcurlyeq , i.e., the relation given by $a \succ b$ if and only if $a \succcurlyeq b$ and $b \not\succcurlyeq a$. (Note,

however, that \succ_Γ is not necessarily the strict part of \succeq_Γ .) A relation \succcurlyeq is complete if for all $a \neq b$, either $a \succcurlyeq b$ or $b \succcurlyeq a$. Relation \succcurlyeq is anti-symmetric if $a \succcurlyeq b$ and $b \succcurlyeq a$ implies $a = b$ (i.e., iff \succcurlyeq -equivalence is no more than equality). A partial order is an anti-symmetric pre-order. A total pre-order is a complete pre-order. If \succcurlyeq is a total pre-order then $a \succ b$ if and only if $b \not\succcurlyeq a$. A total order is a complete partial order. We say that a relation is acyclic if its transitive closure is anti-symmetric, i.e., there are no cycles $a \succcurlyeq a' \cdots \succcurlyeq a$ for different a, a', \dots . A relation \succcurlyeq' extends (or, alternatively, contains) relation \succcurlyeq if $\succcurlyeq' \supseteq \succcurlyeq$, i.e., if $a \succcurlyeq' b$ holds whenever $a \succcurlyeq b$ holds.

Semantics

Sequences of worsening swaps can be considered as a proof theory for this system of conditional preference. In [13] a semantics is given in terms of total orders (based on the semantics for CP-nets [2]); in the case of an inconsistent CP-theory, the semantic entailment relation becomes degenerate. To deal with this problem, [5] defines an extended semantics for CP-nets in terms of total pre-orders. We show how this semantics can be generalised to CP-theories, extending also the semantics in [13].

Let \succcurlyeq be a total pre-order on \underline{V} . We say that \succcurlyeq satisfies conditional preference statement φ if $\alpha \succcurlyeq \beta$ holds whenever β is a worsening swap from α w.r.t. φ ; this is if and only if \succcurlyeq extends the relation φ^* . We say that \succcurlyeq satisfies a CP-theory Γ if it satisfies each element φ of Γ , i.e., if \succcurlyeq extends the relation Γ^* . Because \succcurlyeq is transitive, this holds if and only if \succcurlyeq extends \succ_Γ .

For different outcomes α and β we say that $\Gamma \models' (\alpha, \beta)$ if $\alpha \succcurlyeq \beta$ holds for all total pre-orders \succcurlyeq satisfying Γ . We also say, as in [13], that $\Gamma \models (\alpha, \beta)$ if $\alpha \succcurlyeq \beta$ holds for all total orders \succcurlyeq satisfying Γ . We say that Γ is *consistent* if there exists some *total order* satisfying Γ .

The following theorem² shows that swapping sequences are complete with respect to the semantics based on total pre-orders. Also, in the case of consistent CP-theories, the two semantic consequence relations are equivalent.

Theorem 1 Let $\Gamma \subseteq \mathcal{L}_V$ be a CP-theory and let $\alpha, \beta \in \underline{V}$ be different outcomes. Then (i) the relation \succ_Γ is the intersection of all total pre-orders satisfying Γ ; (ii) $\Gamma \models' (\alpha, \beta)$ if and only if $\alpha \succ_\Gamma \beta$; (iii) Γ is consistent if and only if \succ_Γ is irreflexive if and only if \succeq_Γ is a partial order; (iv) if Γ is consistent then $\Gamma \models (\alpha, \beta)$ if and only if $\Gamma \models' (\alpha, \beta)$.

The semantics suggests a general approach to finding an upper approximation of \succ_Γ : we consider a subset \mathcal{M} of the set of all total pre-orders (which might be thought of as a set of “preferred” models) and define that α is preferred to β (with respect to this approximation) if $\alpha \succcurlyeq \beta$ for all \succcurlyeq in \mathcal{M} which satisfy Γ . (It is an “upper approximation” in the sense that the approximation contains the relation \succ_Γ .) We use this kind of approach in the next section.

3 Pre-ordered Search Trees

A pre-ordered search tree is a rooted directed tree (which we imagine being drawn with the root at the top, and children below parents). Associated with each node r in the tree is a variable Y_r , which is instantiated with a different value in each of the node’s children (if it

² The proof of this result, and proofs of other results in the paper are included in a longer version of the paper available at the 4C website: <http://www.4c.ucc.ie/>.

has any), and also a pre-ordering \geq_r of the values of Y_r . A directed edge in the tree therefore corresponds to an instantiation of one of the variables to a particular value. Paths in the tree from the root down to a leaf node correspond to sequential instantiations of different variables. We also associate with each node r a set of variables A_r which is the set of all variables $Y_{r'}$ associated to nodes r' above r in the tree (i.e., on the path from the root to r), and an assignment a_r to A_r corresponding to the assignments made to these variables in the edges between the root and r . The root node r^* has $A_{r^*} = \emptyset$ and $a_{r^*} = \top$, the assignment to the empty set of variables. Hence r' is a child of r if and only if $A_{r'} = A_r \cup \{Y_r\}$ (where $A_r \not\ni Y_r$) and $a_{r'}$ extends a_r (with an assignment to Y_r).

More formally, define a node r to be a tuple $\langle A_r, a_r, Y_r, \geq_r \rangle$, where $A_r \subseteq V$ is a set of variables, $a_r \in A_r$ is an assignment to those variables, $Y_r \in V - A_r$ is another variable, and \geq_r is a total pre-order on the set \underline{Y}_r of values of Y_r . We make two restrictions on the choice of this total pre-order: firstly, it is assumed not to be the trivial complete relation on \underline{Y} ; so there exists some $y, y' \in \underline{Y}$ with $y \not\geq_r y'$. We also assume that total pre-order \geq_r satisfies the following condition (which we require so that the associated ordering on outcomes is transitive): if there exists a child of node r associated with instantiation $Y_r = y$, then y is not \geq_r -equivalent to any other value of Y , so that $y \geq_r y' \geq_r y$ only if $y' = y$. In particular, \geq_r totally orders the values (of Y_r) associated with the children of r .

For outcome α , define the *path to α* to be the path from the root which includes all nodes r such that α extends a_r . To generate this, for each node r , starting from the root, we choose the child associated with the instantiation $Y_r = \alpha(Y_r)$ (there is at most one such child); the path finishes when there exists no such child.

Node r is said to *decide outcomes α and β* if it is the deepest node (i.e., furthest from the root) which is both on the path to α and on the path to β . Hence α and β both extend the tuple a_r (but they may differ on variable Y_r). We compare α and β by using \geq_r , where r is the unique node which decides α and β .

Each pre-ordered search tree σ has an associated ordering relation \succ_σ on outcomes which is defined as follows. Let $\alpha, \beta \in \underline{V}$ be outcomes. We define $\alpha \succ_\sigma \beta$ to hold if and only if $\alpha(Y_r) \geq_r \beta(Y_r)$, where r is the node which decides α and β . We therefore then have that α and β are \succ_σ -equivalent if and only if $\alpha(Y_r)$ and $\beta(Y_r)$ are \geq_r -equivalent; also: $\alpha \succ_\sigma \beta$ holds if and only if $\alpha(Y_r) >_r \beta(Y_r)$. This ordering is similar to a lexicographic ordering in that two outcomes are compared on the first variable on which they differ.

The definition implies immediately that \succ_σ is reflexive and complete; it can be shown easily that it is also transitive. Hence it is a total pre-order. We say that pre-ordered search tree σ *satisfies* conditional preference theory Γ iff \succ_σ satisfies Γ .

Definition of Upper Approximation. For a given CP-theory Γ we define the relation \sqsupseteq_Γ (abbreviated to \sqsupseteq) as follows: $\alpha \sqsupseteq \beta$ holds if and only if $\alpha \succ_\sigma \beta$ holds for all σ satisfying Γ (i.e., all σ such that \succ_σ satisfies Γ). Relation \sqsupseteq is then the intersection of all pre-ordered search tree orders which satisfy Γ . The intersection of a set of reflexive and transitive relations containing \succ_Γ is clearly reflexive and transitive, and contains \succ_Γ :

Proposition 1 For any CP-theory Γ , the relation \sqsupseteq_Γ is a pre-order which is an upper approximation of \succ_Γ , i.e., if $\alpha \succ_\Gamma \beta$ then $\alpha \sqsupseteq_\Gamma \beta$.

This implies, in particular, that if outcomes α and β are incompatible with respect to \sqsupseteq_Γ then they are incomparable with respect to \succ_Γ .

Example continued. Consider the pre-ordered search tree σ_1 with just one node, the root node $r = \langle \emptyset, \top, Y, y > \bar{y} \rangle$. Let α and β be any outcomes with $\alpha(Y) = y$ and $\beta(Y) = \bar{y}$. We then have $\alpha \succ_{\sigma_1} \beta$ since the node r decides α and β , and $\alpha(Y) >_r \beta(Y)$. In particular, this implies that σ_1 satisfies φ_2 . If outcomes γ and δ agree on variable Y , then γ and δ are \succ_{σ_1} -equivalent because $\gamma(Y) = \delta(Y)$. Hence σ_1 satisfies φ_1, φ_3 and φ_4 and so satisfies Γ . This implies that $\beta \not\sqsupseteq_\Gamma \alpha$, so, in particular, $xy\bar{z} \not\sqsupseteq xy\bar{z}$.

Now consider the pre-ordered search tree σ_2 which has root node $\langle \emptyset, \top, X, x > \bar{x} \rangle$ with a single child node $\langle \{X\}, x, Z, z > \bar{z} \rangle$. This also satisfies Γ . For example, to check that σ_2 satisfies φ_4 we can reason as follows: let α and β be any outcomes such that $(\alpha, \beta) \in \varphi_4^*$, so that $\alpha(X) = \beta(X) = \bar{x}$, $\alpha(Y) = \beta(Y) = \bar{z}$, $\alpha(Z) = \bar{z}$ and $\beta(Z) = z$. Then the root node $r' = \langle \emptyset, \top, X, x > \bar{x} \rangle$ decides α and β because its single child is associated with $X = x$, which is incompatible with α and β . Now, $Y_{r'} = X$ and α and β agree on X so $\alpha(X)$ and $\beta(X)$ are $\geq_{r'}$ -equivalent; in particular, $\alpha(X) \geq_{r'} \beta(X)$. Hence $\alpha \succ_{\sigma_2} \beta$. Pre-ordered search tree σ_2 strictly prefers $x\bar{y}z$ to $xy\bar{z}$, which shows that $xy\bar{z} \not\sqsupseteq x\bar{y}z$. We've shown that both \succ_Γ -undominated solutions are also \sqsupseteq -undominated. In fact, in this case, \sqsupseteq_Γ is actually equal to \succ_Γ .

4 Computation of Upper Bound on Preference

Outcome α is \sqsupseteq -preferred to β if and only if α is preferred to β in all pre-ordered search trees satisfying Γ . At first sight this definition looks computationally very unpromising for two reasons: (i) direct testing of whether a pre-ordered search tree satisfies Γ is not feasible, as Γ^* will typically contain exponentially many pairs; (ii) there will very often be a huge number of pre-ordered search trees satisfying Γ .

In this section we find ways of getting round these two problems. We first (Section 4.1) find simpler equivalent conditions for a pre-ordered search tree σ to satisfy Γ ; then, in 4.2, we use the results of 4.1 to recast the problem of testing dominance with respect to the upper approximation, allowing a simple and efficient algorithm.

4.1 Equivalent conditions for σ to satisfy Γ

Consider a pre-ordered search tree σ , and let α be any outcome. Associated with the path to α is the sequence of variables Y_1, \dots, Y_k which are instantiated along that path (i.e., associated with the nodes on the path), starting with the root node. If W is a set of variables and X is a variable not in W , we say that “*on the path to α , X appears before any of W* ” if the following condition holds: $Y_j \in W$ implies that $Y_i = X$ for some $i < j$, i.e., if some element of W occurs on the path then X occurs earlier on the path.

Proposition 2 The following pair of conditions are necessary and sufficient for a pre-ordered search tree σ to satisfy the CP-theory Γ :

- (1) For any $\varphi \in \Gamma$ and outcome α extending u_φ : on the path to α , X_φ appears before W_φ ;
- (2) for any node r and any $\varphi \in \Gamma$ with $X_\varphi = Y_r$ we have $x_\varphi \geq_r x'_\varphi$ if u_φ is compatible with a_r .

Relation \sqsupseteq_a^X . Because \geq_r is transitive, condition (2) can be written equivalently as: for all nodes r in σ , $\geq_r \supseteq \sqsupseteq_a^X$, where \sqsupseteq_a^X is defined to be the transitive closure of the set of pairs (x, x') of values of X over all statements $u : x > x' [W]$ in Γ such that u is compatible with a . Note that relation \sqsupseteq_a^X is monotonic decreasing

with respect to a : if b extends a (to variables not including X) then \square_a^X contains \square_b^X ; this is because if u_φ is compatible with b then u_φ is compatible with a .

Let $A \subseteq V$ be a set of variables, let $a \in \underline{A}$ be an assignment to A and let $Y \in V - A$ be some variable not in A . We say that Y is *a-choosable* if $X_\varphi \in A$ for all $\varphi \in \Gamma$ satisfying (a) u_φ compatible with a and (b) $W_\varphi \ni Y$. Note that if $W_\varphi = \emptyset$ for all $\varphi \in \Gamma$, as in CP-nets, then, for all a , every variable is *a-choosable*. If we are attempting to construct a node r of a pre-ordered search tree satisfying Γ , where a_r is the associated assignment, then we need to pick a variable Y_r which is a_r -choosable, because of Proposition 2(1). This condition has the following monotonicity property: suppose $A \subseteq B \subseteq V$, and $Y \notin B$; suppose also that b is an assignment to B extending assignment a to variables A . Then Y is b -choosable if Y is a -choosable.

Define pre-ordered search tree node r to satisfy Γ if Y_r is a_r -choosable and \geq_r satisfies condition (2) above, i.e., $\geq_r \supseteq \square_{a_r}^{Y_r}$. It can be seen that Y_r is a_r -choosable for each node r in pre-ordered search tree σ if and only if condition (1) of Proposition 2 is satisfied. This leads to the following result.

Proposition 3 *A pre-ordered search tree σ satisfies Γ if and only if each node of σ satisfies Γ .*

4.2 Computation of upper bound on preference relation

In this section we consider a fixed conditional preference theory Γ . Suppose we are given outcomes α and β , and we wish to determine if $\beta \trianglerighteq \alpha$ or not. By definition, $\beta \not\trianglerighteq \alpha$ if and only if there exists a pre-ordered search tree σ satisfying Γ with $\beta \not\succ_\sigma \alpha$, i.e., with $\alpha \succ_\sigma \beta$. Therefore, an approach to showing $\beta \not\trianglerighteq \alpha$ is to construct a pre-ordered search tree σ with $\alpha \succ_\sigma \beta$. The key is to construct the path from the root which will form the intersection of the path to α and the path to β ; for each node r on this path we need to choose a variable Y_r with certain properties. If α and β differ on Y_r it needs to be possible to choose the local relation \geq_r so that $\alpha(Y_r) >_r \beta(Y_r)$. If α and β agree on Y_r then we need to ensure that the local relation is such that this node can have a child. With this in mind we make the following definitions.

Suppose α and β are both outcomes which extend partial tuple $a \in \underline{A}$. Define variable Y to be *pickable given a with respect to* (α, β) if $Y \notin A$ and (i) Y is *a-choosable*; (ii-a) if $\alpha(Y) = \beta(Y)$ then $\alpha(Y)$ is not \square_a^Y -equivalent to any other value in \underline{Y} ; (ii-b) if $\alpha(Y) \neq \beta(Y)$ then $\beta(Y) \not\succ_a^Y \alpha(Y)$. If Y is pickable given a with respect to (α, β) , and $\alpha(Y) \neq \beta(Y)$ then we say that Y is *decisive given a (with respect to (α, β))*.

The following lemma describes a key monotonicity property. It follows immediately from the previously observed monotonicity properties of being *a-choosable*, and of \square_a^Y .

Lemma 1 *Let α and β be two outcomes which both extend tuples a and b , where $a \in \underline{A}$ and $b \in \underline{B}$ and $A \subseteq B \subseteq V$ (so b extends a). Let Y be a variable not in B . If Y is pickable given a with respect to (α, β) then Y is pickable given b with respect to (α, β) .*

A *decisive sequence* (w.r.t. (α, β)) is defined to be a sequence Y_1, \dots, Y_k of variables satisfying the following three conditions:

- for $j = 1, \dots, k-1$, $\alpha(Y_j) = \beta(Y_j)$,
- $\alpha(Y_k) \neq \beta(Y_k)$
- for $j = 1, \dots, k$, Y_j is pickable given a_j (with respect to (α, β)), where a_j is α restricted to $\{Y_1, \dots, Y_{j-1}\}$; in particular, Y_k is decisive given a_k .

Proposition 4 *There exists a decisive sequence w.r.t. (α, β) if and only if there exists a pre-ordered search tree σ satisfying Γ with $\alpha \succ_\sigma \beta$.*

Since $\beta \triangleright \alpha$ holds if and only if there exists no pre-ordered search tree σ satisfying Γ with $\alpha \succ_\sigma \beta$, Proposition 4 implies the following result.

Proposition 5 *For outcomes α and β , $\beta \triangleright \alpha$ holds if and only if there exists no decisive sequence with respect to (α, β) .*

Therefore to determine if $\beta \triangleright \alpha$ or not, we just need to check if there exists a decisive sequence Y_1, \dots, Y_k . The monotonicity lemma implies that we do not have to be careful about the variable ordering: a variable which is pickable at one point in the sequence is still pickable at a later point; this means that we can choose, for each j , Y_j to be any pickable variable, knowing that we will not have to backtrack, as any previously available choices remain available later.

The following algorithm takes as input outcomes α and β and determines if $\beta \triangleright \alpha$ or not.

```

procedure Is  $\beta \triangleright \alpha$ ?
if  $\alpha = \beta$  then return true and stop;
for  $j := 1, \dots, n$ 
  let  $a_j$  be  $\alpha$  restricted to  $\{Y_1, \dots, Y_{j-1}\}$ ;
  if there exists a variable which is decisive given  $a_j$  w.r.t.  $(\alpha, \beta)$ 
    then return false and stop;
  if there exists a variable which is pickable given  $a_j$  w.r.t.  $(\alpha, \beta)$ 
    then let  $Y_j$  be any such variable;
    else return true and stop.

```

The correctness of the algorithm follows easily from Proposition 5 and the monotonicity lemma.

Theorem 2 *Let Γ be a CP-theory, and let α and β be outcomes. The above procedure is correct, i.e., it returns **true** if $\beta \triangleright_\Gamma \alpha$, and it returns **false** if $\beta \not\triangleright_\Gamma \alpha$.*

Example continued. Now let $\alpha = \bar{x}\bar{y}z$ and $\beta = \bar{x}\bar{y}\bar{z}$. Since for all $\varphi \in \Gamma$, $W_\varphi = \emptyset$, each variable is *a-choosable* for any a . The relation \square_\top^Z contains pair (z, \bar{z}) because of $\varphi_3 = y : z > \bar{z}$ (anything is compatible with $a = \top$). It also contains pair (\bar{z}, z) because of $\varphi_4 = \bar{x} : \bar{z} > z$ and so $\beta(Z) \sqsupseteq_\top^Z \alpha(Z)$ which implies that Z is not pickable given \top with respect to (α, β) since $\alpha(Z) \neq \beta(Z)$. On the other hand, X and Y are both pickable given \top (but not decisive). Suppose we select $Y_1 = Y$, and so $a_2 = \bar{y}$. Variable Z is still not pickable, but X is still pickable given a_2 (by Lemma 1) so we get $Y_2 = X$ and $a_3 = \bar{x}\bar{y}$. Relation $\square_{a_3}^Z$ is empty so Z is now pickable and hence decisive (giving decisive sequence Y, X, Z) proving that $\beta \not\triangleright \alpha$. A shorter decisive sequence is X, Z which corresponds to pre-ordered search tree σ_2 which strictly prefers α to β .

Complexity of approximate dominance checking We assume that the size $|\underline{X}|$ of the domain of each variable X is bounded by a constant; we will consider the complexity in terms of n , the number of variables, and of $m = |\Gamma|$, where we assume that m is at least $O(n)$. This algorithm can be implemented to have complexity at worst $O(mn^2)$, or, more precisely, $O(mn(w+1))$ where w is the average of $|W_\varphi|$ over $\varphi \in \Gamma$. Clearly $w < n$. For some special classes such as CP-theories representing CP-nets or TCP-nets, w is bounded by a constant, and so the complexity is then $O(mn)$.

5 Comparison and Discussion

An upper approximation $\succ_{p(\Gamma)}$ for \succ_Γ was defined in [13], which was refined to upper approximation \gg_Γ in [12]. It follows easily from their construction that $\gg_\Gamma \subseteq \succ_{p(\Gamma)}$ when the latter is defined.

Both these require consistency, and strong acyclicity properties on the ordering of variables used in statements in Γ . In particular, in both cases, it must be possible to label the set of variables V as $\{X_1, \dots, X_n\}$ in such a way that for any $\varphi \in \Gamma$, if $X_i \in U_\varphi$, and $X_j \in \{X_\varphi\} \cup W_\varphi$ then $i < j$. It can be proved using Proposition 5 that \sqsupseteq is never a worse upper approximation than \gg_Γ or $\succ_{p(\Gamma)}$.

Proposition 6 *Let α and β be two different outcomes such that $\alpha \sqsupseteq \beta$. Then $\alpha \gg_\Gamma \beta$ if Γ is such that \gg_Γ is defined; hence also $\alpha \succ_{p(\Gamma)} \beta$ if $\succ_{p(\Gamma)}$ is defined.*

Example continued. The upper approximations of [13, 12] are not applicable because Γ is not consistent. If we restore consistency by removing φ_4 from Γ then they are applicable but give a poorer upper approximation; in particular they both have $xy\bar{z}$ preferred to $x\bar{y}z$ (essentially because they make Y a more important variable than Z , as Y is a parent of Z), so that they miss undominated solution $x\bar{y}z$.

Application to constrained optimisation

In the constrained optimisation algorithm in [3], and the amendments in [13, 12], a search tree is used to find solutions, where the search tree is chosen so that its associated total ordering on outcomes extends \succ_Γ . Methods for finding such search trees have been developed in [12]. We can make use of this search tree as follows, amending the constrained optimisation approach of [12] in the obvious way: when we find a new solution α we check if it is \sqsupseteq -undominated with respect to each of the current known set K of \sqsupseteq -undominated solutions. If so, then α is an \sqsupseteq -undominated solution, since it cannot be \sqsupseteq -dominated by any solution found later. We add α to K , and continue the search. This is an anytime algorithm, but if we continue until the end of the search, K will be the complete set of \sqsupseteq -undominated solutions, which is a subset of the set of \succ_Γ -undominated solutions, since $\sqsupseteq \supseteq \succ_\Gamma$. For the inconsistent case, by definition, no such search tree can exist. Instead we could use a pre-ordered search tree satisfying Γ , and continue generating solutions with this for as long as it totally orders solutions. This may well be successful for cases where the inconsistency is relatively localised and among less preferred outcomes, such as in the example.

Crudeness of the approximation

As illustrated by the example, \sqsupseteq_Γ can be a close approximation of \succ_Γ . However, computing dominance with respect to \succ_Γ appears in general to be extremely hard [7] whereas our approximation \sqsupseteq_Γ is of low order polynomial complexity. One would therefore not expect \sqsupseteq_Γ always to be a close approximation. To illustrate this, consider outcomes α and β which differ on all variables (or, more generally on all variables not in $W_\Gamma = \bigcup_{\varphi \in \Gamma} W_\varphi$). Then any variable which is pickable is decisive, so, by Proposition 5, $\beta \sqsupseteq_\Gamma \alpha$ if and only if there exists no variable which is pickable given \top with respect to (α, β) . A variable is \top -choosable if and only if it is not in W_Γ , so $\beta \sqsupseteq_\Gamma \alpha$ if and only if for all $Y \in V - W_\Gamma$, $\beta(Y) \sqsupseteq_\top \alpha(Y)$. The relation \sqsupseteq_\top does not depend at all on u_φ , for $\varphi \in \Gamma$, so, for such α and β , whether $\beta \sqsupseteq_\Gamma \alpha$ holds or not does not depend at all on u_φ , for $\varphi \in \Gamma$. In particular, if $\beta \succ_{\Gamma_*} \alpha$ holds, where Γ_* is Γ in which each

u_φ is changed to \top , then, by Proposition 1, $\beta \sqsupseteq_\Gamma \alpha$ holds, since for such α and β , $\beta \sqsupseteq_\Gamma \alpha$ if and only if $\beta \sqsupseteq_{\Gamma_*} \alpha$. Since \succ_{Γ_*} can easily be a very crude upper approximation of \succ_Γ , this suggests that \sqsupseteq_Γ may often not be a close approximation for such pairs of outcomes, i.e., we may easily have $\beta \sqsupseteq_\Gamma \alpha$ without $\beta \succ_\Gamma \alpha$.

However, this does not necessarily matter for constrained optimisation. There will often be a very large number of optimal solutions, and we may well only wish to report a small fraction of them; it is not necessarily important that the upper approximation is a close approximation, just that \sqsupseteq is a sufficiently sparse (i.e., weak) relation, so that there are still liable to be a good number of solutions which are \sqsupseteq -undominated.

Summary

In this paper we have constructed a new upper approximation of conditional preference in CP-theories, which is very much more widely applicable than previous approaches, as well as being a better approximation. Furthermore, an efficient algorithm for dominance testing with respect to approximate preference has been derived.

A Solver for QBFs in Nonprenex Form¹

Uwe Egly² and Martina Seidl³ and Stefan Woltran²

Abstract. Various problems in artificial intelligence (AI) can be solved by translating them into a quantified boolean formula (QBF) and evaluating the resulting encoding. In this approach, a QBF solver is used as a black box in a rapid implementation of a more general reasoning system. Most of the current solvers for QBFs require formulas in prenex conjunctive normal form as input, which makes a further translation necessary, since the encodings are usually not in a specific normal form. This additional step increases the number of variables in the formula or disrupts the formula's structure. Moreover, the most important part of this transformation, prenexing, is not deterministic. In this paper, we focus on an alternative way to process QBFs without these drawbacks and describe a solver, qpro, which is able to handle arbitrary formulas. To this end, we extend algorithms for QBFs to the non-normal form case and compare qpro with the leading normal-form provers on problems from the area of AI.

1 Introduction

Formal frameworks are often suitable for the representation of application problems (like planning, scheduling, etc.) which can then be solved by automated reasoning tools. Many important problems in artificial intelligence (AI) (like problems in knowledge representation) can be encoded efficiently using quantified boolean formulas (QBFs), which are an extension of classical propositional formulas, permitting existential and universal quantifications over propositional atoms. QBFs have been proven to be a powerful framework for the rapid implementation of reasoning tasks from these areas (see, e.g., [6, 13, 24]), mainly because there has been made a significant progress in the development of QBF solvers in the last few years [19]. Almost all of these solvers expect the input formula to be in a certain *prenex conjunctive normal form* (PCNF), requiring all quantifiers to be in front of a purely propositional formula, which has to be in conjunctive normal form (CNF). However, natural encodings of problems from AI do not yield QBFs in such a normal form, and thus the particular instances have to be transformed. The transformation is performed in two steps, namely *prenexing* and transformation of the resulting purely propositional matrix into CNF. The drawbacks of this transformation are an increase in both formula size and variable number, or, even worse, the formula's structure is disrupted.

In this paper, we present a prover, qpro, which works on arbitrary QBFs. Its basic procedure is a generalized DPLL algorithm with enhanced dependency-directed backtracking techniques. The space requirements for qpro are modest; it runs in polynomial space (wrt the length of the input formula). The motivation to circumvent formulas

in PCNF and to work with arbitrary QBFs is the problem to generate “good” normal forms in this logic. The main problem here is the handling of quantifiers at the places where they occur. This is in contrast to first-order logic. We explain in the following aspects of normalization for different logics and discuss why QBFs are problematic.

It is well known how a propositional (or first-order formula) can be translated into a satisfiability-equivalent CNF, such that the structural information is retained by new atoms [23, 10, 8]. Together with their definition, such new atoms can mimic the effect of the analytic cut rule in full calculi like Gentzen systems resulting in drastically shorter proofs [3, 11]. Moreover, as experiments showed [14, 21], such structure-preserving translations are not only beneficial from a theoretical point of view, but can also speed-up automated theorem provers for practical problems. In the last few years, similar results have been obtained for the case of prenex QBFs and an optimized handling of the newly introduced atoms has been proposed [1].

We consider the problem to construct a prenex form of a QBF. The prenexing transformation cannot be carried out deterministically; the chosen normalization strategy crucially influences the runtimes (also depending on the concrete solver used), see e.g., [15, 26]. In fact, this phenomenon mirrors a similar observation from classical theorem proving in *first-order logic*, where classes of formulas exist for which different quantifier shifting strategies (resulting in different prenex forms) yield a non-elementary difference of proof size (and search-space size) [4, 12]. Clearly, the impact of the prenex forms is less drastic for QBFs because of the simpler underlying logic, but there are indications that prenexing impacts the runtime of highly optimized state-of-the-art solvers [18].

In first-order logic, skolemization can be used to encode the properties of (usually) existential quantifiers by Skolem functions. In a nutshell, skolemization gets rid of existential quantifiers “in place”. The introduced Skolem functions encode two properties of quantifier rules in full first-order calculi: (i) the eigenvariable condition and (ii) non-permutabilities between quantifier rules. Condition (i) is satisfied by the requirement to introduce a globally new function symbol, and condition (ii) is handled by the occur check in the unification algorithm. Due to the weaker syntax of QBFs, the introduction of Skolem functions is not possible and therefore this conceptually simple tool is not directly applicable in the context of QBFs.

The outline of the paper is as follows: Section 2 introduces necessary definitions and notations. Sections 3 and 4 are devoted to the formal underpinnings of the prover. Section 5 provides experiments and comparisons. Finally, we discuss the results as well as related and future work in Section 6.

2 Background

We introduce the language \mathcal{L}_P of QBFs as an extension of the language of propositional logic. The alphabet of \mathcal{L}_P consists of paren-

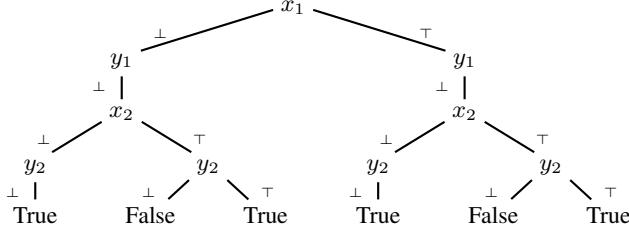

Figure 1. The branching tree of the example QBF ϕ .

theses, the truth constants \top and \perp , a countable set of variables \mathcal{P} , the unary connective \neg (negation), the binary connectives \vee (disjunction) and \wedge (conjunction), and the quantifier symbols \forall (universal) and \exists (existential). A literal is a variable or a negated variable.

We define the language of *quantified propositional logic* over a set of variables \mathcal{P} as the smallest set, $\mathcal{L}_{\mathcal{P}}$, satisfying the conditions:

1. If $x \in \mathcal{P} \cup \{\top, \perp\}$, then $x \in \mathcal{L}_{\mathcal{P}}$ and $(\neg x) \in \mathcal{L}_{\mathcal{P}}$;
2. if $\phi, \psi \in \mathcal{L}_{\mathcal{P}}$, then $(\phi \circ \psi) \in \mathcal{L}_{\mathcal{P}}$, where $\circ \in \{\vee, \wedge\}$;
3. if $\phi \in \mathcal{L}_{\mathcal{P}}$, $x \in \mathcal{P}$, and Qx does not occur in ϕ , then $(Qx \phi) \in \mathcal{L}_{\mathcal{P}}$, where $Q \in \{\forall, \exists\}$.

Any element of $\mathcal{L}_{\mathcal{P}}$ is called a *quantified boolean formula* (QBF). If no ambiguities arise, we omit parentheses when convenient. Moreover, for a set $X = \{x_1, \dots, x_n\}$ of variables, and $Q \in \{\forall, \exists\}$, we write $QX\phi$ or $Qx_1 \dots x_n \phi$ as a short-hand for $Qx_1 \dots Qx_n \phi$.

Note that we allow negation only in front of a variable or a truth constant. Formulas which obey this restriction are said to be in *negation normal form* (NNF). The NNF of any QBF can be obtained by applying DeMorgan's laws and the removal of double negation. Since this transformation can be done deterministically and since the increase of the formula size is negligible, we only consider QBFs in NNF. From a technical point of view, QBFs in NNF have the advantage that polarities of complex subformulas do not come into play.

The scope of a quantifier (occurrence) Qx in a QBF ϕ is defined as ψ , where $Qx \psi$ is the subformula corresponding to the occurrence of Qx in ϕ . An occurrence of a variable x is called existential (resp. universal) if it is located within the scope of a quantifier $\exists x$ (resp. $\forall x$). Unless stated otherwise, we consider *closed* QBFs, i.e., each occurrence of a variable x is located in the scope of a quantifier Qx .

We denote by $\phi[x/\psi]$ the result of substituting each occurrence of a variable x in a QBF ϕ by a QBF ψ . The semantics of a QBF is then given as follows: A QBF $\exists x \psi$ is true iff $\psi[x/\perp]$ or $\psi[x/\top]$ is true. Dually, a QBF $\forall x \psi$ is true iff $\psi[x/\perp]$ and $\psi[x/\top]$ are true. The other connectives are treated according to the standard evaluation rules of propositional logic, providing the usual recursive definition of the truth value of a QBF. Two closed QBFs are called equivalent if they possess the same truth value.

The sequence of the variable assignments when evaluating a QBF can be illustrated by a branching tree. The nodes contain the variables and the two subtrees of a node x correspond to the subproblems, where x is replaced by \perp or \top , as indicated by the labels of the arcs. The leaves contain the resulting truth values. If x is existentially (resp. universally) quantified and one subproblem evaluates to true (resp. false), then the second subproblem can be omitted. As an example, we show in Figure 1 the branching tree of the true formula

$$\phi = \forall x_1 \exists y_1 (\forall x_2 \exists y_2 ((x_2 \vee \neg y_2) \wedge (\neg x_2 \vee y_2)) \vee (x_1 \wedge y_1)).$$

Definition 1 A QBF ϕ is given in *prenex normal form* (PNF) if ϕ is of the form $Q_1 X_1 \dots Q_m X_m \psi$, where $Q_i \in \{\forall, \exists\}$ and ψ is purely

```
BOOLEAN split(QBF φ in NNF) {
    switch (simplify (φ)):
        case T: return True;
        case ⊥: return False;
        case (φ1 ∨ φ2): return (split(φ1) || split(φ2));
        case (φ1 ∧ φ2): return (split(φ1) && split(φ2));
        case (QXψ): select x ∈ X;
            if Q = ∃ return (split(ψ[x/T]) || split(ψ[x/⊥]));
            if Q = ∀ return (split(ψ[x/T]) && split(ψ[x/⊥]));
    }
}
```

Figure 2. The basic algorithm.

propositional. Moreover, if ψ is in conjunctive normal form, ϕ is said to be in *prenex conjunctive normal form* (PCNF).

The PCNF format is required by most of the available QBF solvers.

Any QBF can be translated into an equivalent QBF in PNF, but there are several ways to do this. The concept of different *prenexing strategies* is discussed in [15, 26]. We give here only some intuition.

First, the *dependencies* between the quantifiers in a QBF are given by common occurrences on paths in the formula tree. To avoid a formal definition, consider the following example

$$\psi = \exists x ((\forall y_1 \exists z_1 \forall u_1 \exists v_1 \psi_1) \wedge (\forall y_2 \exists z_2 \psi_2) \wedge (\exists y_3 \forall z_3 \psi_3)),$$

where the ψ_i 's are propositional formulas. Then, $\forall y_1$ depends on $\exists x$, $\exists z_1$ depends on $\forall y_1$ as well as on $\exists x$, $\forall y_2$ depends on $\exists x$, etc. but, e.g., $\exists z_2$ does not depend on $\forall y_1$. We say that a QBF has *depth m*, if the sequences of depending quantifiers provide at most $m-1$ alternations. Observe that ψ has depth 5 as witnessed by the “path” $\exists x \forall y_1 \exists z_1 \forall u_1 \exists v_1$. The aim of prenexing is to “linearize” quantifier dependencies (which in fact form a partial order) without increasing the depth of the QBF. We consider here four different *prenexing strategies*, namely “↑”, “↓”, “ $\exists \downarrow \forall \uparrow$ ”, and “ $\exists \uparrow \forall \downarrow$ ”. Hereby, “↑” (resp. “↓”) denotes that any quantifier is placed as outermost (resp. innermost) as possible in the prefix. “ $\exists \downarrow \forall \uparrow$ ” and “ $\exists \uparrow \forall \downarrow$ ” follow the same concept but now the handling is depending on the particular quantifier, i.e., whether it concerns an existential or a universal one. Thus, for our example formula ψ , we derive different PNFs of ψ having the same depth:

$$\begin{aligned} \uparrow &: \exists x y_3 \forall y_1 y_2 z_3 \exists z_1 z_2 \forall u_1 \exists v_1 (\psi_1 \wedge \psi_2 \wedge \psi_3); \\ \exists \downarrow \forall \downarrow &: \exists x y_3 \forall y_1 y_2 \exists z_1 z_2 \forall u_1 z_3 \exists v_1 (\psi_1 \wedge \psi_2 \wedge \psi_3); \\ \exists \downarrow \forall \uparrow &: \exists x \forall y_1 y_2 \exists z_1 y_3 \forall u_1 z_3 \exists v_1 z_2 (\psi_1 \wedge \psi_2 \wedge \psi_3); \\ \downarrow &: \exists x \forall y_1 \exists z_1 y_3 \forall u_1 y_2 z_3 \exists v_1 z_2 (\psi_1 \wedge \psi_2 \wedge \psi_3). \end{aligned}$$

QBFs in PNF are prototypical problems for complexity classes in the *polynomial hierarchy*. In fact, the evaluation problem of QBFs $\exists X_1 \forall X_2 \dots Q_i X_i \phi$ is Σ_i^P -complete with $Q_i = \exists$ if i is odd and $Q_i = \forall$ if i is even. Dually, evaluating $\forall X_1 \exists X_2 \dots Q_i X_i \phi$ is Π_i^P -complete, with $Q_i = \forall$ if i is odd, and $Q_i = \exists$ if i is even.

3 A Generalization of the DPLL Procedure

In this section we present the most important formal underpinnings of the presented solver qpro which relies on a generalized variant of the decision procedure due to Davis, Putnam, Loveland, and Logemann (DPLL for short). The DPLL procedure [9] represents one of the most successful algorithms to decide the truth value of a propositional formula. This method has been adapted for QBFs (in PCNF format) and it is used in many state-of-the-art solvers.

We generalize DPLL in such a way that it is applicable to arbitrary formulas in $\mathcal{L}_{\mathcal{P}}$, i.e., such that DPLL can be directly applied to QBFs

in NNF without additional transformations to PCNF. Figure 2 shows a simplified version of the program code of our decision procedure.

Note that DPLL is a direct implementation of the semantics for QBFs. The formula is split into subproblems, whose return values are treated according to the connective, the variables are replaced by truth constants, and simplifications are applied until a truth value is obtained. The basic decision procedure is thus a simple search-based backtracking algorithm which works in polynomial space with respect to the size of the input formula.

The function `simplify`(ϕ) in Figure 2 returns a formula which results from ϕ by applying numerous equivalence-preserving transformations, including, e.g., the following ones:

- (a) $\neg T \Rightarrow \perp$; $\neg \perp \Rightarrow T$;
- (b) $T \wedge \phi \Rightarrow \phi$; $\perp \wedge \phi \Rightarrow \perp$; $T \vee \phi \Rightarrow T$; $\perp \vee \phi \Rightarrow \phi$;
- (c) $(Qx \phi) \Rightarrow \phi$, $Q \in \{\forall, \exists\}$, x does not occur in ϕ ;
- (d) $\forall x(\phi \wedge \psi) \Rightarrow (\forall x\phi) \wedge (\forall x\psi)$;
- (e) $\forall x(\phi \vee \psi) \Rightarrow (\forall x\phi) \vee \psi$, whenever x does not occur in ψ ;
- (f) $\exists x(\phi \vee \psi) \Rightarrow (\exists x\phi) \vee (\exists x\psi)$;
- (g) $\exists x(\phi \wedge \psi) \Rightarrow (\exists x\phi) \wedge \psi$, whenever x does not occur in ψ .

Rewritings (d)–(g) are known as *miniscoping*. Note that the application of miniscoping is dynamic within the algorithm, due to the repetitive substitution of variables and simplifications of subformulas. Further simplifications are derived from generalizations of other well known concepts.

Definition 2 Let ϕ be a QBF, ψ a subformula of ϕ , $Q \in \{\forall, \exists\}$, and $\circ \in \{\vee, \wedge\}$. A literal $l \in \{x, \neg x\}$ is called

- local unit (wrt ψ) in ϕ , if ψ is of the form $(l \circ \psi')$;
- global unit (wrt ψ) in ϕ , if ψ is of the form $Qx(l \circ \psi')$;
- pure (wrt ψ) in ϕ , if ψ is of the form $Qx\psi'$, and \bar{l} does not occur in ψ' , where $\bar{x} = \neg x$ and $\bar{\neg x} = x$.

Proposition 1 Let ϕ be a closed QBF and let $l = x$ (resp. $l = \neg x$) be a (i) local-unit (ii) global-unit (iii) pure literal wrt a subformula ψ in ϕ , where ψ is given according to Definition 2. Then, ϕ is equivalent to the QBF resulting from ϕ by replacing ψ in case of

- (i) by $\begin{cases} l \circ \psi'[x/\top] & (\text{resp. } l \circ \psi'[x/\perp]) \\ l \circ \psi'[x/\perp] & (\text{resp. } l \circ \psi'[x/\top]) \end{cases}$ if $\circ = \wedge$;
- (ii) by $\begin{cases} (l \circ \psi')[x/\top] & (\text{resp. } (l \circ \psi')[x/\perp]) \\ (l \circ \psi')[x/\perp] & (\text{resp. } (l \circ \psi')[x/\top]) \end{cases}$ if x is existential;
- (iii) by $\begin{cases} \psi'[x/\top] & (\text{resp. } \psi'[x/\perp]) \\ \psi'[x/\perp] & (\text{resp. } \psi'[x/\top]) \end{cases}$ if x is universal.

Note that (ii) and (iii) delete Qx in ψ by an implicit application of (c) (since all occurrences of x in the scope of Qx have been replaced by \perp or \top). Also observe the following difference between (i) and (ii). In (i), the literal occurrence l in $(l \circ \psi)$ is not affected by the substitution of x , while in (ii) the substitution of x concerns also l in $(l \circ \psi)$. Note that (ii) yields—together with (a) and (b)—a replacement of the entire subformula $\psi = Qx(l \circ \psi')$ in ϕ by \top (resp. \perp), in the case $Q = \exists, \circ = \vee$ (resp. $Q = \forall, \circ = \wedge$). Finally, observe that (ii) also applies to formulas of the form $\psi = Qx_1 Q_1 X_1 \dots Q_n X_n (l \circ \psi'')$ since, by definition of QBFs, $x \notin X_i$, and with (e) and (g), we can transform ψ to be of form $Qx(l \circ \psi'')$.

The remaining part of the extended DPLL procedure in Figure 2 is straightforward but we have to face three sources of indeterminism

within the switch statement: if `simplify`(ϕ) returns a QBF $\phi_1 \vee \phi_2$ or $\phi_1 \wedge \phi_2$, we have to select (i) which subformula to evaluate first; this part differs from PCNF solvers, where such a decision is not necessary; if `simplify`(ϕ) returns $QX\psi$, with $Q \in \{\forall, \exists\}$, we have to select (ii) on which variable $x \in X$ to branch, and (iii) which subproblem (i.e., $\psi[x/\top]$ or $\psi[x/\perp]$) to consider first. Choice (ii) is obviously restricted by the dependencies between the quantifiers, since universal and existential quantifiers must not be permuted.

4 Dependency-Directed Backtracking

In this section we briefly describe an important technique called *dependency-directed backtracking* (DDB), which is known to be crucial for the efficiency of the DPLL procedure. In QBF solvers for PCNF, this technique only works for false subproblems. Starting from [20], we generalize this technique to arbitrary formulas, for which it can be applied to *true and false subproblems*. DDB for false subproblems applies to existential variables, whereas DDB for true subproblems applies to universal variables.

When we inspect a branching tree, we may notice that some branches (together with the corresponding subtrees) can be omitted without influencing the (partial) evaluation result. In this case, the result is independent from the assignments of some variables. If we have set such a variable x to one truth value, we can safely omit the assignment of x to the other truth value at this point in the branching tree during backtracking. Consider Figure 1 as an example and observe that the tree is *symmetric*, i.e., the left and the right subtree of x_1 (both with root y_1) are identical. Suppose the prover has finished the left half of the branching tree. Under the assignment \perp for x_1 , the resulting simplified formula $\phi' : \forall x_2 \exists y_2 ((x_2 \vee \neg y_2) \wedge (\neg x_2 \vee y_2))$ evaluates to true. Since x_1 is a universal variable, the next assignment for it is \top . A clever solver notices that x_1 has no influence on the truth value of ϕ' with the consequence that ϕ' is true under the new assignment. So, no further assignments are performed because we can utilize the result of the left subtree with root y_1 . What we have described here is DDB on true subproblems (neglecting substitutions of unit and pure literals, however, for the matter of presentation). The more common DDB on false subproblems works as expected.

We have implemented two different sound and complete backtracking techniques, namely *labeling* and *relevance sets*. Since the latter is superior to the former and since all experiments have been performed using the latter, we only describe *DDB by relevance sets* here. We present this technique only for true subproblems, but it works dually for false ones.

Let R_y denote the *relevance set* for a node y . If the solver reaches a leaf l in the branching tree, only those variables whose assignments determine the truth value of the formula (i.e., the label of l) form R_l . Assume we return from a subtree P_1 with root x_1 to the variable x directly above x_1 during backtracking and P_1 is true. If x is existential, then $R_x = R_{x_1}$. If x is universal, then we check whether x is contained in R_{x_1} . If $x \notin R_{x_1}$ holds, then the other subproblem P'_1 is true and $R_x = R_{x_1}$. Otherwise, the relevance set R'_{x_1} of P'_1 has to be considered. We construct R_x as follows. If $x \notin R'_{x_1}$ holds, then $R_x = R'_{x_1}$. Otherwise, R is set to $R_{x_1} \cup R'_{x_1}$.

5 Experimental Evaluation

In this section we compare the performance of our new solver `qpro` against the established systems QuBE-BJ [17] (v1.2), `sKizzo` [5] (v0.4), `semprop` [20] (rel. 24/02/02), and `quantor` [7] (rel. 25/01/04). These solvers have been selected because they have shown to be

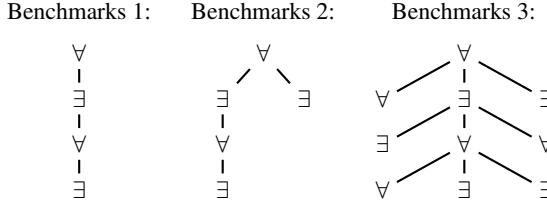

Figure 3. Quantifier dependencies of the different benchmarks.

competitive in previous QBF evaluations and do not deliver wrong results on our benchmarks. Moreover, QuBE–BJ and semprop implement backtracking techniques, similar to the one used in qpro. Finally, sKizzo and quantor try to extract original quantifier dependencies from a PCNF, and thus may detect similar structural information on the input formula as qpro has got *a priori* from the input of the corresponding nonprenex formula.

All solvers except qpro require the input to be in PCNF. We thus apply the following test strategy: Given a benchmark QBF ϕ not in PCNF, we (i) provide ϕ as input to qpro; (ii) translate ϕ into PCNF and provide the outcome as input to the other solvers. The exact way we obtained the PCNFs is discussed below. We have chosen the following benchmark formulas (not in PCNF).⁴

1. Encodings for satisfiability in modal logic K .
2. Encodings for correspondence tests in answer-set programming.
3. Encodings of reasoning with nested counterfactuals.

In what follows, we briefly describe the benchmarks. For detailed information, the reader is referred to the according references.

The first set of benchmarks contains instances which were also used in the TANCS’98 comparison of provers for modal logics. Applying the encoding from [22] yields QBFs with a linear dependency among the quantifiers. Hence, the translation to PNF is fully determined (there is just one way to shift the quantifiers in front of the formula).

The benchmarks in the second set encode correspondence tests between propositional logic programs under the answer-set semantics, where it is checked whether two programs provide equal projected answer-sets under any program extension over a specified alphabet, cf. [25]. For the benchmarks, we use two strategies, namely “ \uparrow ” and “ \downarrow ” to obtain formulas in PCNF.

The benchmarks in the third set encode the problem of reasoning over nested counterfactuals [15]. For this set of formulas, the quantifier dependencies allow for several different translations into PCNF. We have applied each strategy from [15] to the PCNF solvers. To be fair, we show only the results for the best strategy of each solver.

The structural differences between these sets are best illustrated by the quantifier dependencies of the formulas. We depict them for the case of QBFs of depth 4 in Figure 3. Hence, the chosen benchmarks provide an increasing complexity in their structure, and therefore, an increasing disruption of the structure during the transformation to PNF can be expected. In particular, for Benchmarks 1, we just can investigate the effect of applying the transformation of one shifting strategy, since the prefix is already determined by the encoding. Benchmarks 2 allow to analyze the effect of prenexing if there is only a small deviation from a linear quantifier dependency. In fact, using either strategy “ \uparrow ” or “ \downarrow ”, one can place the group of existential quantifiers from the right path either together with the upper or the lower set of existential quantifiers from the left path. Finally, Benchmarks 3 provide formulas, for which different PNFs can be obtained.

⁴ PCNF versions are part of the QBFLIB, <http://www.qbflib.org/>.

Table 2. Benchmarks 2: Answer Set Correspondence.

We ran our tests on an Intel Xeon 3 GHz with 4GB of RAM. All solvers are used with their predefined standard options. For each instance, we set a timeout of 100 seconds. We report both the number of timeouts per set of benchmarks, as well as the average runtimes, where formulas with timeout are considered to be solved in 100 seconds. In what follows, we present our results on the benchmarks.⁵

Benchmarks 1: Modal Logic K. This set contains 378 formulas arranged in 18 subsets, with 21 formulas each. Half of the formulas evaluates to true. Depending on the modal depth of the original formula, the depth of the encodings ranges from 5 to 133; the number of variables ranges from less than 40 to more than 4300. Due to the transformation into PCNF, the number of variables increases up to more than 12800 in the worst case. The results are given in Table 1.

Benchmarks 2: Answer-Set Correspondence. Here, the test series comprise 1000 instances (465 are true and 535 are false). We ran each problem on two different encodings, S and T, where T is an explicit optimization of S (see [25] for details). The problem of answer-set correspondence is Π_4^P -complete, and thus all QBFs in this set have depth 4. The quantifier dependencies, as depicted in Figure 3, are the same for S and T and suggest to distinct between two strategies for obtaining PCNFs, viz. \uparrow and \downarrow . The QBFs possess, in case of S, 200 variables and, in case of T, 152 variables. The additional translation into PCNF yields, in case of S, QBFs over 2851 variables and, in case of T, QBFs over 2555 variables. The results for each solver on each combination of the chosen translation and (in the case of PCNF solvers) prenexing strategy are given in Table 2.

Benchmarks 3: Nested Counterfactuals. The final set of benchmarks are encodings of nested counterfactual reasoning, separated by

⁵ We highlight the best runtime for each test set (discrepancies due to measurement inaccuracy are ignored).

the depth of the resulting QBFs which ranges from 4 to 8. For each depth, we created 50 instances, where the QBFs contain 183, 245, 309, 375, and 443 variables. The transformation to PCNF increases the number of variables to 464, 600, 786, 934, and 1132. In total, we have about 60% true and 40% false instances. As mentioned above, these encodings allow for several different prenexing strategies. For space reasons, we do not present the results for each strategy here, but Table 3 shows the results for the *best* strategy which has been derived for each solver on the entire set of QBFs. Recall that for qpro we do not need to apply any such strategy.

		number of timeouts				average runtimes (in sec.)			
		qpro	QuBE-BJ	semprop	sKizzo	quantor	qpro	QuBE-BJ	semprop

6 Discussion and Conclusion

We presented a new QBF solver, qpro, which significantly differs from previous approaches by its ability to process arbitrary QBFs instead of QBFs in PCNF. We sketched generalizations of the DPLL procedure necessary to handle arbitrary QBFs and briefly discussed implemented performance-improving techniques like different forms of dependency-directed backtracking. Future work calls for an analysis how the different pruning techniques influence performance.

In practical applications, QBF solvers can be used as a black box in reasoning systems to solve encodings of the problems considered. Usually such encodings are not in PCNF and, as we have shown in our experiments, avoiding the additional translation into PCNF may result in much better performance. In what follows, we briefly discuss two main observations from our experiments.

- The more information on quantifier dependencies is lost due to prenexing, the more competitive qpro turns out to be. Table 3 contains those benchmarks where this effect is most apparent. Although we compare qpro here against the PCNF solvers together with their *best* suited strategy, qpro significantly outperforms all other solvers.
- Table 2 presents results for two different encodings of the same problem where T is an explicit optimization of S. These results show that qpro is less depending on the chosen encoding, whereas the performance of PCNF solvers differs much more. In fact, qpro performs better on the unoptimized encoding S, in the case the “wrong” prenexing strategy “↑” is used for the PCNF solvers.

Finally, we briefly discuss related systems.

- There are a few further solvers, namely QUBOS [2], boole⁶, and zqsat [16], which also allow arbitrary QBFs as input, but rely on different techniques. QUBOS simplifies the QBF and then constructs an equivalent propositional formula which is evaluated by SAT solvers, whereas boole is based on binary decision diagrams (BDDs). Thus both need exponential space in the worst case. We have included boole in our pre-tests, but it was not competitive at the benchmarks. We also neglected QUBOS, because it yielded wrong results on some problems. Finally, zqsat implements DPLL using zero-compressed BDDs. The comparison to zqsat is subject to future work.
- In [18], an extension to QuBE was suggested, where the input is a QBF in PCNF together with information on quantifier dependencies. Contrary to this approach, ours avoids the bounded renaming of

⁶ <http://www.cs.cmu.edu/~modelcheck/bdd.html>.

variables during the prefix construction together with the necessity to transform the matrix into CNF. This enables us to dynamically (i) apply miniscoping and (ii) recognize independent subproblems which can be solved in parallel. Nonetheless, the results in [18] lead to observations in the same direction as ours. Future work will include a detailed comparison of the two approaches, which will be done as soon as the modified QuBE system is available.

Knowledge Engineering for Bayesian Networks: How Common Are Noisy-MAX Distributions in Practice?

Adam Zagorecki¹ and Marek Druzdzel²

Abstract. One problem faced in knowledge engineering for Bayesian networks is the exponential growth of the number of parameters in their conditional probability tables (CPTs). The most common practical solution is application of the noisy-OR (or their generalization, the noisy-MAX) gates, which take advantage of independence of causal interactions and provide a logarithmic reduction of the number of parameters required to specify a CPT. In this paper, we propose an algorithm that fits a noisy-MAX distribution to an existing CPT and we apply it to search for noisy-MAX gates in three existing practical Bayesian networks. We show that noisy-MAX gate provides a surprisingly good fit for as many as 50% of CPTs in these networks. The importance of this finding is that it provides an empirical justification for the use of the noisy-MAX gate as a powerful knowledge engineering tool.

1 INTRODUCTION

Bayesian networks [1] provide a convenient and sound framework for encoding uncertain knowledge and for reasoning with it. A Bayesian network (BN) is essentially an acyclic directed graph encoding a factorization of a joint probability distribution. The structure of the graph represents the variables and independencies among them, while the probability distributions over the individual variables conditional on their direct predecessors (parents) represent individual components of the factorization.

When a node of a BN and all its parents are discrete, the conditional probability distributions are stored in *conditional probability tables* (CPTs) indexed by all possible combinations of states of the parents. This poses considerable difficulties to knowledge engineering, to learning BNs from data, and to inference algorithms for BNs. An ingenious practical solution to this problem has been the application of parametric conditional distributions, such as the noisy-OR. By taking advantage of *independence of causal interaction* (ICI), these gates offer a reduction of the number of parameters required to specify a conditional probability distribution from exponential to linear in the number of parents.

The two most widely applied ICI distributions are the binary noisy-OR model [2] and its extension to multi-valued variables, the noisy-MAX model [3, 4]. Noisy-OR and noisy-MAX gates have proven their worth in many real-life applications (e.g., [5, 6, 7]). Their foremost advantage is a small number of parameters that are sufficient to specify the entire CPT. This leads to a significant reduction of effort in knowledge elicitation from experts [3, 5], improves

the quality of distributions learned from data [8], and reduces the spatial and temporal complexity of algorithms for Bayesian networks [9, 10].

Our research aims at better understanding of the applicability of the noisy-MAX gates in practical BN models. We achieve this by developing a technique for fitting noisy-MAX relationships to existing, fully specified CPTs. Having this technique, we can examine CPTs in existing practical BN models for whether they can be approximated by the noisy-MAX model.

We analyze CPTs in three existing sizeable Bayesian network models: ALARM [11], HAILFINDER [12] and HEPAR II [8]. We show that the noisy-MAX gate provides a surprisingly good fit for a significant percentage of distributions in these networks. We observed this in both, distributions elicited from experts and those learned from data and for two measures of distance between distributions. We test the robustness of this result by fitting the noisy-MAX distribution to randomly generated CPTs and observe that the fit in this case is poor. Obtaining a randomly generated CPT that can be reasonably approximated by a noisy-MAX gate is extremely unlikely, which leads us to the conclusion that our results are not a coincidence. We investigate the influence of the conversion to the noisy-MAX on the precision of posterior probability distributions.

We envision two applications of this technique. The first is a possible refocusing of knowledge engineering effort from obtaining an exponential number of numerical probabilities to a much smaller number of noisy-MAX parameters. While a parametric distribution may be only an approximation to a set of general conditional probability distributions, the precision that goes with the latter is often only theoretical. In practice, obtaining large numbers numerical probabilities is likely to lead to expert exhaustion and result in poor quality estimates. Focusing the expert's effort on a small number of parameters of a corresponding parametric distribution should lead to a better quality model. The second application of our technique is in approximate algorithms for Bayesian networks. Whenever the fit is good, a CPT can be replaced by an ICI gate, leading to potentially significant savings in computation [9].

The remainder of this paper is organized as follows. Section 2 introduces the noisy-OR and the noisy-MAX gates. Section 3 proposes our algorithm for fitting noisy-MAX parameters to an arbitrary CPT. Section 4 presents the empirical results of the experiments testing the goodness of fit for several existing practical networks. In Section 5, we propose an explanation of the observed results.

2 NOISY-OR AND NOISY-MAX

We will represent random variables by upper-case letters (e.g., X) and their values by indexed lower-case letters, (e.g., x_1). We use

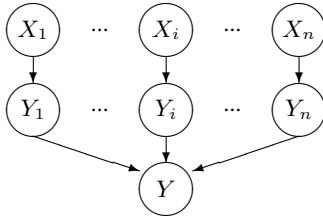

Figure 1. Direct modelling of noisy-OR

$Rng(X)$ to denote the range (the set of possible values) of a variable X . We assume that all variables are discrete. Let there be n binary nodes X_1, \dots, X_n , each with values from $Rng(X_i) = \{x_i, \bar{x}_i\}$. Let the variables X_i be the parents of an effect variable Y that assumes values y and \bar{y} .

A useful concept for modeling the noisy-OR by means of the deterministic OR, is that of the *inhibitor* nodes [1, 10], which model individual probabilistic relations between each cause and the effect individually. The general model including inhibitor nodes is shown in Fig. 1. The CPT of Y defines how those individual effects combine to produce Y . For the noisy-OR model, the CPT of node Y is equivalent to a deterministic OR. The *inhibitor* nodes Y_i introduce *noise* — the probabilistic effect of X_i on Y . The CPT of each Y_i is of the form: $\Pr(y_i|x_i) = p_i$ where $p_i \in [0, 1]$, and $\Pr(y_i|\bar{x}_i) = 0$. The noisy-MAX [3, 4] is basically an extension of the noisy-OR model to multi-valued variables. The noisy-MAX assumes that the variable Y has n_y states and that these states are ordered. The inhibitor nodes Y_i take values from the same domain as Y and their states follow the same ordering. Every parent variable X_i has n_i values. We use q_{ijk} to denote the element of CPT of inhibitor node Y_i that corresponds to the j -th value of parent node X_i and k -th value of Y : $\forall_{ijk} q_{ijk} = \Pr(y_i^k|x_i^j)$. Probabilities q_{ijk} are noisy-MAX parameters. The inhibitor variables Y_i have the same range as Y and their CPTs are constrained in the following way:

$$q_{ijk} = \begin{cases} 1 & \text{if } j = 1, k = 1 \\ 0 & \text{if } j = 1, k \neq 1 \\ p \in [0 \dots 1] & \text{if } j \neq 1 \end{cases}$$

The CPT of Y is a deterministic MAX defined by the ordering relation over states of Y . It is a common practice to add a *leak* term to the noisy-OR model. The leak is an auxiliary cause that serves the purpose of modeling the influence of causes that are not explicitly included in the model. In our experiments, we always assume that the noisy-MAX model includes the leak probability.

3 CONVERTING CPT INTO NOISY-MAX GATE

In this section, we propose an algorithm that fits a noisy-MAX distribution to an arbitrary CPT. In other words, it identifies the set of noisy-MAX parameters that produces a CPT that is the *closest* to the original CPT. Let C_Y be the CPT of a node Y that has n parent variables X_1, \dots, X_n . Each variable X_i can take one of n_{X_i} possible values. We use \mathbf{p}_i to denote i -th combination of the parents of Y and \mathbf{P} to denote the set of all combinations of parents values, $\mathbf{P} = \{\mathbf{p}_1, \dots, \mathbf{p}_m\}$, where m is the product of the numbers of possible values of the X_i s, i.e., $m = \prod_{i=1}^n n_{X_i}$. There exist several measures of similarity of two probability distributions of which two are commonly used: Euclidean distance and Kullback-Leibler (KL) divergence. The main difference between the two is that the Euclidean

distance is based on absolute differences and, hence, is insensitive to large relative differences in very small probabilities, which is its major drawback. The KL divergence addresses this problem, but on the other hand, the problem with KL divergence is that for cases when the estimated probability is zero and the goal probability is non-zero, it is infinity. In our experiments, in such cases we replaced zero with a constant close to zero, which is a common practice.

The problem of defining a distance between two CPTs is somewhat more complicated, because a CPT is a set of probability distributions. The easiest approach is to define distance between two CPTs as a sum of distances of corresponding probability distributions in both CPTs. However, in practice not all distributions in the CPT are equally important. This is because typically some of the configurations of parents' states are far more likely than the others.

Definition 1 (Euclidean distance between two CPTs) *The distance D_E between two CPTs, $\Pr_A(Y|\mathbf{P})$ and $\Pr_B(Y|\mathbf{P})$ is a weighted sum of Euclidean distances between their corresponding probability distributions:*

$$\begin{aligned} D_E(\Pr_A(Y|\mathbf{P}), \Pr_B(Y|\mathbf{P})) &= \\ &= \sum_{i=1}^m w_{\mathbf{p}_i} \sum_{j=1}^{n_Y} \left(\Pr_A(y_j|\mathbf{p}_i) - \Pr_B(y_j|\mathbf{p}_i) \right)^2. \end{aligned} \quad (1)$$

Definition 2 (KL divergence between CPTs) *The divergence D_{KL} between the goal CPT $\Pr_A(Y|\mathbf{P})$ and its approximation $\Pr_B(Y|\mathbf{P})$ is a weighted sum of KL divergences between their corresponding probability distributions:*

$$\begin{aligned} D_{KL}(\Pr_A(Y|\mathbf{P}), \Pr_B(Y|\mathbf{P})) &= \\ &= \sum_{i=1}^m w_{\mathbf{p}_i} \sum_{j=1}^{n_Y} \Pr(y_j|\mathbf{p}_i) \ln \frac{\Pr_A(y_j|\mathbf{p}_i)}{\Pr_B(y_j|\mathbf{p}_i)}, \end{aligned} \quad (2)$$

In both definitions $w_{\mathbf{p}_i}$ is a weighting constant for each distribution in the CPT and $w_{\mathbf{p}_i} = P(\mathbf{p}_i)$.

Definition 3 (MAX-based CPT) *A MAX-based CPT $\Pr_q(Y|\mathbf{P})$ is a CPT constructed from a set of noisy-MAX parameters \mathbf{q} .*

Our goal is to find for a given fully specified CPT $\Pr_{cpt}(Y|\mathbf{P})$, such set of the noisy-MAX parameters \mathbf{q} that minimizes the Euclidean distance between the original CPT and the MAX-based CPT $\Pr_q(Y|\mathbf{p}_i)$. For simplicity, we will use θ_{ij} to denote the element of CPT that corresponds to the i -th element of \mathbf{P} and j -th state of Y . When this parameter is given in a fully defined CPT, we use upper index θ_{ij}^{cpt} , and when the parameter was obtained from the MAX-based CPT, we use upper index θ_{ij}^{max} . We can now rewrite Eq. 1 as:

$$\sum_{i=1}^m w_{\mathbf{p}_i} \sum_{j=1}^{n_Y} (\theta_{ij}^{cpt} - \theta_{ij}^{max})^2.$$

Because further part of our discussion relies heavily on cumulative probabilities, we introduce cumulative probability distributions based on the parameters θ_{ij} and q_{ij} . We define Θ_{ij} as:

$$\Theta_{ij} = \begin{cases} \sum_{k=1}^j \theta_{ik} & \text{if } j \neq 0 \\ 0 & \text{if } j = 0, \end{cases}$$

which constructs a cumulative probability distribution function for $\Pr(Y|\mathbf{p}_i)$. It is easy to notice, that $\theta_{ij} = \Theta_{ij} - \Theta_{i(j-1)}$. The next step is to express the MAX-based CPT parameters θ_{ij}^{max} in terms of the noisy-MAX parameters. In similar manner, we define the cumulative probability distribution of noisy-MAX parameters as:

$$Q_{ijk} = \begin{cases} \sum_{l=1}^k q_{ijl} & \text{if } j \neq 0 \\ 0 & \text{if } j = 0. \end{cases}$$

Pradhan et al. [6] proposed an algorithm exploiting cumulative probability distributions for efficient calculation of the MAX-based CPT that computes parameters of the MAX-based CPT as follows:

$$\Theta_{ij}^{max} = \prod_{x_p^r \in \mathbf{p}_i} Q_{prj}. \quad (3)$$

The product in Eq. 3 is taken over all elements of the cumulative distributions of noisy-MAX parameters, such that the values of a parent node X_i belong to a combination of parent states in CPT. Eq. 4 shows how to compute the element θ_{ij}^{max} from the noisy-MAX parameters:

$$\begin{aligned} \theta_{ij}^{max} &= \Theta_{ij}^{max} - \Theta_{i(j-1)}^{max} \\ &= \prod_{x_p^r \in \mathbf{p}_i} Q_{prj} - \prod_{x_p^r \in \mathbf{p}_i} Q_{pr(j-1)} \\ &= \prod_{x_p^r \in \mathbf{p}_i} \sum_{k=1}^j q_{prk} - \prod_{x_p^r \in \mathbf{p}_i} \sum_{k=1}^{j-1} q_{prk}. \end{aligned} \quad (4)$$

However, parameters θ_{ij}^{max} have to obey the axioms of probability, which means that we have only $n_Y - 1$ independent terms and not n_Y , as the notation suggests. Hence, we can express θ_{ij}^{max} in the following way:

$$\theta_{ij}^{max} = \begin{cases} \prod_{x_p^r \in \mathbf{p}_i} \sum_{k=1}^j q_{prk} - \prod_{x_p^r \in \mathbf{p}_i} \sum_{k=1}^{j-1} q_{prk} & \text{if } j \neq n_Y \\ 1 - \prod_{x_p^r \in \mathbf{p}_i} \sum_{k=1}^{n_Y-1} q_{prk} & \text{if } j = n_Y. \end{cases}$$

Theorem 1 *The distance D_E between an arbitrary CPT $\Pr_{cpt}(Y|\mathbf{P})$ and a MAX-based CPT $\Pr_q(Y|\mathbf{P})$ of noisy-MAX parameters \mathbf{q} as a function \mathbf{q} has exactly one minimum.*

Proof 1 *We prove that for each noisy-MAX parameter $q \in \mathbf{q}$, the first derivative of D_E has exactly one zero point. We will subsequently show that the second derivative is always positive, which indicates that D_E has exactly one minimum and proves the theorem. The first derivative of D_E over q is*

$$\begin{aligned} \frac{\partial}{\partial q} \sum_{i=1}^m w_{\mathbf{p}_i} \sum_{j=1}^{n_Y-1} \left(\theta_{ij}^{cpt} - \prod_{x_p^r \in \mathbf{p}_i} \sum_{k=1}^j q_{prk} + \prod_{x_p^r \in \mathbf{p}_i} \sum_{k=1}^{j-1} q_{prk} \right)^2 \\ + \frac{\partial}{\partial q} w_{\mathbf{p}_i} \sum_{i=1}^m \left(- \sum_{j=1}^{n_Y-1} \theta_{ij}^{cpt} + \prod_{x_p^r \in \mathbf{p}_i} \sum_{k=1}^{n_Y-1} q_{prk} \right)^2. \end{aligned}$$

Each of the three products contains at most one term q and, hence, the expression takes the following form:

$$\frac{\partial}{\partial q} \sum_{i,j} (A_{ij} + B_{ij}q)^2, \quad (5)$$

where A_{ij} and B_{ij} are constants. At least some of the terms B_{ij} have to be non-zero (because external sum in Eq. 5 runs over all elements of the CPT). The derivative

$$\frac{\partial}{\partial q} \sum_{i,j} (A_{ij} + B_{ij}q)^2 = 2 \sum_{i,j} (A_{ij}B_{ij}) + 2q \sum_{i,j} B_{ij}^2$$

is a non-trivial linear function of q . The second order derivative is equal to $2 \sum_{i,j} B_{ij}^2$ and always takes positive values. Therefore, there exist exactly one local minimum of the original function.

In our approach, for a given CPT we try to identify the set of noisy-MAX parameters that minimizes the distances D_E or D_{KL} .

The problem amounts to finding the minimum of the distance which is a multidimensional function of the noisy-MAX parameters. We proved that for the Euclidean distance, there exists exactly one local minimum. Therefore, any mathematical optimization method ensuring convergence to a single minimum can be used. In case of KL divergence, we have no guarantee that there exists exactly one local minimum. But for the purpose of our experiments, this is a conservative assumption. To perform our experiments we implemented a simple gradient descent algorithm that takes a CPT as an input and produces noisy-MAX parameters and a measure of fit as an output.

4 HOW COMMON ARE NOISY-MAX GATES IN REAL MODELS

We decided to test several sizeable real world models in which probabilities were specified by an expert, learned from data, or combination of both. Three models that contained sufficiently large CPTs which were defined without parametric distributions were available to us: ALARM [12], HAILFINDER [11] and HEPAR II [8]. We verified by contacting the authors of these models that none of the CPTs in these networks were specified using the noisy-OR/MAX assumption. For each of the networks, we first identified all nodes that had at least two parents and then we applied our conversion algorithm to these nodes. HEPAR contains 31 such nodes, while ALARM and HAILFINDER contain 17 and 19 such nodes respectively. We tried to fit the noisy-MAX model to each of these nodes using both D_E and D_{KL} measures.

We used two criteria to measure the goodness of fit between a CPT and its MAX-based equivalent: (1) *Average*, the average Euclidean distance (with square root, not weighted by probabilities of parents instantiations) between the two corresponding parameters and (2) *Max*, the maximal absolute value of difference between two corresponding parameters, which is an indicator of the single worst parameter fit for a given CPT.

Fig. 2 shows the results for the three tested networks for Euclidean and KL measures respectively. The figures show the distance for all networks on one plot. The nodes in each of the networks are sorted according to the corresponding distance (*Average* or *MAX*) and the scale is converted to percentages. We can see for the *MAX* distance that for roughly 50% of the variables in two of the networks the greatest difference between two corresponding values in the compared CPTs was less than 0.1.

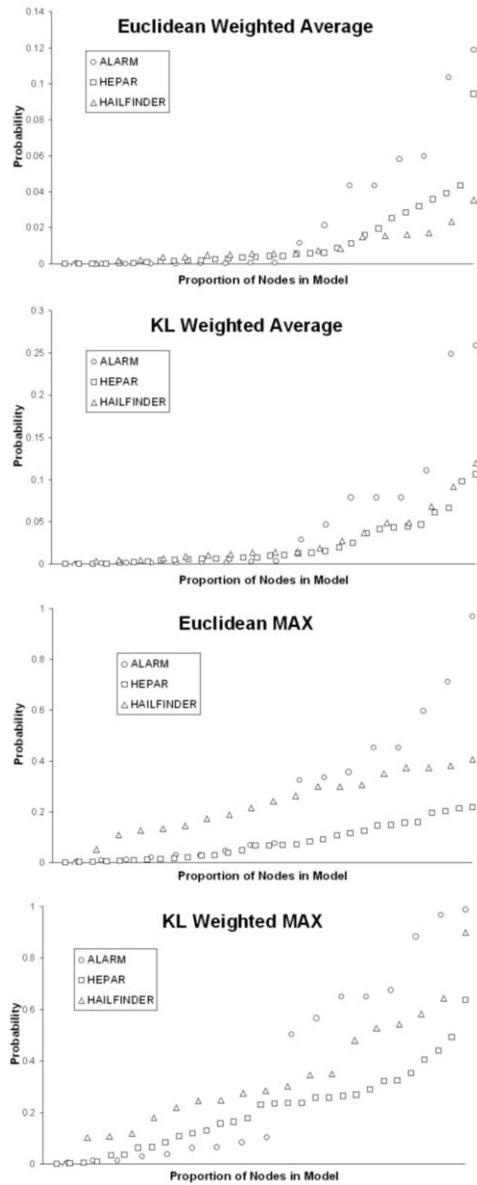

Figure 2. The Average and MAX distance for the nodes of the three analyzed networks obtained using weighted distances.

One possible explanation of our findings is that the noisy-MAX model is likely to fit well any randomly selected CPT. We decided to verify this by generating CPTs for binary nodes, with 2-5 parents (10,000 CPTs for every number of parents, for a total of 40,000 CPTs), whose parameters were sampled from the uniform distribution. Fig. 3 shows the results. On the X-axis there are generated CPTs sorted according to their fit to the noisy-OR using average and MAX measures. Except for the cases with two parents, the results are qualitatively different from the results we obtained using real-life models. They clearly indicate that approximating a randomly generated CPT by the noisy-OR is highly improbable. Additionally, these results can provide empirical grounds for interpretation of values of distance measures.

The small difference in the conditional probabilities does not necessarily imply that differences in the posterior probabilities will be of

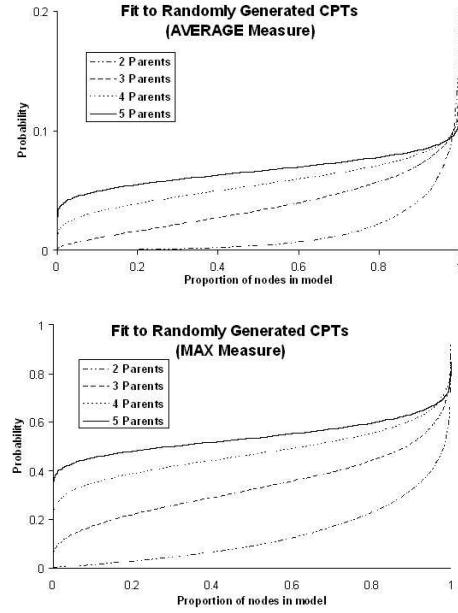

Figure 3. The Average and MAX distances for randomly generated CPTs.

a similar magnitude. We decided to test the accuracy of models with some nodes converted into the noisy-MAX. For each of the tested networks we converted one by one the selected nodes into noisy-MAX gates using Euclidean and KL measures. In this way, after each node had been converted, the new model was created. For each such model we generated random evidence using logic sampling for 10% of the nodes in the network and calculated the posterior probability distributions over the remaining nodes. We compared these posterior probabilities to those obtained in the original model, which we treated as the gold standard. We repeated the procedure described above 1000 times for each of the three models.

We decided to perform fit of the noisy-MAX model to CPTs without taking into account the probabilities of parent instantiations. One may argue that to answer the question if a local distribution fits the noisy-MAX should not take into account the proper distribution of parent variables. It is equivalent to assuming that the constants w_{P_i} in Eqs. 1 and 2 are always equal to 1. We decided to report these results together with the weighted distances. In the sequel, we will refer to uniformly weighted distributions as *simple* and the weighted according to probabilities of parent combinations as *weighted*.

Fig. 4 shows the results of tests for accuracy of posterior probabilities for the three networks. On the X-axis there are nodes sorted by the goodness of fit. On the Y-axis there is absolute average maximal error between posterior probabilities for 1,000 trials. We observe a consistent tendency that the accuracy of the posterior probabilities is poorer for nodes that have worse fit to the noisy-MAX. From these results one can conclude that the weighted KL divergence is superior to other distances, when it comes to CPTs which are good fits to the noisy-MAX (these at the left hand side of X-axis). The nodes on the right hand side are usually not of interest, because they represent nodes that are not good fit anyway. The nature of maximal error can explain the weighted distances' worse performance in case of HEPAR II network. The HEPAR II network has many small probabilities, and these lead to orders of magnitude differences in probabilities of parents' instantiations. The weighted distances work well on the

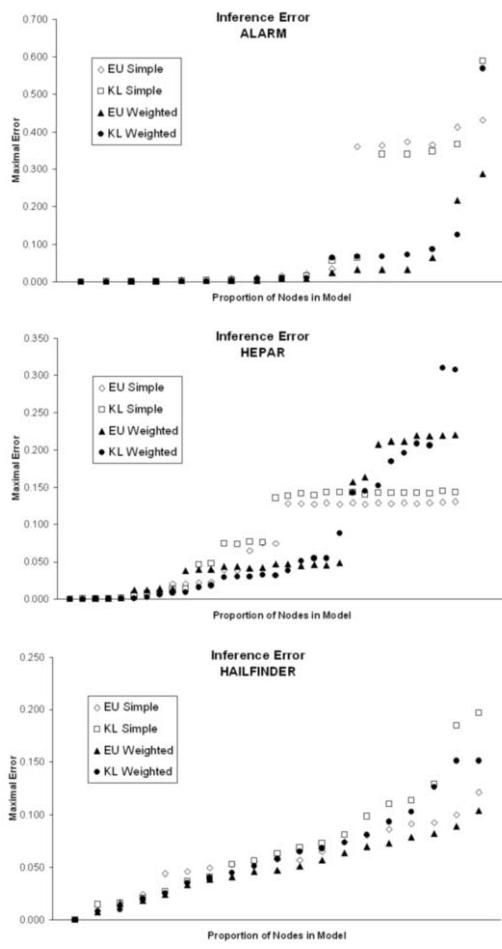

Figure 4. Accuracy of the posterior probabilities for the three networks. Evidence sampled from the posterior distribution.

average, but their performance can be worse for less likely scenarios and this additionally can be amplified by using the maximal measure, which captures the worst case scenario.

In the later version of the HEPAR II model domain expert's knowledge was used to identify variables that are candidates for the noisy-MAX distributions [8]. We had an access to this later version of the model and we could compare results obtained by our algorithm to the variables indicated by the expert. The surprising part is that the expert did not identify variables that were the best fit – she listed only 4 of the 10 variables with the best fit. Apparently the experts strategy was to convert as much as possible variables with large CPTs to the noisy-MAX, even though they were not a good fit. After some closer investigation, we concluded that these nodes are indeed a good fit to the noisy-MAX, but they required relatively complex manipulations on the order of states to fit the noisy-MAX model which was possibly beyond expert's modeling skills.

5 DISCUSSION

In this paper, we introduced two measures of distance between two CPTs – one based on the Euclidean distance and one based on the KL divergence. We proved that Euclidean distance between any CPT and a MAX-based CPT, as a function of the noisy-MAX parame-

ters of the latter, has exactly one minimum. We applied this result to an algorithm that given a CPT finds a noisy-MAX distribution that provides the best fit to it. Subsequently, we analyzed CPTs in three existing Bayesian network models using both measures. Our experimental results suggest that the noisy-MAX gate may provide a surprisingly good fit for as many as 50% of CPTs in practical networks. We demonstrated, that this result can not be observed in randomly generated CPTs. We tested the influence of accuracy of the approximation of a CPTs by noisy-MAX gates on the accuracy of posterior probabilities showing that models with some nodes converted to the noisy-MAX provide good approximation of the original models. Our results provide strong empirical support for the practical value of the noisy-MAX models. We showed that the relation defined by the noisy-MAX often approximates interactions in the modeled domain reasonably well. It seems to us, based on this result, that the independence of causal interactions is fairly common in real-world distributions.

A Unified Model for Multilabel Classification and Ranking

Klaus Brinker¹ and Johannes Fürnkranz² and Eyke Hüllermeier¹

Abstract. Label ranking studies the problem of learning a mapping from instances to rankings over a predefined set of labels. Hitherto existing approaches to label ranking implicitly operate on an underlying (utility) scale which is not calibrated in the sense that it lacks a natural zero point. We propose a suitable extension of label ranking that incorporates the calibrated scenario and substantially extends the expressive power of these approaches. In particular, our extension suggests a conceptually novel technique for extending the common *learning by pairwise comparison* approach to the multilabel scenario, a setting previously not being amenable to the pairwise decomposition technique. We present empirical results in the area of text categorization and gene analysis, underscoring the merits of the calibrated model in comparison to state-of-the-art multilabel learning methods.

1 INTRODUCTION

Label ranking, a particular preference learning scenario [7], studies the problem of learning a mapping from instances (typically represented by feature vectors) to rankings over a finite number of predefined *labels*, in this context also referred to as *alternatives*. Approaches that operate in this framework include *Ranking by pairwise comparison* (RPC) as a natural extension of pairwise classification [6] and *constraint classification* which aims at learning a linear utility function for each label [8].

Although this framework is very general in the sense that simpler learning problems, such as classification or l -multilabel classification can be embedded as special cases, it is restricted to ranking the labels on a non-calibrated scale, that is, a scale which lacks a natural zero-point. Learning problems, such as conventional multilabel learning, which require a bipartite partition into complementary sets (relevant and non-relevant) do not admit a representation as special instances of either RPC or constraint classification. More generally, as a consequence of the underlying non-calibrated scales, both approaches cannot learn to determine the relevant/non-relevant cutoff, even though this information is specified in the training data.

We will present a general model avoiding the aforementioned drawbacks by incorporating a calibrated scale which contains a natural zero-point. Extending conventional label ranking approaches, this novel framework provides a means to represent and learn bipartite partitions of alternatives. In particular, it suggests a conceptually new technique for extending the common pairwise classification learning approach to the multilabel scenario, a setting previously not being amenable to a pairwise decomposition technique.

2 LABEL RANKING

In label ranking, the problem is to learn a mapping from instances $x \in \mathcal{X}$ to rankings \succ_x (total strict orders) over a finite set of labels $\mathcal{L} = \{\lambda_1, \dots, \lambda_c\}$, where $\lambda_i \succ_x \lambda_j$ means that, for instance x , label λ_i is preferred to λ_j . A ranking over \mathcal{L} can be represented by a permutation as there exists a unique permutation τ such that $\lambda_i \succ_x \lambda_j$ iff $\tau(\lambda_i) < \tau(\lambda_j)$, where $\tau(\lambda_i)$ denotes the position of the label λ_i in the ranking. The target space of all permutations over c labels will be referred to as \mathcal{S}_c .

It has been pointed out in several publications [8; 6; 3] that a variety of learning problems may be viewed as special cases of label ranking (perhaps supplemented by a straightforward projection of the output space \mathcal{S}_c) hence underscoring the importance of this setting. Among those are the following:

- *Multiclass Classification:* A single class label λ_i is assigned to each example x . This implicitly defines the set of preferences $R_x = \{\lambda_i \succ_x \lambda_j \mid 1 \leq j \neq i \leq c\}$. The output space \mathcal{S}_c is projected to the first component.
- *l-Multilabel Classification:* Each training example x is associated with a subset $P_x \subseteq \mathcal{L}$ of possible labels. This implicitly defines the set of preferences $R_x = \{\lambda_i \succ_x \lambda_j \mid \lambda_i \in P_x, \lambda_j \in \mathcal{L} \setminus P_x\}$. The output space is projected to the first l components.

RPC and constraint classification provide a general means to extend arbitrary (linear) binary classification algorithms to the label ranking scenario. Both approaches require (not necessarily complete) sets of pairwise preferences associated with the training instances to learn a ranking model which, as a post-processing step, may be projected from \mathcal{S}_c to the specific output space \mathcal{Y} .

The key idea of RPC is to learn, for each pair of labels (λ_i, λ_j) , a binary model $\mathcal{M}_{ij}(x)$ that predicts whether $\lambda_i \succ_x \lambda_j$ or $\lambda_j \succ_x \lambda_i$ for an input x . In order to rank the labels for a new instance, predictions for all pairwise label preferences are obtained and a ranking that is maximally consistent with these preferences is derived, typically by means of a voting scheme.³ This technique describes a natural extension of pairwise classification, i.e., the idea to approach a multiclass classification problem by learning a separate model for each pair of classes.

As we will see in the next section, conventional multilabel classification can not be embedded as a special case of the label ranking setting because, even though RPC or constraint classification could be used to rank the labels, they do not include a mechanism for extracting the set of relevant labels from this ranking.

³ To account for equal vote statistics, we consider random tie breaking in our implementation.

3 MULTILABEL CLASSIFICATION AND RANKING

Multilabel classification refers to the task of learning a mapping from an instance $x \in \mathcal{X}$ to a set $P_x \subset \mathcal{L}$, where $\mathcal{L} = \{\lambda_1, \dots, \lambda_c\}$ is a finite set of predefined labels, typically with a small to moderate number of alternatives. Thus, in contrast to multiclass learning, alternatives are not assumed to be mutually exclusive such that multiple labels may be associated with a single instance. The set of labels P_x are called *relevant* for the given instance, the set $N_x = \mathcal{L} \setminus P_x$ are the *irrelevant* labels.

A common approach to multilabel classification is *binary relevance learning* (BR). BR trains a separate binary relevance model \mathcal{M}_i for each possible label λ_i , using all examples x with $\lambda_i \in P_x$ as positive examples and all those with $\lambda_i \in N_x$ as negative examples. For classifying a new instance, all binary predictions are obtained and then the set of labels corresponding to positive relevance classification is associated with the instance. This scenario is, for example, commonly used for evaluating algorithms on the REUTERS text classification benchmark [10].

In the following, we will study the task of *multilabel ranking*, which is understood as learning a model that associates with a query input x both a ranking of the complete label set $\{\lambda_1, \dots, \lambda_c\}$ and a bipartite partition of this set into relevant and irrelevant labels. Thus, multilabel ranking can be considered as a generalization of both multilabel classification and ranking.

In conventional label ranking, a training example typically consists of an instance $x \in \mathcal{X}$, represented with a fixed set of features, and a set of pairwise preferences over labels $R_x \subset \mathcal{L}^2$, where $(\lambda, \lambda') \in R_x$ is interpreted as $\lambda \succ_x \lambda'$. In multilabel classification, the training information consists of a set P_x of relevant labels and, implicitly, a set $N_x = \mathcal{L} \setminus P_x$ of irrelevant labels. Note that this information can be automatically transformed into a set of preferences $\hat{R}_x = \{(\lambda, \lambda') \mid \lambda \in P_x \wedge \lambda' \in N_x\}$ (cf. Fig. 1 (a)).

While it is straightforward to represent the training information for multilabel classification as a preference learning problem, the algorithms that operate in this framework only produce a ranking of the available options. In order to convert the learned ranking into a multilabel prediction, the learner has to be able to autonomously determine a point at which the learned ranking is split into sets of relevant and irrelevant labels. Previous applications of ranking techniques to multilabel learning, such as [2], have ignored this problem and only focused on producing rankings, but not on determining this correct *zero point* for splitting the ranking.

Multilabel ranking can, for example, be realized if the binary classifiers provide real-valued confidence scores or *a posteriori* probability estimates for classification outcomes. Schapire & Singer [12] included an *ad hoc* extension to multilabel ranking in their experimental setup by ordering labels according to decreasing confidence scores.

In the following, we will introduce calibrated ranking, a conceptually new technique for extending the common pairwise learning approach to the multilabel scenario, a setting previously not being amenable to a pairwise decomposition approach. Within our framework, RPC can solve both multilabel classification and ranking problems in a consistent and generally applicable manner.

4 CALIBRATED LABEL RANKING

In this section, we will propose a general model avoiding the aforementioned drawbacks by incorporating a calibrated scale which con-

tains a natural zero-point. This zero-point provides a means to distinguish between the top and the complementary set of labels.

Let us proceed to a formal definition of the hypothesis space underlying the *calibrated label ranking framework*:

Definition 4.1 (Calibrated Label Ranking Model). Denote by \mathcal{X} a nonempty input space and by \mathcal{S}_c^0 the space of permutations over the set $\{\lambda_0, \lambda_1, \dots, \lambda_c\}$, that is, the original set of labels plus an additional virtual label λ_0 . Then, a model $h : \mathcal{X} \rightarrow \mathcal{S}_c^0$ is referred to as a calibrated label ranking model.

The key idea is to use the virtual label λ_0 as a split point between relevant and irrelevant labels: all relevant labels are preferred to λ_0 , which in turn is preferred to all irrelevant labels. Thus, a *calibrated ranking*

$$\lambda_{i_1} \succ \dots \succ \lambda_{i_j} \succ \lambda_0 \succ \lambda_{i_{j+1}} \succ \dots \succ \lambda_{i_c} \quad (1)$$

induces both a ranking among the labels,

$$\lambda_{i_1} \succ \dots \succ \lambda_{i_j} \succ \lambda_{i_{j+1}} \succ \dots \succ \lambda_{i_c}, \quad (2)$$

and a bipartite partition into

$$P = \{\lambda_{i_1}, \dots, \lambda_{i_j}\} \quad \text{and} \quad N = \{\lambda_{i_{j+1}}, \dots, \lambda_{i_c}\} \quad (3)$$

in a straightforward way.

As sketched in the previous section, the training information for a multilabel ranking problem consists of a set of preferences R_x , and subsets of labels $P_x, N_x \subset \mathcal{L}$ with $P_x \cap N_x = \emptyset$, which distinguish, respectively, *positive* labels that should be ranked above the zero-point element λ_0 and *negative* labels to be ranked below.⁴ The bipartite partitions associated with the training instances is used to, with the help of the virtual label λ_0 , induce additional constraints: the calibrated classifier h should predict $\lambda \succ_x \lambda_0$ for all $\lambda \in P_x$ and vice-versa $\lambda_0 \succ_x \lambda'$ for all $\lambda' \in N_x$ (cf. Fig. 1 (b)). Moreover, as a consequence of transitivity, it should predict $\lambda \succ_x \lambda'$ for all $\lambda \in P_x$ and $\lambda' \in N_x$ (Fig. 1 (c)). Combining the new partition-induced preference constraints with the original set of pairwise preferences for the training data, i.e.,

$$\begin{aligned} R'_x &\stackrel{\text{def}}{=} R_x \cup \{(\lambda, \lambda_0) \mid \lambda \in P_x\} \\ &\quad \cup \{(\lambda_0, \lambda') \mid \lambda' \in N_x\} \\ &\quad \cup \{(\lambda, \lambda') \mid \lambda \in P_x \wedge \lambda' \in N_x\}, \end{aligned} \quad (4)$$

the calibrated ranking model becomes amenable to previous approaches to the original label ranking setting: The calibrated ranking model can be learned by solving a conventional ranking problem in the augmented calibrated hypothesis space, which may be viewed as a ranking problem with $c + 1$ alternatives, with respect to the modified sets of constraints R'_x on the original labels $\lambda_1, \dots, \lambda_c$ and the virtual label λ_0 . Therefore, this unified approach to the calibrated setting enables many existing techniques, such as RPC and constraint classification [1], to incorporate and exploit partition-related preference information and to generalize to settings where predicting the zero-point is required. We will discuss an exemplary application of this framework to pairwise ranking in Section 5.

⁴ In general, we do not need to assume complete training data, neither for the sets of preferences (R_x might even be empty) nor for the partitions (which do not necessarily have to cover all the labels, i.e., $P_x \cup N_x \neq \mathcal{L}$). Besides, in a *noisy learning scenario*, it may happen that $(\lambda', \lambda) \in R_x$ even though $\lambda \in P_x$ and $\lambda' \in N_x$. In this paper, we will not further consider these cases, and assume a strict multilabel scenario.

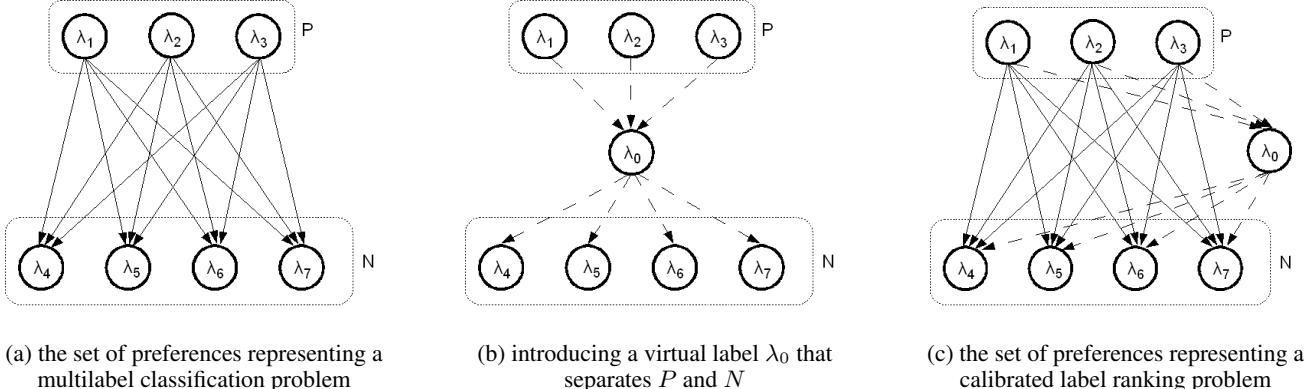

Figure 1. Calibrated Label Ranking

4.1 Relation to Binary Relevance Learning

Conventional pairwise label ranking learns a binary preference model M_{ij} for all combinations of labels λ_i and λ_j with $1 \leq i < j \leq c$,⁵ where instances x with $(\lambda_i, \lambda_j) \in R_x$ are associated with positive and those with $(\lambda_j, \lambda_i) \in R_x$ with negative class labels (cf. Figure 1 (b)). In the calibrated scenario, the partition-related constraints with respect to λ_0 as defined in (4) are required to learn an additional set of binary preference models M_{0j} with $1 \leq j \leq c$. It is important to notice, that these additional models are identical to the common binary-relevance models M_j .

Theorem 4.2. *The models M_{0j} that are learned by a pairwise approach to calibrated ranking, and the models M_j that are learned by conventional binary ranking are equivalent.*

Proof. Each training example x , for which label λ_j is relevant, is, by definition, a positive example in the training set for model M_j . The calibrated ranking approach adds the preference $\lambda_j \succ_x \lambda_0$, which means that x will be a negative example for M_{0j} . Similarly, if λ_j is irrelevant, x is negative for M_j and positive for M_{0j} . Assuming a symmetric learner, the learned models will be the equivalent in the sense that $M_j = -M_{0j}$. \square

Thus, calibrated RPC may be viewed as a method for combining RPC with conventional binary ranking, in the sense that the binary models that are learned for RPC, and the binary models that are learned for BR, are pooled into a single ensemble. However, CRPC provides a new interpretation to the BR models, that not only allows for ranking the labels, but also to determine a suitable split into relevant and irrelevant categories.

By training a larger number of pairwise models, the calibrated extension of RPC achieves two potential advantages over simple relevance learning. Firstly, it provides additional information about the ranking of labels. Secondly, it may also improve the discrimination between relevant and irrelevant labels. In fact, it is legitimate to assume (and indeed supported by empirical evidence in the next section) that the additional binary models can somehow “stabilize” the related classification. For example, while an error of model $M_j = -M_{0j}$ definitely causes a misclassification of label λ_j in simple relevance learning, this error might be compensated by the models M_{ij} , $1 \leq i \neq j \leq c$, in the case of RPC. The prize to pay is, of course, a higher computational complexity, which, as we will show in the next section, depends on the maximum number of labels for an example.

⁵ The case $i > j$ is typically not required as a consequence of the symmetry of binary classifiers with respect to positive and negative instances.

4.2 Computational Complexity

In this section, we will derive bounds for the number of training examples that are constructed for training the pairwise classifiers. The total computational complexity depends on the complexity of the base classifier used for processing these examples. In brief, super-linear classifiers like SVMs will profit from distributing the workload on many small problems instead of fewer larger problems as for the BR approach.

Theorem 4.3. *CRPC is trained on $O(lcn)$ examples, where $l = \max_x |P_x|$ is the maximum number of relevant labels that may be associated with a single training example, c is the number of possible labels, and n is the number of original training examples.*

Proof. In previous work, it has been shown that training a pairwise classifier requires $O(cn)$ training examples [5]. To see this, note that each of the n original training examples will only appear in the training sets of $c - 1$ models, therefore the total number of training examples that have to be processed is $(c - 1)n$.

For multilabel classification, RPC will compare a training example's $|P_x|$ relevant labels to all $|N_x| = c - |P_x|$ labels that are not relevant for this example. In addition, CRPC will include every example in the c training sets of the models M_{0j} , $j = 1 \dots c$.

Thus, each example occurs in $|P_x| \times |N_x| + c = |P_x|(c - |P_x|) + c < |P_x|c + c < (l + 1)c$ training sets, and the total number of training examples is therefore $O(lcn)$. \square

This result shows that the complexity of training CRPC depends crucially on the maximum number of labels in the training examples. For the case of $l = 1$, i.e., for conventional pairwise classification, we get the linear bound that was shown in [5].⁶ For multilabel classification with a maximum number of l labels per example, we still have a bound that is linear in the number of examples and the number of classes, i.e., the complexity is within a factor of l of the $O(cn)$ examples needed for training a BR. We would like to point out that in many practical applications, the bound l is determined by the procedure that is used for labeling the training examples, and is independent of c . A typical example is the number of keywords that are assigned to a text, which is rarely ever more than ten.

Thus, for practical purposes, the complexity of CRPC is within a constant factor of l of the complexity of BR. Of course, the worst-case complexity, which would occur when all possible label subsets are *a priori* equally likely, is $O(c^2n)$.

⁶ Note that the O -notation hides, in this case, a constant factor of two, which results from the introduction of the virtual label λ_0 .

5 EMPIRICAL EVALUATION

The purpose of the following section is to provide an empirical comparison of calibrated RPC with the common binary-relevance approach in the domain of multilabel classification and ranking. The datasets that were included in the experimental setup cover two application areas in which multilabeled data are frequently observed: *text categorization* and *bioinformatics*.

- **Yeast:** The Yeast gene functional multiclass classification problem consists of 1500 genes in the training and 917 in the test set, represented by 103 features, where each gene is associated with a subset of the 14 functional classes considered [4].
- **Reuters2000:** The Reuters Corpus Volume I is one of the currently most widely used test collection for text categorization research. As the full corpus contains more than 800000 newswire documents, we restricted our experiments to a subset distribution of five times 3000 training and 3000 test documents which is publicly available as a preprocessed version.⁷ The documents are represented using stemmed word frequency vectors (normalized to unit length) with a TFIDF weighting scheme and elimination of stopwords resulting in 47152 features. Each document is associated with a subset of the 101 categories present in the dataset. The number of categories was reduced to 10 in our experiments by sequentially grouping the original categories into buckets of roughly equal size where each bucket corresponds to a single new label which is associated with positive relevance if at least one of the labels in the bucket is relevant.

We replicated the experimental setup in [4] to conduct the empirical evaluation on the Yeast dataset where a predefined split into training and test data was given. The four different measures considered cover both multilabel classification and ranking performance:

Preliminaries: For a multilabel ranking model h and a given instance x , let $\tau(\lambda_i)$ denote the position of λ_i in the predicted ranking (with

λ_0 being removed from the ranking), $\tau^{-1}(i)$ the label λ having assigned position i , and P the set of relevant labels as predicted by CRPC.

Precision (PREC) assesses the multilabel ranking performance and is a frequently used measure in Information Retrieval:

$$\text{PREC}(h, x, P_x) \stackrel{\text{def}}{=} \frac{1}{|P_x|} \sum_{\lambda \in P_x} \frac{|\{\lambda' \in P_x | \tau(\lambda') \leq \tau(\lambda)\}|}{\tau(\lambda)} \quad (5)$$

The ranking loss (RANKLOSS) also measures ranking performance as it evaluates the average fraction of pairs of labels which are not correctly ordered:

$$\text{RANKLOSS}(h, x, P_x) \stackrel{\text{def}}{=} \frac{|\{(\lambda, \lambda') \in P_x \times N_x | \tau(\lambda) > \tau(\lambda')\}|}{|P_x||N_x|}$$

The one-error loss (ONEERROR) evaluates the multilabel ranking performance from a restricted perspective as it only determines if the top-ranked label is actually relevant:

$$\text{ONEERROR}(h, x, P_x) \stackrel{\text{def}}{=} \begin{cases} 1 & \text{if } \tau^{-1}(1) \notin P_x, \\ 0 & \text{otherwise.} \end{cases} \quad (6)$$

The Hamming loss (HAMLOSS) assesses the multilabel classification performance in terms of the average binary (non-)relevant error:

$$\text{HAMLOSS}(h, x, P_x) \stackrel{\text{def}}{=} \frac{1}{|\mathcal{L}|} |P \Delta P_x| \quad (7)$$

In compliance with [4], support vector machines (SVMs) [13] provided the underlying classifiers for the binary-relevance multilabel model, as well as for the calibrated ranking model which was built on top of SVMs with polynomial kernels. The degree of the kernel varied from 1 to 9 and the margin-error penalty was fixed to $C = 1$. Linear kernels with $C \in \{1, 10, 100\}$ were used on the Reuters2000 dataset as they have demonstrated excellent performance in many publications studying text mining problems [9].

The empirical results on the Yeast dataset, depicted in Table 1, demonstrate that the calibrated ranking model is a promising alternative to the common binary-relevance approach to multilabel classification and ranking. Over a wide range of parameter values, the performance of the calibrated ranking is superior to the binary-relevance approach and comparatively stable, thus indicating a high level of robustness. For the optimal choice of parameters with respect to the testset (which could be approximately determined by cross-validation or leave-one-out estimation in practice), the gap is decreasing while calibrated ranking still outperforms its binary-relevance counterpart on three of the four evaluation measures. Interestingly, the only measure for which both approaches achieve comparable accuracy, namely the Hamming loss, evaluates the multilabel accuracy

⁷ <http://www.csie.ntu.edu.tw/~cjlin/libsvmtools/datasets/>

in a manner that seems to be more tailored to the binary-relevance approach from a theoretical point of view as it computes the average (independently measured) binary-relevance error. Note that although the pattern observed in Table 1 might suggest that further increasing the degree of the polynomial kernel could improve the experimental results of the binary-relevance approach, this assumption could not be validated in an additional experiment. Despite that we could not set up a perfect replication of [4] as certain parameters (e.g., the margin-penalty values C) were not published, we nevertheless note that the performance of calibrated RPC compares favorably to those reported in [4] for the ranking and Hamming loss, while the results in terms of precision are comparable to those of the herein proposed SVM ranking algorithm. With respect to the one-error loss the performance is slightly worse. Moreover, there is a substantial margin between the performance of Boostexter [12], a boosting-based multilabel learning system, on the Yeast benchmark dataset (as published in [4]) and the calibrated ranking technique with respect to all four evaluation measures considered in the experimental setup.

The empirical results on the Reuters2000 dataset (see Table 2) clearly support the conclusions drawn from the Yeast dataset. In terms of the Hamming loss, both approaches achieve comparable accuracy, while calibrated ranking outperforms binary-relevance multilabel learning for the remaining evaluation measures. Again, the margin is typically smaller for the optimal choice of parameter values, whereas the difference in accuracy is larger when comparing the results with the parameter C being fixed. Moreover, calibrated ranking tends to be more stable than binary-relevance learning with respect to the choice of the underlying binary classifiers. Furthermore, additional experiments using different methods for reducing the number of labels, such as selecting only the most frequent relevant labels (cf., [12]), showed qualitatively comparable outcomes.

6 RELATED WORK

Schapire & Singer [11] derived a family of multilabel extensions in the framework of AdaBoost (referred to as AdaBoost.MH and AdaBoost.MR) which provided the algorithmic basis for the Boostexter text and speech categorization system [12]. For the online learning setting, a computationally efficient class of perceptron-style algorithms for multilabel classification and ranking was proposed in [2]. In a manner similar to the above mentioned approaches, the multilabel generalization of support vector machines advocated by Elisseeff & Weston [4] exploits comparative preferences among pairs of labels as defined for the multilabel case in Section 2, while lacking a natural approach to determine the relevance zero-point in the multilabel ranking.

7 CONCLUDING REMARKS

We have proposed a unified extension to overcome the severe restriction on the expressive power of previous approaches to label ranking induced by the lack of a calibrated scale. This unified approach to the calibrated ranking setting enables general ranking techniques, such as ranking by pairwise comparison and constraint classification, to incorporate and exploit partition-related preference information and to generalize to settings where predicting the zero-point is required. In particular, the calibrated extension suggests a conceptually novel technique for extending the common learning by pairwise comparison technique to the multilabel scenario, a setting previously not being amenable to pairwise decomposition. A particular limitation of the binary-relevance extension to multilabel ranking, which is not

shared by the calibrated framework, consists in the fact that it only applies to soft-classifiers providing confidence scores in the prediction. Exploring the benefits of calibrated ranking with binary-valued classifiers is a promising aspect of future work. Experimental results in the areas of text categorization and gene analysis underscore the merits of our calibrated framework from an empirical point of view.

Learning by Automatic Option Discovery from Conditionally Terminating Sequences

Sertan Girgin¹ and Faruk Polat² and Reda Alhajj³

Abstract. This paper proposes a novel approach to discover options in the form of conditionally terminating sequences, and shows how they can be integrated into reinforcement learning framework to improve the learning performance. The method utilizes stored histories of possible optimal policies and constructs a specialized tree structure online in order to identify action sequences which are used frequently together with states that are visited during the execution of such sequences. The tree is then used to implicitly run corresponding options. Effectiveness of the method is demonstrated empirically.

1 Introduction

Reinforcement learning (RL) is the problem faced by an agent that must learn behavior through trial-and-error interactions with a dynamic environment by gaining percepts and rewards from the world and taking actions to affect it [3, 9]. In most of the realistic and complex domains, the task that the agent is trying to solve is composed of various subtasks and has a hierarchical structure formed by the relations between them [1]. Each of these subtasks repeats many times at different regions of the state space. Although, all instances of the same subtask, or similar subtasks, have almost identical solutions (sub-behaviors), without any (self) guidance an agent has to learn these solutions independently, going through similar learning stages again and again. This situation affects the learning process in a negative way, making it difficult to converge to optimal behavior in a reasonable time.

The main reason of the problem is the lack of abstractions, that would allow to share solutions between similar subtasks. *Temporally abstract actions* are macro actions that generalize primitive actions and last for a period of time [10]. In most applications, they are part of the problem specification and provided by the system developer prior to learning based on extensive domain knowledge; this becomes more difficult as the complexity of the problem increases. An alternative way is to construct options automatically using domain information acquired during learning. Most of the research conducted on this topic has focused on two main approaches. The first approach starts by identifying possible subgoals of the problem, then abstractions solving them are generated and utilized. Various statistics (such as visit frequencies of states) [5, 8] or graph theoretical notions (such as bottleneck states connecting the strongly connected components of the state space) [6, 7] are used to identify subgoals. Solutions of the subgoals are explicitly generated by means of additional rein-

forcement learning processes, such as action replay executed on restricted sub-problems with artificial rewards. Although these methods are effective in general, subtasks with similar policies but different subgoals result in independent abstractions. In relatively less explored second approach, temporal abstractions are generated directly, without identifying subgoals, by analyzing common parts of multiple policies. An example of this approach is proposed by McGovern, where sequences that occur frequently on successful action trajectories are detected, and options are created for those which pass a static filter that eliminates sequences leading to similar results [4]. One drawback of this method is that common action sequences are identified at regular intervals, which is a costly operation and requires all state and action histories be stored starting from the beginning of learning. Also, since every prefix of a frequent sequence has at least the same frequency, the number of possible options increases rapidly unless limited in a problem specific way.

In this work, we propose a method which efficiently discovers useful options in the form of conditionally terminating action sequences without storing all observations. From the histories of states, actions and reward, we first generate trajectories of possible optimal policies, and then convert them into a tree structure. This helps to identify and compactly represent frequently used sub-sequences of actions together with states that are visited during their execution. As learning progresses, this tree is constantly updated and used to implicitly run represented options. We demonstrate the effectiveness of this approach by reporting test results on two domains.

The rest of the paper is organized as follows: In Section 2 we describe the standard reinforcement learning framework of discrete time, finite Markov decision processes. The notion of options, and specifically conditionally terminating sequences, is defined in Section 3. A method to discover the options online during the learning is described in Section 4. We present experimental results in Section 5. Section 6 is conclusions.

2 Background

A *Markov decision process*, MDP, is a tuple $\langle S, A, T, R \rangle$, where S is a finite set of states, A is a finite set of actions, $T : S \times A \times S \rightarrow [0, 1]$ is a state transition function such that $\forall s \in S, \forall a \in A, \sum_{s' \in S} T(s, a, s') = 1$, and $R : S \times A \rightarrow \mathbb{R}$ is a reward function. $T(s, a, s')$ denotes the probability of making a transition from state s to state s' using action a . $R(s, a)$ is the *immediate* reward received when action a is executed in state s . A (stationary) *policy*, $\pi : S \times A \rightarrow [0, 1]$, is a mapping that defines the probability of selecting an action from a particular state. If $\forall s \in S, \pi(s, a_s) = 1$ and $\forall a \in A, a \neq a_s, \pi(s, a) = 0$ then π is called a *deterministic policy*. The *value* of a policy π at state

³ University of Calgary, Calgary, Alberta, Canada; and Global University, Beirut, Lebanon, alhajj@cpsc.ucalgary.ca

s , denoted $V^\pi(s)$, is the expected infinite discounted sum of reward that the agent will gain if it starts in state s and follows π [3]. It is defined as: $V^\pi(s) = \sum_{t=0}^{\infty} \gamma^t E(r_t | \pi, s_0 = s)$, where r_t is the reward received at time t , and γ is the discount factor. Let $Q^\pi(s, a)$ denote the expected infinite discounted sum of reward that the agent will gain if it selects action a at s , and then follows π : $Q^\pi(s, a) = (R(s, a) + \gamma \sum_{s' \in S} T(s, a, s') V^\pi(s'))$; then, we have $V^\pi(s) = \sum_{a \in A} \pi(s, a) Q^\pi(s, a)$. $V^\pi(s)$ and $Q^\pi(s, a)$ are called policy's state value function and action value function, respectively. In a Markov decision process, the objective of an agent is to find an *optimal policy*, π^* , which maximizes state value function for all states (i.e., $\forall \pi, \forall s \in S, V^{\pi^*}(s) \geq V^\pi(s)$). Every MDP has a deterministic stationary optimal policy; and for all optimal policies, the state value function is identical; and $\forall s \in S$, the following Bellman equation holds: $V^*(s) = \max_{a \in A} (R(s, a) + \gamma \sum_{s' \in S} T(s, a, s') V^*(s')) = \max_{a \in A} Q^*(s, a)$. V^* and Q^* are called the optimal value functions. Using Q^* , π^* can be specified as $\pi^*(s) = \arg \max_{a \in A} Q^*(s, a)$. When the reward function R and the state transition function T are known, π^* can be found by using *dynamic programming* techniques [3]. When such information is not readily available, Monte Carlo or temporal-difference (TD) learning methods are used. Instead of requiring complete knowledge of the underlying model, these approaches rely on experience in the form of sample sequences of states, actions, and rewards collected from on-line or simulated trial-and-error interactions with the environment.

3 Options

The *options* framework of Sutton et. al. [10] extends the theory of reinforcement learning to include temporally extended courses of action. Formally, an option is a tuple $\langle I, \pi, \beta \rangle$, where $I \subseteq S$ is the set of states that the option can be initiated, called *initiation set*, π is the option's local policy and β is the termination condition. Once an option is initiated by an agent at a state $s \in I$, π is followed and actions are selected according to π until the option terminates (stochastically) at a specific condition determined by β . In a *Markov option*, action selection and option termination decisions are made solely on the basis of the current state, i.e., $\pi : S \times A \rightarrow [0, 1]$, and $\beta : S \rightarrow [0, 1]$. During option execution, if the environment makes a transition to state s , then the Markov option terminates with probability $\beta(s)$ or else continues, determining the next action a with probability $\pi(s, a)$.

Markov options are limited in their ability to represent some useful abstractions, such as terminating after a given number of steps, or carrying out a sequence of actions irrespective of the consequences (as in open-loop control). For more flexibility, *Semi-Markov options* extend Markov policies and allow π and/or β to depend on all prior events since the option was initiated. Let $s_t, a_t, r_{t+1}, s_{t+1}, a_{t+1}, \dots, r_\tau, s_\tau$ be the sequence of states, actions and rewards observed by the agent starting from time t until τ . As in [10], we will call this sequence the *history* from t to τ , and denote it by $h_{t\tau}$. If the set of all possible histories is denoted by Ω , then in a Semi-Markov option β is defined over Ω as, $\beta : \Omega \rightarrow [0, 1]$, and similarly π is a function of Ω , $\pi : \Omega \times A \rightarrow [0, 1]$.

In this work, we concentrate on Semi-Markov options in the form of conditionally terminating sequences. Following [4], we define a *conditionally terminating sequence*, *ct-sequence* in short, of length n as a sequence of initiation set and action tuples $\sigma = \langle I_1, a_1 \rangle \langle I_2, a_2 \rangle \dots \langle I_n, a_n \rangle$, where $I_i \subseteq S$ and $a_i \in A$. At step i of the execution of σ , if current state s is in I_i then agent selects action a_i and the sequence advances to the next step; otherwise the

sequence terminates. Here, $a_1 a_2 \dots a_n$ is called the *action sequence* of σ and denoted by A_σ . $I_\sigma = I_1$ and $a_\sigma = a_1$ are the initiation set and first action of σ , respectively. Let $I_{\sigma,i}$ and $a_{\sigma,i}$ denote the i^{th} initiation set and action of σ . For every ct-sequence σ one can define a corresponding Semi-Markov option $\sigma_\sigma = \langle I, \pi, \beta \rangle$ as follows: $I = I_{\sigma,1}$,

$$\begin{aligned} \pi(h_{t\tau}, a) &= \begin{cases} 1, & \text{if } \beta(h_{t\tau}) = 1 \wedge a = a_{\sigma, \tau-t+1} \\ 0, & \text{otherwise} \end{cases} \\ \beta(h_{t\tau}) &= \begin{cases} 1, & \text{if } \tau - t < n \wedge s_\tau \in I_{\sigma, \tau-t+1} \\ 0, & \text{otherwise} \end{cases} \end{aligned}$$

Conditionally terminating sequences can be used to represent frequently occurring and useful patterns of actions in a reinforcement learning problem. For example, consider a 5×5 grid world, in which the agent's goal is to reach the top rightmost square as soon as possible (i.e., with minimum number of actions). At each time step, it can move to one of the four neighboring cells if there is a cell on that direction. Assume the set of states consists of pairs representing the row and column indexes of the cells on the grid: $S = \{(0, 0), \dots, (4, 4)\}$; $A = \{n, s, e, w\}$ is the set of possible actions, and $[(r_1, c_1), (r_2, c_2)]$ denotes the rectangular region on the grid with corners at (r_1, c_1) and (r_2, c_2) . In order to reach the goal cell, one of the useful action patterns that can be used by the agent is to move diagonally in the north-east direction, i.e., e followed by n or vice versa. These patterns can be represented by ct-sequences: $\sigma_{en} = \langle [(0, 0), (3, 3)], e \rangle \langle [(0, 1), (3, 4)], n \rangle$ and $\sigma_{ne} = \langle [(0, 0), (3, 3)], n \rangle \langle [(1, 0), (4, 3)], e \rangle$, respectively.

Let $|\sigma|$ be the length of a ct-sequence σ , and $\sigma^{i,j} = \langle I_{\sigma,i}, a_{\sigma,i} \rangle \dots \langle I_{\sigma,j}, a_{\sigma,j} \rangle$ denotes the ct-sequence obtained from σ by taking initiation set and action tuples starting from i up to j . We use σ^i as a short notation for $\sigma^{i,|\sigma|}$. Given two ct-sequences u and v , if $|u| \leq |v|$ and the action sequence of v starts with the action sequence of u , then u is called a *predecessor* of v , indicated by $u \preceq v$. For example, moving diagonally in the north-east direction two times can be represented by a ct-sequence $\sigma_{enen} = \langle [(0, 0), (2, 2)], e \rangle \langle [(0, 1), (2, 3)], n \rangle \langle [(1, 1), (3, 3)], e \rangle \langle [(1, 2), (3, 4)], n \rangle$, and $\sigma_{en} \preceq \sigma_{enen}$. Although not necessary, initiation sets of a preceded sequence generally are supersets of corresponding initiation sets of the successor, as in case of σ_{en} and σ_{enen} .

If a sequence is a predecessor of another one, then it is possible to merge the two sequences to obtain a new ct-sequence that reflects behavior of both sequences. Let u and v be two ct-sequences such that $u \preceq v$. Their union is defined as $u \cup v = \langle I_{u,1} \cup I_{v,1}, a_{u,1} \rangle \dots \langle I_{u,|u|} \cup I_{v,|u|}, a_{u,|u|} \rangle \langle I_{v,|u|+1}, a_{v,|u|+1} \rangle \dots \langle I_{v,|v|}, a_{v,|v|} \rangle$. When started at a state s , $u \cup v$ behaves like u if $s \in I_u \setminus I_v$, and like v otherwise. Note $u \cup v$ may behave like v even if $s \notin I_v$, under the condition that after executing $|u|$ steps, v can continue thereafter. Also, depending on the actual observed states, the course of action followed by $u \cup v$ may switch between u and v . In particular, let $s_{t+1} s_{t+2} \dots s_{t+k}$ be the sequence of states observed during the execution of $u \cup v$, and suppose that there exist states s_{t+i} and s_{t+j} such that $s_{t+i} \in I_{u,i} \setminus I_{v,i}$ and $s_{t+j} \in I_{v,j} \setminus I_{u,j}$, where $1 \leq j < i < k$. Then, if started at s_t , v would terminate at s_{t+i} , and similarly u would terminate at s_{t+j} without having opportunity to advance to step k . Note that $u \cup v$ switches to v at step i and to u at step j . Therefore, the union of two ct-sequences not only combines but also generalizes their behavior in favor of longer execution patterns, when possible.

Now suppose that we are given a set of ct-sequences $\Sigma = \{\sigma_1, \dots, \sigma_n\}$ to be used in a RL problem. Furthermore, assume that the option to be executed at state s is chosen on the basis of

the probability distribution $P(s, \cdot)$ determined by a given function $P : S \times \Sigma \rightarrow [0, 1]$. The set Σ can be represented in a compact form using a *stochastic ct-sequence* which extends conditionally terminating sequences to allow different action sequences be followed depending on the history of events back to starting of its execution. Let \bar{I}_ς denote the set of states at which a stochastic ct-sequence ς can be initiated, and \bar{f}_ς be the set of possible first actions that can be selected by ς . A stochastic ct-sequence is defined inductively as:

1. A ct-sequence σ is a stochastic ct-sequence; its initiation set and first action set are I_σ and $\{f_\sigma\}$, respectively.
2. Given a ct-sequence u and a stochastic ct-sequence v , their concatenation $u \circ v$, defined as executing u followed by v , is a stochastic ct-sequence with $\bar{I}_{u \circ v} = \bar{I}_u$ and $\bar{f}_{u \circ v} = \bar{f}_u$.
3. For a given set of stochastic ct-sequences $\Xi = \{\varsigma_1, \varsigma_2, \dots, \varsigma_n\}$ such that each ς_i is either a ct-sequence or of the form $\sigma \circ \varsigma$ where σ is a ct-sequence, and for any two ς_i and $\varsigma_j \in \Xi$, $\bar{f}_{\varsigma_i} \cap \bar{f}_{\varsigma_j} = \emptyset$, i.e., first action set of all sequences are all distinct from each other, then another stochastic ct-sequence $\odot_t \Xi$ is defined as:

$$\odot_t \Xi = \begin{cases} \varsigma_i, & \text{if } s \in \bar{I}_{\varsigma_i} \setminus \bigcup_{j \neq i} \bar{I}_{\varsigma_j} \\ \mu_{\Xi, t}, & \text{otherwise} \end{cases}$$

where s is the current state, and $\mu_{\Xi, t} : \Omega \times \Xi \rightarrow [0, 1]$ selects and executes one of $\varsigma_1, \dots, \varsigma_n$ according to a probability distribution based on the observed history of the last t steps. Here, $\odot_t \Xi$ behaves like ς_i if any other $\varsigma_j \in \Xi$ is not applicable at state s . $\bar{I}_{\odot_t \Xi} = \bar{I}_{\varsigma_1} \cup \dots \cup \bar{I}_{\varsigma_n}$ and $\bar{f}_{\odot_t \Xi} = \bar{f}_{\varsigma_1} \cup \dots \cup \bar{f}_{\varsigma_n}$.

4. Nothing generated by rules other than 1-3 is a ct-sequence.

Let u be a ct-sequence and v be a stochastic ct-sequence. Their combination, denoted $u \otimes_t v$, that behaves both like u and v can be defined as follows depending on the form of v :

- If v is a ct-sequence, then (i) If $u \preceq v$ (or $v \preceq u$), then $u \otimes_t v = u \cup v$ (or $v \cup u$). (ii) If $f_u \neq f_v$, i.e., their first actions are different from each other, then $u \otimes_t v = \odot_t \{u, v\}$. (iii) If $A_{u^{1, k-1}} = A_{v^{1, k-1}}$ and $a_{u, k} \neq a_{v, k}$, i.e., their action sequences have a maximal common prefix of length $k - 1$, then $u \otimes_t v = (u^{1, k-1} \cup v^{1, k-1}) \circ (\odot_{t+k} \{u_k, v_k\})$.
- if $v = \sigma \circ \varsigma$ where σ is a ct-sequence, then, (i) if $|u| < |\sigma|$ and $u \preceq \sigma$, i.e., action sequence of u is a prefix of action sequence of σ , then $u \otimes_t v = (\sigma \cup u) \circ \varsigma$ (ii) if $\sigma \preceq u$, then $u \otimes_t v = (\sigma \cup u^{1, |\sigma|}) \circ (u^{|\sigma|+1} \otimes_{t+|\sigma|+1} \varsigma)$ (iii) if $f_u \neq f_\sigma$, i.e., first actions of u and σ are different from each other, then $u \otimes_t v = \odot_t \{u, v\}$ (iv) if $A_{u^{1, k-1}} = A_{\sigma^{1, k-1}}$ and $a_{u, k} \neq a_{\sigma, k}$, i.e., action sequences of u and σ differ at a position $k \leq |\sigma|$, then $u \otimes_t v = (\sigma^{1, k-1} \cup u^{1, k-1}) \circ (\odot_{t+k} \{u^k, \sigma^k \circ \varsigma\})$
- if $v = \odot_t \{\varsigma_1, \dots, \varsigma_n\}$, then $u \otimes_t v = \odot_t \{\varsigma_1, \dots, \varsigma_{i-1}, u \otimes_t \varsigma_i, \varsigma_{i+1}, \dots, \varsigma_n\}$ if $f_u \in \bar{f}_{\varsigma_i}$, and $u \otimes_t v = \odot_t \{\varsigma_1, \dots, \varsigma_n, u\}$ otherwise.

For example, given $\sigma_{ee} = \langle [(0, 0), (4, 2)], e \rangle \langle [(0, 1), (4, 3)], e \rangle$ corresponding to the action pattern of moving east twice in 5×5 grid world, we have $\sigma_{en} \otimes_t \sigma_{ee} = \langle I_{\sigma_{en, 1}} \cup I_{\sigma_{ee, 1}}, e \rangle \circ I'$, where s is the state observed by the agent after executing first action and I' is $\langle I_{\sigma_{en, 2}}, n \rangle$ if $s \in [(0, 4), (3, 4)]$, $\langle I_{\sigma_{ee, 2}}, e \rangle$ if $s \in [(4, 1), (4, 3)]$, and either one otherwise. Depending on s , $\sigma_{en} \oplus_t \sigma_{ee}$ continues its behavior either as σ_{en} or σ_{ee} (see Figure 1).

Now, let $\prod \Sigma = \sigma_1 \otimes_0 (\sigma_2 \otimes_0 (\dots \otimes_0 (\sigma_{n-1} \otimes_0 \sigma_n) \dots))$, $\Gamma_{\eta, t}$ be the sequence of actions taken during the last t steps of history $\eta \in \Omega$, and define $\mu_{\Xi, t} : \Omega \times \Xi \rightarrow [0, 1]$ as $\mu_{\Xi, t}(\eta, \varsigma) = \max\{P(s, \sigma_i) : s \in \bar{I}_{\odot_t \Xi}\}$

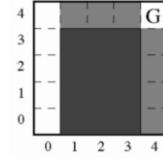

Figure 1. After the first step, $\sigma_{en} \oplus \sigma_{ee}$ behaves like σ_{en} if current state is in the right light shaded area, behaves like σ_{ee} if it is in the top light shaded area, and either as σ_{en} or σ_{ee} if it is in the dark shaded area.

$A_{\sigma_i^{1, t-1}} = \Gamma_{\eta, t-1}$ and $a_{\sigma_i, t} \in \bar{f}_\varsigma$. If $\sigma_\tau \in \Sigma$ is selected by P at state s and executed successfully $|\sigma_\tau|$ steps until termination, then initiated at s , $\prod \Sigma$ takes exactly the same actions as σ_τ , and exhibit the same behavior and therefore can be used to represent ct-sequences in Σ up to P .

We can computationally represent a stochastic ct-sequence ς , and consequently $\prod \Sigma$ defined above, in a natural form by using a rooted tree T_ς , called *sequence tree*. Each edge of the sequence tree is labeled with an action, and there is a node for every action sequence p that can be generated by ς when executed, denoted by ν_p . The root node designates the empty action sequence. Let p and q be two action sequences such that $q = pa$ where $a \in A$, then ν_p is connected to ν_q by an edge with label a . Furthermore, ν_q is associated with an initiation set I_{ν_q} specifying the states where action a can be selected after the execution of action sequence p . A node with $k > 1$ outgoing edges is called a decision point of order k . Let E_ν be the set of labels on out-going edges of ν . If ν is a decision point then ν is assigned a branching condition $\vartheta_\nu : \Omega \times E_\nu \rightarrow [0, 1]$ which selects one of the actions in E_ν based on the observed history. Given a stochastic ct-sequence ς , its corresponding sequence tree can be constructed in linear time recursively by creating and connecting decision points starting from the root node, based on the structure of ς .

Initiated at state s , a sequence tree T_ς selects actions by following a path starting from the root node and choosing edges according to initiation sets and branching conditions of nodes. Let $\widehat{\nu}$ denote the active node of T_ς , which is initially the root node, $e_{u, v}$ denotes the action on the label of the edge connecting u to v , and s be the current state. Let $N = \{\nu_1, \dots, \nu_k\}$ be the set of child nodes of $\widehat{\nu}$ with initiation sets containing s . At each step, if $N = \emptyset$, then execution of T_ς terminates. If $N = \{\nu_i\}$, then action $e_{\widehat{\nu}, \nu_i}$ is selected and $\widehat{\nu}$ is set to ν_i , or else, action a is selected using probability distribution $\vartheta_{\widehat{\nu}}(\eta, \cdot)$ and $\widehat{\nu}$ is set to ν_i such that $e_{\widehat{\nu}, \nu_i} = a$.

When the set of ct-sequences, Σ , is known in advance, a stochastic ct-sequence $\prod \Sigma$ and corresponding sequence tree $T_{\prod \Sigma}$ can be constructed and utilized instead of sequences in Σ . However, if such an information is not available prior to learning, it is still possible to discover useful ct-sequences online, as learning progresses, and iteratively build a sequence tree to represent them based on histories observed by the agent as we describe in the next section.

4 Discovering Ct-sequences

A history that starts with state s and obtained by following a policy π until the end of an episode (or between designated conditions such as when a reward peak is reached) is called a π -history of s . Let π' and π^* denote the agent's current policy and an optimal policy, respectively, and $h' = s_1 a_1 r_2 \dots r_t s_t$ be a π' -history of length t for state s_1 . Total cumulative reward of h' is defined as $r(h') = r_2 + \gamma r_3 + \dots + \gamma^{t-1} r_t$. Now, suppose that in h' a state appears at two positions i and j , i.e., $s_i = s_j, i \neq j$; and consider

the sequence $h'' = s_1 a_1 r_2 \dots r_i s_i a_{j+1} r_{j+1} \dots r_t s_t$, where s_i and s_j are united and the sequence in between is removed. h'' is also a (synthetic) π' -history for state s_1 and could be a better candidate for being a π^* -history if $r(h'') > r(h')$. Every suffix of h' of the form $h'_i = s_i a_i r_{i+1} \dots r_t s_t$ for $i = 2..t - 1$ is also a π' -history. Combining these two observations, we can generate a set of π^* -history candidates by processing h' from back to front. Let bh'_s denote the π' -history for state s with maximum total cumulative reward; initially $bh'(s_{t-1}) = s_{t-1} a_{t-1} r_{t-1} s_t$. For each $s_i, i = t - 2..1$, if s_i is not encountered before (i.e., for $j > i, s_j \neq s_i$) or $r_i + \gamma r(bh'_{s_{i+1}})$ is higher than the total cumulative reward of the current bh'_{s_i} , $r(bh'_{s_i})$, then bh'_{s_i} is replaced by $s_i a_i r_{i+1} b h'_{s_{i+1}}$. Finally, for each unique s_i in (s_1, \dots, s_t) , resulting bh'_{s_i} is used as a probable π^* -history for state s_i . For every π' -history $h' = s_1 a_1 r_2 \dots r_t s_t$, there is a corresponding ct-sequence $\sigma_{h'} = \langle \{s_1\}, a_1 \rangle \dots \langle \{s_{t-1}\}, a_{t-1} \rangle$. Let H_i be the set of such ct-sequences generated at i^{th} episode. As learning progresses, ct-sequences with action sequences that are part of useful subpolicies, and their successors, would appear more frequently in the recent H_i 's, whereas occurrence rate of ct-sequences with dominated subpolicies or that are less general would be low. Therefore, by keeping track of such ct-sequences and generalizing them, one can identify valuable abstractions and utilize them to improve learning performance. This can be accomplished efficiently using a modified version of a sequence tree.

An *extended* sequence tree is a sequence tree which has additional eligibility and expected reward attributes. Let p and q be two action sequences such that $q = pa$ where $a \in A$, then ν_p is connected to ν_q by an edge $e_{p,q}$ with label $\langle a, \psi \rangle$ where ψ denotes the eligibility of $e_{p,q}$, an indicator of how frequent action sequence q is executed, and ν_q holds a list of tuples $\langle s_1, \xi_{s_1}, R_{s_1} \rangle, \dots, \langle s_k, \xi_{s_k}, R_{s_k} \rangle$ stating that a can be selected at s_i after executing p with an expected total cumulative reward of R_{s_i} . ξ_{s_i} is the eligibility of s_i at ν_q , which indicates how frequent a is actually selected at state s_i after p is executed. $I_{\nu_p} = \{s_1, \dots, s_k\}$ is the initiation set of ν_p . A π -history $h = s_1 a_1 r_2 \dots r_t s_t$ can be added to an extended sequence tree T by starting from the root node and following edges according to their labels. Let \hat{n} denote the active node of T , which is initially the root node. For $i = 1..t - 1$, if there is a node n such that \hat{n} is connected to n by an edge $e_{\hat{n},n} = \langle a_i, \psi_{\hat{n},n} \rangle$, then (i) $\psi_{\hat{n},n}$ is incremented. (ii) if n contains a tuple $\langle s_i, \xi_{s_i}, R_{s_i} \rangle$, then ξ_{s_i} is incremented and R_{s_i} is updated if $r(h_i) > R_{s_i}$, otherwise a new tuple $\langle s_i, 1, r(h_i) \rangle$ is added to n , and (iii) \hat{n} is set to n afterwards. If such a node n does not exist, a new node with tuple $\langle s_i, 1, r(h_i) \rangle$ is created, and \hat{n} is connected to this node by an edge $e = \langle a_i, 1 \rangle$; the new node becomes the active node.

After each episode, based on the sequence of states, actions and rewards observed during the episode (or between two termination conditions in case of non-episodic tasks) a set of probable π^* -histories are generated and added to the path tree. The eligibility values of edges are decremented by a factor of $0 < \psi_{decay} < 1$, and eligibility values in the tuples of each node are decremented by a factor of $0 < \xi_{decay} \leq 1$. For an action sequence σ that is frequently used, edges on the path from the root node to the node representing σ and tuples with visited states would have high eligibility values, whereas they would decay to 0 for sequences that are used less. Hence, in order to filter traces of previous policies that are no longer useful, tuples with eligibility values less than a given threshold, $\xi_{threshold}$, are removed from the nodes, and each node with empty tuple list is removed from the tree together with incoming edge and the subtree rooted at it. Similarly, edges with eligibility value less than a given threshold $\psi_{threshold}$, and all connected nodes are also pruned. The

resulting extended sequence tree after performing these operations represents recent potential ct-sequences in a compact form. Since branching conditions are not available in an extended sequence tree, action selection procedure previously defined for sequence trees must be slightly modified; At node n if multiple children nodes ν_1, \dots, ν_k contain a tuple $\langle s, \xi_{s,\nu_i}, R_{s,\nu_i} \rangle$ for the current state s , then one of them is selected on the basis of R_{s,ν_i} and/or ξ_{s,ν_i} . Since ct-sequences represented by the resulting tree are constantly updated, it is not feasible to directly integrate them into RL framework by extending the value functions and Bellman equations to include options. Instead, a flat policy approach can be used by triggering the execution of the tree (and consequently represented ct-sequences) with a given probability and reflecting the action selections to underlying RL algorithm for value function updates.

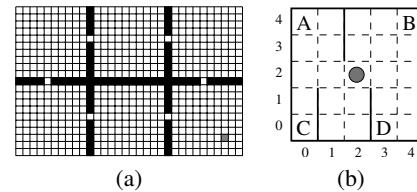

Figure 2. (a) Six-room maze, and (b) Dietterich's taxi domain.

5 Experiments

We applied the method described in Section 4 to regular Q-learning on two test domains, a six-room maze and Dietterich's taxi problem [2], and compared its performance with other RL algorithms. In all cases, the initial Q-values are set to 0, the learning rate and discount factor are $\alpha = 0.125$, and $\gamma = 0.9$, respectively. ϵ -greedy action selection mechanism is used with $\epsilon = 0.1$. In the six-room maze problem, the agent's task is to move from a randomly chosen position in the top left room to the grey shaded goal location in the bottom right room. The primitive actions are movement to a neighboring cell in four directions (Figure 2a). Each action succeeds with probability 0.9 or moves the agent perpendicular to the desired direction with probability 0.1. The agent only receives a reward of 1 when it reaches the goal location. For all other cases, it receives a small negative reward of -0.01 . Therefore, it must learn to reach the goal state as quickly as possible to maximize total discounted reward. In this task, for a better performance the agent needs to learn to make use of the passages connecting the rooms, which are the bottleneck states. Figure 3 shows sliding window (20 episodes) average of number of steps for reaching the goal averaged over 30 runs. ψ_{decay} , ξ_{decay} , and eligibility thresholds are 0.95, 0.99, and 0.01, respectively. Sequence tree is processed with a probability of 0.3 to run represented option. While processing the tree, Q-values are updated using the update rule of Q-learning on the basis of selected actions and observed states. At decision points, actions are chosen ϵ -greedily based on rewards of the tuples. For $Sarsa(\lambda)$ algorithm, λ is taken as 0.98. Used in the *macro-q* algorithm are predefined options which move the agent from any cell in a room, except bottom right one which contains the goal location, to one of two doorways that connect to neighboring rooms in minimum number of steps. As can be seen from Figure 3, Q-learning with sequence tree outperforms other algorithms and learns faster. This shows that the method is successful in discovering and utilizing ct-sequences that are indeed useful for the solution.

In the taxi problem, a taxi agent moves around on a 5×5 grid world, containing obstacles that limit the movement (Figure 2b), and tries to transport passengers located at predefined locations, to either

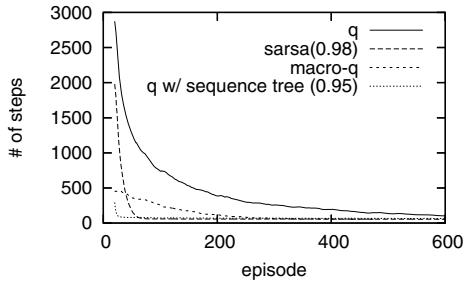

Figure 3. Results for six-room maze problem.

the same location or to another one. At each time step, the agent can either move one square in one of four directions, attempt to *pickup* a passenger, or attempt to *drop-off* the passenger being carried. If a move action would cause the agent to hit a wall, the position of the agent does not change. The movement actions are non-deterministic and with 0.2 probability agent may move perpendicular to the desired direction. Passengers can not be co-located at the same position but their destinations can be the same. There is an immediate reward of +20 if a passenger is transported successfully, -10 if pickup or drop-off actions are executed incorrectly, and -1 for any other action. An episode ends when all passengers are transported to their destinations. In order to maximize the overall cumulative reward, the agent must transport the passenger using minimum number of actions. Initial position of the taxi agent, locations and destinations of the passengers are selected randomly with uniform probability. Compared to six-room maze, taxi domain has a larger state space and possesses a hierarchical structure with repeated subtasks. Results for the taxi problem with one and two passengers are plotted in Figure 4. For the *macro-q* algorithm, predefined options that move the agent from any position to one of predefined locations in minimum number of steps are used. Various ψ_{decay} values are tested, other parameters are the same as in maze problem. Q-learning with sequence tree performs better than all other RL algorithms. The reason that it performs better than *macro-q* is the fact that *macro-q* needs to learn which options are optimal whereas Q-learning with sequence tree starts to use sub-optimal sequences immediately. Note that the convergence rate of algorithms that do not make use of abstractions decrease as common subtasks become more prominent. The results also show that the proposed method is effective in identifying solutions in such cases. Figure 5 shows the size of the sequence tree in terms of the number of nodes for different values of ψ_{decay} . Although their performances are similar, sequence tree shrinks considerably as ψ_{decay} decreases.

6 Conclusions

We emphasized the usefulness of discovering Semi-Markov options automatically using domain information acquired during learning. Further, we demonstrated the importance of constructing a dynamic and compact sequence-tree from histories. Experiments highlighted the effectiveness of utilizing such a tree in the learning process. Our future work will examine guaranteed convergence of the proposed method and its adaptation to larger domains, possibly involving continuous state variables.

Least Squares SVM for Least Squares TD Learning

Tobias Jung¹ and Daniel Polani²

Abstract. We formulate the problem of least squares temporal difference learning (LSTD) in the framework of least squares SVM (LS-SVM). To cope with the large amount (and possible sequential nature) of training data arising in reinforcement learning we employ a subspace based variant of LS-SVM that sequentially processes the data and is hence especially suited for online learning. This approach is adapted from the context of Gaussian process regression and turns the unwieldy original optimization problem (with computational complexity being cubic in the number of processed data) into a reduced problem (with computational complexity being linear in the number of processed data). We introduce a QR decomposition based approach to solve the resulting generalized normal equations incrementally that is numerically more stable than existing recursive least squares based update algorithms. We also allow a forgetting factor in the updates to track non-stationary target functions (i.e. for the use with optimistic policy iteration). Experimental comparison with standard CMAC function approximation indicate that LS-SVMs are well-suited for online RL.

1 Introduction

Least-squares TD (LSTD) One very important subproblem in reinforcement learning (RL) is the policy evaluation problem, e.g. see [13]. The goal is to compute the value function under a fixed policy π (we assume a deterministic π), which is taken to be the infinite horizon, discounted sum of rewards $V^\pi(\mathbf{x}) = E^\pi \{ \sum_{i=0}^{\infty} \gamma^i r_i \mid \mathbf{x}_0 = \mathbf{x} \}$ for the Markov chain resulting from starting in state \mathbf{x} and choosing actions according to policy π afterwards. Here r_i denotes the reward obtained while traversing from state \mathbf{x}_{i-1} to \mathbf{x}_i , and $\gamma \in [0, 1]$ denotes a discount factor. The expectation E^π is meant wrt. the distribution of complete trajectories. However, the Bellman equation allows us to write V^π just using the distribution of the successor states \mathbf{x}' , i.e. $V^\pi(\mathbf{x}) = E^\pi \{ r_t + \gamma V^\pi(\mathbf{x}') \mid \mathbf{x}_{t-1} = \mathbf{x} \}$. To compute V^π from actual trajectories we can employ temporal difference learning, e.g. TD(0), which employs *incremental* updates of the form $[r + \gamma V(\mathbf{x}')] - V(\mathbf{x})$ for the observed transition from \mathbf{x} to \mathbf{x}' as an unbiased estimate for the true (unknown) expectation. It works well in conjunction with parametrized function approximation and is usually trained with (stochastic) gradient descent.

A variant that computes a solution in closed form is LSTD [2, 8], minimizing the Bellman residuals for *all* observed transitions in a least squares sense. This approach is more efficient since it makes simultaneous use of all transitions seen so far. One disadvantage³

¹ University of Mainz, Germany, email: tjung@informatik.uni-mainz.de

² University of Hertfordshire, UK, email: d.polani@herts.ac.uk

³ Also, if the transitions are stochastic, we need a second independent sample for each transition [1]. To allow a clearer exposition of our algorithm we will only consider deterministic transitions. For stochastic MDPs this problem can be side-stepped by least squares fixed point approximation [2, 8].

of LSTD is that it involves solving (recursively) the corresponding normal equations which is more costly than mere gradient descent and has limited its use to parametrized function approximation.

In this paper we aim to exploit the data efficiency of LSTD and the superior generalization capabilities of kernel-based methods as underlying function approximator. Kernel-based methods (e.g. SVM) are a flexible and more powerful alternative to parametric methods, since the solution does not depend on a small number of features chosen beforehand but is expanded in the training data itself. In the past, kernel-based methods have mostly been used for batch RL [4]. More recently, based on the online sparsification for Gaussian process regression (GPR) from [3], a GPR approach for online TD learning was proposed in [5].

Our approach is in some respects similar to theirs (since generally the predictor obtained from LS-SVM equals the posterior mean of the GPR and the regularization parameter just corresponds to the noise estimate). Our contribution lies 1.) in an alternative, elegant derivation using LS-SVM, 2.) presenting a QR decomposition based update scheme that is numerically more stable, 3.) including a forgetting factor to track non-stationary target functions (i.e. for the use with optimistic policy iteration) and 4.) providing further experimental evidence that kernel-based learning is well-suited for RL.

LS-SVM for LSTD Assume we have observed the t deterministic transitions $\{(\mathbf{x}_{i-1} \rightarrow \mathbf{x}_i, r_i)\}_{i=1}^t$, $\mathbf{x}_i \in \mathcal{X} \subset \mathbb{R}^d$, $r_i \in \mathcal{Y} \subset \mathbb{R}$. The goal is to find a function $V : \mathcal{X} \rightarrow \mathcal{Y}$ which minimizes the residuals for the given data and generalizes well to unseen data. We proceed in the usual way: choose the reproducing kernel Hilbert space (RKHS) \mathcal{H} of functions $V : \mathcal{X} \rightarrow \mathcal{Y}$ endowed with kernel k , where $k : \mathcal{X} \times \mathcal{X} \rightarrow \mathcal{Y}$ is a symmetric, positive function (e.g. think of Gaussian radial basis functions). To learn the unknown function we solve a Tikhonov functional of the special form

$$\min_{V \in \mathcal{H}} \frac{1}{t} \sum_{i=1}^t \left[(V(\mathbf{x}_{i-1}) - \gamma V(\mathbf{x}_i)) - r_i \right]^2 + \frac{\Lambda}{t} \|V\|_{\mathcal{H}}^2. \quad (1)$$

The first term measures the error in the approximation (of temporal differences) and the second term penalizes the complexity (i.e. the roughness) of the candidate V . The regularization parameter Λ/t controls the trade-off between them. The Representer theorem tells us that every solution to (1) is the sum of kernels centered on the data: i.e. $V(\cdot) = \sum_{i=1}^t \alpha_i k(\mathbf{x}_i, \cdot)$ where $\boldsymbol{\alpha} = (\alpha_1, \dots, \alpha_t)^T$ are the coefficients that we need to determine. Define a $t \times (t+1)$ band matrix \mathbf{D} by setting $d_{ii} = 1$ and $d_{i,i+1} = -\gamma$. Replacing V in (1) by its expansion and using that in RKHS we have the property $\langle k(\mathbf{x}_i, \cdot), k(\mathbf{x}_j, \cdot) \rangle_{\mathcal{H}} = k(\mathbf{x}_i, \mathbf{x}_j)$, we then arrive at

$$\min_{\boldsymbol{\alpha} \in \mathbb{R}^t} \frac{1}{t} \|\mathbf{DK}_{tt} \boldsymbol{\alpha} - \mathbf{r}\|^2 + \frac{\Lambda}{t} \boldsymbol{\alpha}^T \mathbf{K}_{tt} \boldsymbol{\alpha} \quad (2)$$

with \mathbf{K}_{tt} being the $t \times t$ kernel matrix $[\mathbf{K}_{tt}]_{ij} = k(\mathbf{x}_i, \mathbf{x}_j)$ and $\mathbf{r} = (r_1, \dots, r_t)^T$ being the sequence of observed rewards. Solving for $\boldsymbol{\alpha}$ we obtain

$$(\mathbf{H}_{tt}^T \mathbf{H}_{tt} + \Lambda \mathbf{K}_{tt}) \boldsymbol{\alpha} = \mathbf{H}_{tt}^T \mathbf{r}. \quad (3)$$

where the $t \times t$ matrix \mathbf{H}_{tt} is defined as $\mathbf{H}_{tt} =_{\text{def}} \mathbf{D} \mathbf{K}_{tt}$.

The central difficulty when using a non-parametric approach like (1) is that the computational and memory complexity scales badly in the data: the kernel matrix is dense and requires $\mathcal{O}(t^2)$ storage, solving the generalized normal equations (3) requires $\mathcal{O}(t^3)$ operations and even every single prediction using the learned model requires $\mathcal{O}(t)$ operations. Clearly, this would be completely infeasible when used in conjunction with RL. In the next section we review *sparse approximation* as means to overcome this problem.

2 Background: Projection on a subset of kernels

The technique of sparse approximation attempts to approximate the kernel matrix using only a small subset of the data and avoids explicit use and storage of the full $t \times t$ kernel matrix. In the subsequent computations it allows us to consider a greatly reduced number of variables. It is a very common technique in the context of Gaussian process regression [3, 5, 11, 14].

Sparse approximation Sparse approximation is based on the observation that the kernel matrix often has rapidly decaying eigenvalues. Vanishing eigenvalues indicate that the data spans – approximately – a rather low dimensional manifold in the feature space. Thus, instead of using all the data points we can restrict ourselves to use only those composing a basis of this manifold and project the remaining ones onto their span. Let this basis be $\{k(\tilde{\mathbf{x}}_i, \cdot)\}_{i=1}^m$ for a subset of m chosen data points⁴ ($m \leq t$). Now, for arbitrary \mathbf{x}_i kernel $k(\mathbf{x}_i, \cdot)$ is approximated using only the m chosen basis elements

$$k(\mathbf{x}_i, \cdot) \approx \sum_{j=1}^m a_{ij} k(\tilde{\mathbf{x}}_j, \cdot) \quad i = 1 \dots t. \quad (4)$$

In particular \mathbf{a}_i becomes the j -th unit vector if \mathbf{x}_i equals basis element $\tilde{\mathbf{x}}_j$ for some index j , so that the m data points constituting the basis are represented exactly in the feature space. The remaining $t - m$ ones are represented only approximately. To obtain the coefficients a_{ij} we minimize in RKHS \mathcal{H} the distance $d_i := \|k(\mathbf{x}_i, \cdot) - \sum_{j=1}^m a_{ij} k(\tilde{\mathbf{x}}_j, \cdot)\|_{\mathcal{H}}^2$. Writing this in terms of the inner product and setting its derivative to zero we arrive at

$$\mathbf{a}_i = \mathbf{K}_{mm}^{-1} \mathbf{k}_i \quad (5)$$

where \mathbf{K}_{mm} is the $m \times m$ kernel matrix corresponding to the basis elements with $[\mathbf{K}_{mm}]_{ij} = k(\tilde{\mathbf{x}}_i, \tilde{\mathbf{x}}_j)$ and $\mathbf{k}_i = (k(\tilde{\mathbf{x}}_1, \mathbf{x}_i), \dots, k(\tilde{\mathbf{x}}_m, \mathbf{x}_i))^T$. Once we have determined \mathbf{a}_i for input \mathbf{x}_i , we obtain the corresponding approximation error as

$$d_i = k_{ii} - \mathbf{k}_i^T \mathbf{a}_i \quad (6)$$

where $k_{ii} = k(\mathbf{x}_i, \mathbf{x}_i)$. This quantity tells us how well the basis is able to approximate the i -th data point.

⁴ To avoid using cumbersome index sets we just mark data points selected into the basis by a tilde

Online selection of the subset Next we need to deal with the selection of the subset $\{\tilde{\mathbf{x}}_i\}_{i=1}^m$ which is going to make up our basis. Possibilities include a greedy and iterative approach, adding the element to the basis that best represents all remaining non-basis elements [12], the incomplete Cholesky factorization [7] or just random selection [14]. However, all methods but the latter are unsuitable when the data arrives incrementally. For this particular purpose, [3] and later [6] have proposed a greedy online scheme that builds up the basis incrementally and expands it whenever it becomes necessary. We will apply their method in our approach without modification: assume the data arrives sequentially at $t = 1, 2, \dots$ and that we can examine every data point once but cannot revise our decision later. We maintain a list of currently chosen basis-elements \mathcal{D}_m (the dictionary), the inverse \mathbf{K}_{mm}^{-1} and assume that after seeing $t - 1$ samples dictionary \mathcal{D}_m contains m elements. When a new example \mathbf{x}_t arrives we compute how well it can be approximated using \mathcal{D}_m , i.e. we compute (6). If this distance is below some chosen threshold ν , the current basis represents \mathbf{x}_t well enough and we do not need to consider it further. If the distance exceeds the chosen tolerance, we add $k(\mathbf{x}_t, \cdot)$ to the basis: expand $\mathcal{D}_{m+1} = \mathcal{D}_m \cup \{\mathbf{x}_t\}$ and update \mathbf{K}_{mm}^{-1} . Since the change to \mathbf{K}_{mm} just involves appending \mathbf{k}_t , the new inverse can be obtained recursively either using the partitioned matrix inversion formula or the Cholesky factorization. Computational cost and storage is $\mathcal{O}(m^2)$.

It can be shown [6] that for threshold $\nu > 0$ the number m of selected elements is bound by $\text{Const} \cdot \nu^{-d}$, where d is the dimensionality of the input domain $\mathcal{X} \subset \mathbb{R}^d$. Hence, for a continuous stream of data $\{\mathbf{x}_t\}_{t=1}^\infty$ the dictionary remains finite. For any reasonable choice of ν (e.g. $\nu = 10^{-2}$) the number of selected elements m is usually only a fraction of the number t of observed data points and further stops increasing during the later stages of learning.

Solving a reduced problem Distinguish between batch and online selection of the subset. First consider the batch case, where we compute the \mathbf{a}_i after we have determined the m basis elements. Define a $t \times m$ matrix \mathbf{A} with rows \mathbf{a}_i^T from (5). Then we can write

$$\mathbf{A}^T = \mathbf{K}_{mm}^{-1} \mathbf{K}_{tm}^T \quad (7)$$

with \mathbf{K}_{tm} being the m columns of the full kernel matrix corresponding to the m indices of the basis elements. We obtain that $\hat{\mathbf{K}}_{tt} =_{\text{def}} \mathbf{A} \mathbf{K}_{mm} \mathbf{A}^T = \mathbf{K}_{tm} \mathbf{K}_{mm}^{-1} \mathbf{K}_{tm}^T$ is a low-rank approximation of the full kernel matrix \mathbf{K}_{tt} . To benefit from this approximation [12] suggest the following: solve the regularized risk functional (1) using all data points, but allow only the coefficients of the m points constituting the basis to have non-zero values. This leads to a modified problem (c.f. the original problem (2)):

$$\min_{\boldsymbol{\alpha} \in \mathbb{R}^m} \frac{1}{t} \|\mathbf{D} \mathbf{K}_{tm} \boldsymbol{\alpha} - \mathbf{r}\|^2 + \frac{\Lambda}{t} \boldsymbol{\alpha}^T \mathbf{K}_{mm} \boldsymbol{\alpha} \quad (8)$$

and to the system of linear equations

$$(\mathbf{H}_{tm}^T \mathbf{H}_{tm} + \Lambda \mathbf{K}_{mm}) \boldsymbol{\alpha} = \mathbf{H}_{tm}^T \mathbf{r} \quad (9)$$

where the $t \times m$ matrix \mathbf{H}_{tm} is defined as $\mathbf{H}_{tm} = \mathbf{D} \mathbf{K}_{tm}$. Thus we end up solving the $m \times m$ system (9) rather than the $t \times t$ system (3), which reduces computational and storage costs to manageable $\mathcal{O}(m^3)$ and $\mathcal{O}(m^2)$ respectively.

If we assume online selection of the basis elements, to compute the \mathbf{a}_i we can use only the basis elements found up to the current time step (whereas in the batch case we would use the complete basis). Indices in \mathbf{a}_i corresponding to elements added in future are set to

zero. Instead of (7) we obtain that $\tilde{\mathbf{K}}_{tm} =_{\text{def}} \mathbf{A}\mathbf{K}_{mm}$ is only an approximation of the true submatrix \mathbf{K}_{tm} . To indicate this difference, we will use the notation $\tilde{\mathbf{H}}_{tm}$ instead of \mathbf{H}_{tm} in (9).

3 Time recursive solution using the QR method

The usual way to solve the normal equations (9) incrementally for each observed transition $(\mathbf{x}_{t-1} \rightarrow \mathbf{x}_t, r_t)$ is to employ recursive least squares methods. Our approach is different though, we present a QR based solution adapted from the adaptive filtering literature, e.g. [10], which comes at the same cost of $\mathcal{O}(m^2)$ operations per step but has increased numerical stability.

Concerning notation: the first subscript t will denote the current number of transitions and the second subscript m will denote the current number of basis elements. Substituting in (9) the $m \times m$ cross-product matrix by $\Phi_{tm} = (\tilde{\mathbf{H}}_{tm}^T \tilde{\mathbf{H}}_{tm} + \Lambda \mathbf{K}_{mm})$, and the rhs by $m \times 1$ vector $\mathbf{s}_{tm} = \tilde{\mathbf{H}}_{tm}^T \mathbf{r}$ eq. (9) becomes

$$\Phi_{tm} \alpha_t = \mathbf{s}_{tm} \quad (10)$$

Next we introduce the Cholesky factorization $\Phi_{tm} = \Phi_{tm}^{1/2} \Phi_{tm}^{T/2}$ and an auxiliary $m \times 1$ vector \mathbf{q}_{tm} . To solve (10) we first solve $\Phi_{tm}^{1/2} \mathbf{q}_{tm} = \mathbf{s}_{tm}$ and then $\Phi_{tm}^{T/2} \alpha_t = \mathbf{q}_{tm}$.

Assume we have observed $t - 1$ transitions and selected m basis functions. Each update t now proceeds as follows: we check if \mathbf{x}_t is represented by the current basis well enough or if we will need to augment the basis. The involved quantities $\{\Phi_{tm}^{1/2}, \mathbf{q}_{tm}, \mathbf{K}_{mm}^{1/2}\}$ are then updated accordingly. At the end we just solve $\Phi_{tm}^{T/2} \alpha_t = \mathbf{q}_{tm}$ to obtain the desired α_t . Below we sketch the derivation of the central steps (see Fig. 1 for the complete algorithm).

Step 1: Processing new data without augmenting the basis: \mathbf{x}_t is approximately represented by the current dictionary, therefore we only add the row vector $\mathbf{h}_t^T = (\mathbf{k}_{t-1} - \gamma \mathbf{k}_t)^T$ to the designmatrix. Thus,

$$\begin{aligned} \Phi_{tm} &= \left[\begin{array}{c} \tilde{\mathbf{H}}_{t-1,m} \\ \mathbf{h}_t^T \end{array} \right]^T \left[\begin{array}{c} \tilde{\mathbf{H}}_{t-1,m} \\ \mathbf{h}_t^T \end{array} \right] + \Lambda \mathbf{K}_{mm} \\ &= \Phi_{t-1,m} + \mathbf{h}_t \mathbf{h}_t^T \end{aligned}$$

and hence

$$\Phi_{tm} \mathbf{q}_{tm} = \Phi_{t-1,m} \mathbf{q}_{t-1,m} + r_t \mathbf{h}_t.$$

To carry out this update we employ the *array* notation from [10]: we start by arranging the quantities $\{\Phi_{t-1,m}^{1/2}, \mathbf{q}_{t-1,m}\}$ from the previous step and the newly obtained information $\{\mathbf{h}_t, r_t\}$ in a clever way. If we then generate a orthogonal transformation Θ_t to lower triangulize the resulting $(m+1) \times (m+1)$ array

$$\left[\begin{array}{cc} \Phi_{t-1,m}^{1/2} & \mathbf{h}_t \\ \mathbf{q}_{t-1,m} & r_t \end{array} \right] \Theta_t = \left[\begin{array}{cc} \Phi_{tm}^{1/2} & \mathbf{0} \\ \mathbf{q}_{tm} & * \end{array} \right] \quad (11)$$

we can directly read off the desired quantities $\{\Phi_{tm}^{1/2}, \mathbf{q}_{tm}\}$ from the right hand side⁵ of (11) due to the norm and inner product preserving properties of orthogonal transformations. To determine Θ_t we can, for example, apply m Givens rotations to successively annihilate the rightmost column \mathbf{h}_t in (11).

⁵ The * denotes a scalar quantity that is not relevant for us.

Step 2: Processing new data and augmenting the basis: \mathbf{x}_t is not approximately represented by the current dictionary. Now we actually have to perform two substeps. The first substep is to account for the change when adding a new example (which adds the new row $\mathbf{h}_t^T = (\mathbf{k}_{t-1} - \gamma \mathbf{k}_t)^T$ to the designmatrix and is step 1 from above) and the second substep is to account for the change when adding a new basis function (which adds the new column $\tilde{\mathbf{H}}_{t-1,m} \mathbf{a}_t$ to the designmatrix). Setting $h_{tt} = k(\mathbf{x}_{t-1}, \mathbf{x}_t) - \gamma k(\mathbf{x}_t, \mathbf{x}_t)$ we obtain the recursion

$$\begin{aligned} \Phi_{t,m+1} &= \left[\begin{array}{cc} \tilde{\mathbf{H}}_{t-1,m} & \tilde{\mathbf{H}}_{t-1,m} \mathbf{a}_t \\ \mathbf{h}_t & h_{tt} \end{array} \right]^T \left[\begin{array}{cc} \tilde{\mathbf{H}}_{t-1,m} & \tilde{\mathbf{H}}_{t-1,m} \mathbf{a}_t \\ \mathbf{h}_t & h_{tt} \end{array} \right] \\ &\quad + \Lambda \left[\begin{array}{cc} \mathbf{K}_{mm} & \mathbf{k}_t \\ \mathbf{k}_t^T & k_{tt} \end{array} \right] \\ &= \left[\begin{array}{cc} \Phi_{tm} & \Phi_{t-1,m} \mathbf{a}_t + h_{tt} \mathbf{h}_t \\ \mathbf{a}_t^T \Phi_{t-1,m}^T + h_{tt} \mathbf{h}_t^T & \zeta \end{array} \right] \end{aligned}$$

where ζ is short for $\zeta = \mathbf{a}_t^T \Phi_{t-1,m} \mathbf{a}_t + h_{tt}^2 + \Lambda(k_{tt} - \mathbf{a}_t^T \mathbf{k}_t)$. After computing ζ (where we need $\Phi_{t-1,m}$) we perform Step 1 (above) to obtain Φ_{tm} . Then we update the Cholesky factor $\Phi_{tm}^{1/2}$ by solving $\Phi_{tm}^{1/2} \mathbf{u} = \Phi_{t-1,m} \mathbf{a}_t + h_{tt} \mathbf{h}_t$ for \mathbf{u} and setting scalar $\beta = \sqrt{\zeta - \mathbf{u}^T \mathbf{u}}$. Finally we obtain the desired quantities $\{\Phi_{t,m+1}^{1/2}, \mathbf{q}_{t,m+1}\}$ via

$$\begin{aligned} \Phi_{t,m+1}^{1/2} &= \left[\begin{array}{cc} \Phi_{tm}^{1/2} & \mathbf{0} \\ \mathbf{u}^T & \beta \end{array} \right] \\ \mathbf{q}_{t,m+1} &= \left[\begin{array}{c} \mathbf{q}_{tm} \\ (\mathbf{a}_t^T \Phi_{t-1,m}^{1/2} \mathbf{q}_{t-1,m} + h_{tt} r_t - \mathbf{u}^T \mathbf{q}_{tm}) / \beta \end{array} \right] \end{aligned}$$

Exponential forgetting Our contribution to track a non-stationary target function (e.g. when using this approach for optimistic policy iteration and slowly changing policies π) is to include a forgetting factor $0 \ll \lambda < 1$ (e.g. $\lambda = 0.999$) that puts exponentially less emphasis on past experiences. Instead of (9) we solve a modified problem with $\Sigma_t =_{\text{def}} \text{diag}(\lambda^{t-1}, \dots, \lambda, 1)$

$$(\tilde{\mathbf{H}}_{tm}^T \Sigma_t \tilde{\mathbf{H}}_{tm} + \Lambda \lambda^t \mathbf{K}_{mm}) \alpha = \tilde{\mathbf{H}}_{tm}^T \Sigma_t \mathbf{r}$$

The derivation is similar to above, and the resulting updates are summarized in the complete algorithm in Fig. 1.

4 Experiments

Here we use simulation experiments both for policy evaluation (offline learning) and optimal control (online learning) to examine if our approach indeed benefits from better generalization when compared with two standard parametric methods: (1) grid-based tilecoding (CMAC) and (2) radial basis function networks.

Policy evaluation The first experiment is a puddle-world consisting of 101x101 cells (scaled to [0,1]). Possible actions are moving into one of the four adjacent cells. The goal state is the cell in the upper right corner. Each step not leading into the goal yields the reward $r = -0.1$. Three overlapping "puddles" (Gaussians) are placed at random and incur an additional penalty proportional to their activation. The location and spread of the puddles is depicted in Fig. 3. We computed the optimal value function and policy for this domain and generated transitions for 500 different episodes, each starting from a randomly chosen state and following the optimal policy to the goal (resulting in a training set of $\sim 50,000$ observed transitions). We then

Algorithm Online policy evaluation with sparse LS-SVM and exponential forgetting

Store: Dictionary $\mathcal{D}_m = \{\tilde{\mathbf{x}}_i\}_{i=1}^m, \Phi_{tm}^{1/2}, \mathbf{q}_{tm}, \mathbf{K}_{mm}^{1/2}$, current number of basis functions m

Parameter: Accuracy ν , regularization Λ , discount factor γ , forgetting factor λ

Output: Weights α_t for the approximated value function $V(\cdot) = \sum_{i=1}^m \alpha_{ti} k(\tilde{\mathbf{x}}_i, \cdot)$

For $t = 1, 2, \dots$ observe transition $(\mathbf{x}_{t-1} \rightarrow \mathbf{x}_t, r_t)$ under (fixed) policy π

1. Sparse approximation for \mathbf{x}_t

Compute $\mathbf{k}_t, \mathbf{h}_t, k_{tt}, h_{tt}$

Obtain \mathbf{p} from $\mathbf{K}_{mm}^{1/2} \mathbf{p} = \mathbf{k}_t$ and \mathbf{a}_t from $\mathbf{K}_{mm}^{T/2} \mathbf{a}_t = \mathbf{p}$

If $k_{tt} - \mathbf{a}_t^T \mathbf{k}_t > \nu$

Add \mathbf{x}_t to the dictionary, $\mathbf{K}_{mm}^{1/2} \leftarrow [\mathbf{K}_{mm}^{1/2}; \mathbf{0}; \mathbf{p}^T, \sqrt{k_{tt} - \mathbf{p}^T \mathbf{p}}]$, **Goto 3.**

Else **goto 2.**

2. Add data point but do not augment basis ($\{\Phi_{t-1,m}^{1/2}, \mathbf{q}_{t-1,m}\} \mapsto \{\Phi_{tm}^{1/2}, \mathbf{q}_{tm}\}$):

Generate Θ_t to lower triangularize the array

$$\begin{bmatrix} \lambda^{1/2} \Phi_{t-1,m}^{1/2} & \mathbf{h}_t \\ \lambda^{1/2} \mathbf{q}_{t-1,m} & r_t \end{bmatrix} \Theta_t = \begin{bmatrix} \Phi_{tm}^{1/2} & \mathbf{0} \\ \mathbf{q}_{tm} & * \end{bmatrix}$$

and read $\Phi_{tm}^{1/2}, \mathbf{q}_{tm}$ from the rhs. Solve $\Phi_{tm}^{T/2} \alpha_t = \mathbf{q}_{tm}$ if necessary.

3. Add data point and augment basis ($\{\Phi_{t-1,m}^{1/2}, \mathbf{q}_{t-1,m}\} \mapsto \{\Phi_{t,m+1}^{1/2}, \mathbf{q}_{t,m+1}\}$):

Compute $\mathbf{c} = \Phi_{t-1,m}^{T/2} \mathbf{a}_t$ and $d = \mathbf{c}^T \mathbf{q}_{t-1,m}$. Then get $\Phi_{tm}^{1/2}, \mathbf{q}_{tm}$ from 2.

Obtain \mathbf{u} from $\Phi_{tm}^{1/2} \mathbf{u} = \lambda \Phi_{t-1,m}^{1/2} \mathbf{c} + h_{tt} \mathbf{h}_t$

Compute $\beta = \sqrt{\lambda \mathbf{c}^T \mathbf{c} + h_{tt}^2 + \Lambda \lambda^t (k_{tt} - \mathbf{a}_t^T \mathbf{k}_t) - \mathbf{u}^T \mathbf{u}}$

Update

$$\Phi_{t,m+1}^{1/2} = \begin{bmatrix} \Phi_{tm}^{1/2} & \mathbf{0} \\ \mathbf{u}^T & \beta \end{bmatrix}, \quad \mathbf{q}_{t,m+1} = \begin{bmatrix} \mathbf{q}_{tm} \\ (\lambda d + h_{tt} r_t - \mathbf{u}^T \mathbf{q}_{tm}) / \beta \end{bmatrix}$$

and solve $\Phi_{t,m+1}^{T/2} \alpha_t = \mathbf{q}_{t,m+1}$ if necessary.

Figure 1. Online policy evalution with sparse LS-SVM at $\mathcal{O}(m^2)$ operations per step, m being the number of basis functions

wished to examine how fast learning occurs when coupling LSTD with different types of function approximation. The transitions were fed successively into the algorithm and the error between approximation and true value function was measured. Function approximators were: (1) our sparsified LS-SVM (Gaussian kernel, $\sigma = 0.02$ with $\nu = 0.1$ and $\nu = 0.01$, $\Lambda = 10^{-3}$), (2) a CMAC (resolution 7x7x7 and 10x10x10), and (3) a RBF-net with fixed centers (spread uniformly on a 12 x 12 grid, $\sigma = 0.02$). The results are shown in Fig. 3 and indicate that our approach is in fact superior as far as generalization is concerned. Also compare the required resources: CMAC uses 343 and 1000 weights, the RBF-net uses 144 weights and our LS-SVM uses 122 and 202 weights.⁶

Optimal control In the second experiment we examine online learning and pit our LSTD-LSSVM against iterative sarsa(λ) with CMAC, which is the standard setup in RL and works well for many problems. To use LSTD for optimal control we employ optimistic policy iteration, and hence include a forgetting factor $\lambda = 0.999$ in the LS-SVM to cope with the non-stationarity of the value function due to the changing policy. The remaining parameters for LS-SVM were unchanged. Since we only consider learning value functions, we supply a generative model for policy improvement. The sarsa(λ) ($\lambda = 0.5$) setup was appropriately modified. As testbed we used the puddle-world from above and the puck-on-hill task from

[9]. Both tasks are episodic with designated terminal states: each episode starts from a random state and proceeds until either a terminal state is reached or the number of steps exceeds a fixed limit of 500 steps. Various performance criteria were considered, see Fig. 2 for the results. In both cases LS-SVM outperforms CMAC in terms of generalization, i.e. number of observed transitions to achieve good performance. Again sparse LS-SVM requires far less weights to achieve this level of accuracy, to obtain satisfactory results with the CMAC in the puddle-world we even needed to double the resolution (20x20x10). Fig. 3 illustrate the general benefit when using LSTD-LSSVM policy evaluation instead of iterative TD: just after running 20 trials and visiting only a small fraction of the state space the approximated value function has the same overall shape as the true value function.

5 Summary and future work

We formulated the problem of estimating the value function from actual trajectories in a regularization framework using least-squares SVM. The key contribution is a QR-based solution algorithm that is fully incremental, i.e. solves the resulting normal equations independent of the number of observed transitions and can hence be applied to *online* RL. In the future we wish to extend the scope of our work to the full RL problem. Among other things, we will address the issue of exploration, stochasticity in transitions, model-free learning through Q-values, and more comprehensive experiments with high-dimensional control tasks. We also aim to explore other criteria for the subset selection mechanism in sparse approximation (e.g. taking

⁶ Unfortunately we cannot directly compare CPU-time, since our algorithm is implemented in C whereas the other two run in Matlab. Some numbers: our algorithm processes 10,000 training examples with 122 weights in ~ 2 secs. Dominating this cost with $\mathcal{O}(m^2)$ is the number of weights m .

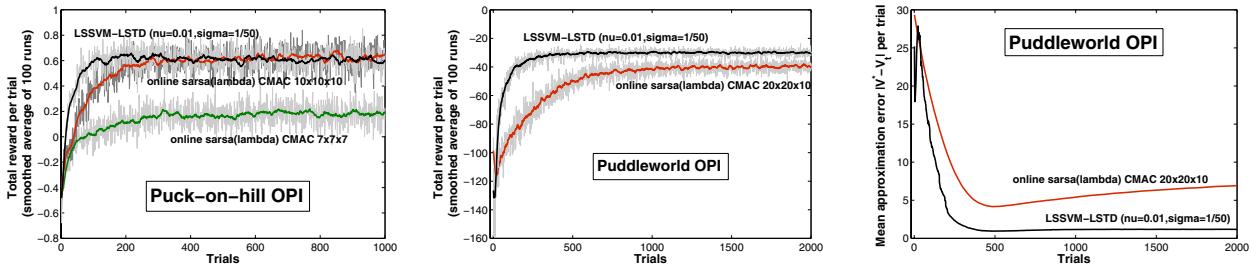

Figure 2. Online learning for optimal control with LS-SVM via optimistic policy iteration (OPI) for two toy problems

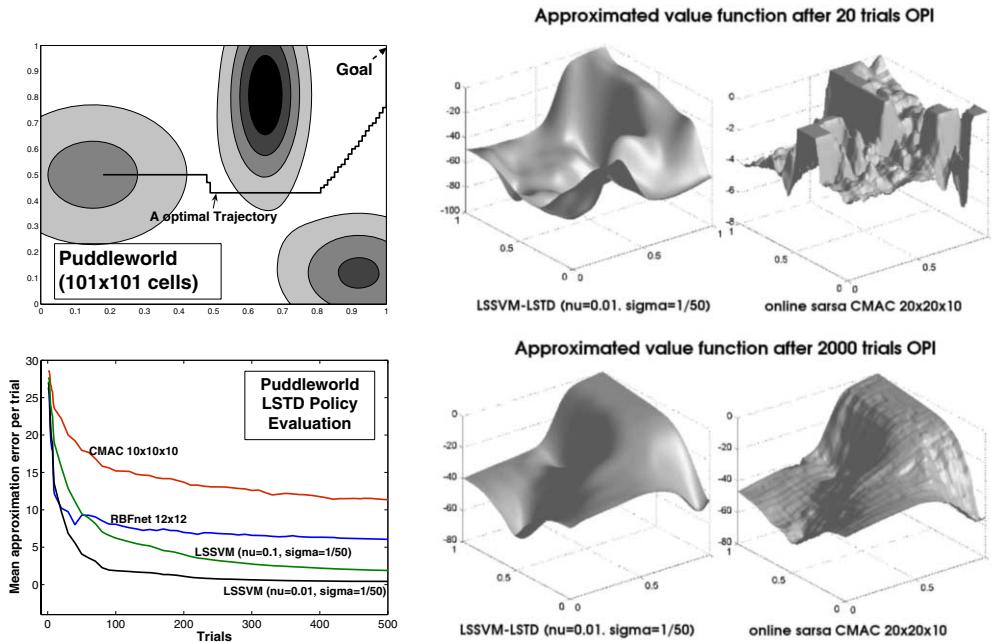

Figure 3. LS-SVM in policy evaluation (left) and OPI (right) for the puddle-world domain

into account the decrease of the error for the final predictor).

We believe that kernel-based methods are very well-suited for RL, since they are data-oriented and thus more flexible than traditional parametric methods: they place parameters where they are needed and when new data arrives and do not waste resources on parts of the state-space that are never visited. Though there is yet not much experimental evidence we believe that this approach could help to tackle high-dimensional control tasks that are yet unsolvable.

Argument Based Rule Learning

Martin Možina and Jure Žabkar and Ivan Bratko¹

Abstract. We present a novel approach to machine learning, called ABML (argumentation based ML). This approach combines machine learning from examples with concepts from the field of argumentation. The idea is to provide expert's arguments, or reasons, for some of the learning examples. We require that the theory induced from the examples explains the examples in terms of the given reasons. Thus arguments constrain the combinatorial search among possible hypotheses, and also direct the search towards hypotheses that are more comprehensible in the light of expert's background knowledge. In this paper we implement ABCN2 as an extension of the CN2 rule learning algorithm, and analyze its advantages in comparison with the original CN2 algorithm.

1 INTRODUCTION

A fundamental problem of machine learning is dealing with large spaces of possible hypotheses. Usually, this problem is addressed either by biasing learning towards simpler hypotheses, i.e. applying Occam's razor, or by using experts' domain knowledge for constraining search. Domingos [5] argues that the former approach is valid only if we honestly believe the target phenomenon is simple, and therefore prefers the use of domain knowledge. However, the problem of the latter approach is the difficulty that experts face when they try to articulate their background knowledge. In this paper, we present a novel approach for constraining search, that is based on the expert's knowledge about chosen learning examples rather than on the whole domain. In this approach, the domain expert explains some of the learning examples, and these examples are then, together with other examples, used in the learning algorithm. Explanation of examples is based on argumentation [10], therefore we call these examples argumented examples. The learning from such examples is called argument based machine learning (ABML), introduced by Bratko and Mozina in [1].

In section 2 we describe the motivation and basic ideas for argument based machine learning. In section 3 we develop an actual implementation of argument based machine learning, i.e. argument based CN2 (ABCN2 for short) as an extension of the well-known rule learning algorithm of Clark and Niblett [4]. In section 4, we demonstrate and analyze the advantages of ABCN2 over the original CN2 on a UCI data set.

2 ARGUMENT BASED MACHINE LEARNING: MOTIVATION AND PROBLEM STATEMENT

Argument based machine learning (ABML; outlined by Bratko and Mozina in [1]) is an approach to machine learning that draws on some

concepts of argumentation theory [10]. In this section we will describe the main motivation for this approach, formulate the learning problem for ABML, and contrast it to the usual ML problem.

Usually the problem of learning from examples is stated as:

- Given examples
- Find a theory that is consistent with the examples

We will now extend this problem statement to that of ABML. In ABML, some of the learning examples are augmented by arguments, or reasons, or (partial) justifications according to principles of argumentation [10]. Defeasible argumentation is a branch of artificial intelligence that analyzes processes of reasoning where arguments for and against a certain claim are produced and evaluated. A typical example of such reasoning is a law dispute at court, where plaintiff and defendant give arguments for their opposing claims, and at the end of the process the party with better arguments wins the case.

In our approach to ABML, arguments are used to explain (or argue) why a certain learning example is in the class as given (arguments for = positive arguments) or why it should not be (arguments against = negative arguments). Examples that are accompanied with arguments are called *argumented examples*. Argumented examples are a means for the domain expert to introduce his (partial) domain knowledge to the learning system prior to learning. The practical advantage of providing prior knowledge in the form of arguments about *individual* examples, in comparison with providing more general domain knowledge, is in that it is easier to explain concrete, specific examples than giving general theories. As arguments are reasons for a specific example, the expert does not have to ensure that the arguments are true for the whole domain. It suffices that they are true in the context of the given argumented example.

To illustrate the idea of argumented examples, consider a simple learning problem: learning about credit approval. Each example is a customer's credit application together with the manager's decision about credit approval. Each customer has a name and three attributes: PaysRegularly (with possible values "yes" and "no"), Rich (possible values "yes" and "no") and HairColor ("black", "blond", ...). The class is CreditApproved (with possible values "yes" and "no"). Let there be three learning examples shown in Table 1.

Table 1. Learning examples for credit approval.

Name	PaysRegularly	Rich	HairColor	CreditApproved
Mrs. Brown	no	yes	blond	yes
Mr. Grey	no	no	grey	no
Miss White	yes	no	blond	yes

The expert's argument for disapproving credit to Mr. Grey can be: Mr. Grey did not receive credit because he does not pay regularly. This is a very reasonable argument, however it does not hold for the whole domain. Mrs. Brown, for instance, did receive credit although she doe does not pay regularly.

¹ Faculty of Computer and Information Science, University of Ljubljana, Slovenia, email: martin.mozina@fri.uni-lj.si

With arguments, the learning problem statement changes to:

- Given examples + supporting arguments for some of the examples
- Find a theory that explains the examples using given arguments

Consider again the examples in Table 1 and assume that an expert gave an argument to Mrs. Brown: Mrs. Brown received the credit because she is rich. A rule learning algorithm might induce the following rule:

IF $HairColor = blond$ THEN $CreditApproved = yes$

This rule correctly explains all examples with class value “yes”. However, according to the definition of learning problem with arguments, induced rules should explain the Mrs. Brown using given arguments. Instead of mentioning hair color, an argument based rule learning algorithm would induce:

IF $Rich = yes$ THEN $CreditApproved = yes$

This rule explains Mrs. Brown example using given arguments (Credit was approved because $Rich = yes$).

The main motivation for using arguments in learning lies in two expected advantages:

1. Reasons (arguments) impose constraints over the space of possible hypotheses, thus reducing search complexity
2. An induced hypothesis should make more sense to an expert as it has to be consistent with given arguments.

Regarding advantage 1, by using arguments, the computational complexity associated with search in the hypothesis space can be reduced considerably, and enable faster and more efficient induction of hypotheses. Furthermore, a reduced number of possible hypotheses also decreases chances that the method will overfit. Regarding advantage 2, there are many possible hypotheses that, from the perspective of a machine learning method, explain the given examples sufficiently well. But some of those hypotheses can be incomprehensible to experts. Using arguments should lead to hypotheses that explain given examples in similar terms to those used by the expert, and correspond to the actual justifications.

3 IMPLEMENTATION

In this paper we introduce an algorithm, called ABCN2, for learning rules in argument-based framework for machine learning. ABCN2, which stands for argument based CN2, is an extension of the well-known CN2 rule induction algorithm of Clark and Niblett [4]. We will start this section with a description of argumented examples that are accepted by ABCN2, and continue with a detailed description of differences between the CN2 algorithm and its argument based counterpart ABCN2. At the end of this section we will describe a method that selects examples from data, which, if argumented, would most likely affect the learning of ABCN2.

3.1 Argumented examples

A learning example E in the usual form accepted by CN2 is a pair (A, C) , where A is an attribute-value vector, and C is a class value. In addition to such examples, ABCN2 also accepts argumented examples. An argumented example AE is a triple of the form:

$$AE = (A, C, Arguments)$$

As usual, A is an attribute-value vector and C is a class value. $Arguments$ is a set of arguments Arg_1, \dots, Arg_n , where an argument Arg_i has one of the following forms:

C because $Reasons$

or

C despite $Reasons$

The former specifies a *positive* argument (speaks for the given class value), while the latter specifies a *negative* argument (speaks against the class value). $Reasons$ is a conjunction of reasons r_1, \dots, r_n ,

$$Reasons = r_1 \wedge r_2 \wedge \dots \wedge r_n$$

where each of the reasons r_i can be in one of five possible forms. These forms are (explanations given to forms assume that r_i is a part of a positive argument; for negative arguments, the explanations are exactly the opposite):

- $X = x_i$ means that value x_i of attribute X is the reason why example is in the class as given. This is the only allowed form for discrete attributes.
- $X > x_i$ (or $X \geq x_i$) means that, as the value of attribute X of example is higher (or equal) than x_i , this is the reason for class value.
- $X < x_i$ (or $X \leq x_i$) the opposite to $X > x_i$ ($X \geq x_i$).
- $X >$ (or $X \geq$) “ X is high”, similar to $X > x_i$ ($X \geq x_i$), just that we do not know the threshold value and it has to be found by ABCN2. Such an argument says that the value of X of example is high enough to be in the class as given.
- $X <$ (or $X \leq$); “ X is low”, the opposite of $X >$ ($X \geq$).

For example, the expert’s argument for approving credit to Mrs. Brown (see Table 1) can be: Mrs. Brown received credit because she is rich. A negative argument can be: Mrs. Brown received credit despite she does not pay regularly. The Brown example would in our syntax be written as:

$$((PaysRegularly = no, Rich = yes, HairColor = blond), \\ CreditApproved = yes, \{CreditApproved = yes \text{ because} \\ Rich = yes, CreditApproved = yes \text{ despite} \\ PaysRegularly = no\}).$$

Arguments given to examples additionally constrain rules *covering* this example. Remember that in CN2, rules have the form:

IF $Complex$ THEN $Class$

where $Complex$ is the conjunction of simple conditions, called *selectors*. For the purpose of this paper, a selector simply specifies the value of an attribute, for example $HairColor = blond$ or a threshold on an attribute value, for example $Salary > 5000$. A rule for our credit approval domain can be:

IF $PaysRegularly = no$ AND $HairColor = blond$ THEN
 $CreditApproved = yes$

The condition part of the rule is satisfied by the attribute values of Mrs. Brown example, so we say that this rule *covers* this example.

A rule R is *consistent* with an argument: C because $Reasons$ (or C despite $Reasons$), if for all reasons r_i of $Reasons$ is true that:

1. If the reason r_i is in one of forms: “ $X = x_i$ ” or “ $X > x_i$ ” or “ $X < x_i$ ” (“ $X \geq x_i$ ” or “ $X \leq x_i$ ”), then exactly the same selector needs to be present in the complex of the rule R .
2. If the reason r_i has the form “ $X >$ ” (or “ $X <$ ”, “ $X \leq$ ”, “ $X \geq$ ”), then the complex of the rule R needs to contain a selector “ $X > x_i$ ” (or “ $X < x_i$ ”, “ $X \geq x_i$ ”, “ $X \leq x_i$ ”). The threshold value x_i does not matter for consistency.

With the use of arguments in examples, the definition of a rule *covering* an example needs to be refined. In the standard definition, a rule covers an example if the condition part of the rule is true for this example. In argument based rule learning, this definition is modified to: A rule R AB-covers an argumented example E if:

1. All conditions in R are true for E (same as in CN2),
2. R is consistent with at least one positive argument of E , and
3. R is not consistent with any of negative arguments of E .

As an illustration of the differences between AB-covering and the usual definition of covering, consider again the Brown example with the argument that she received credit because she is rich and despite she does not pay regularly. Now consider four rules:

- R1: IF $HairColor = blond$ THEN $CreditApproved = yes$.
- R2: IF $PaysRegularly = no$ AND $HairColor = blond$
THEN $CreditApproved = yes$
- R3: IF $PaysRegularly = no$ AND $Rich = yes$
THEN $CreditApproved = yes$
- R4: IF $HairColor = blond$ AND $Rich = yes$
THEN $CreditApproved = yes$.

All four rules cover the Brown example and have 100% accuracy on the above data set. However, Rule 1 does not AB-cover the example, because it is not consistent with the positive argument. For the same reason, rule 2 does not AB-cover the Brown example, but this rule fails also because it is consistent with the negative argument ($PaysRegularly = no$). Rule 3 also fails due to the negative argument, although it is consistent with the positive argument. The last example AB-covers the Brown example.

3.2 ABCN2 - Algorithm

The CN2 algorithm [4, 3] consists of a covering algorithm and a search procedure that finds individual rules by performing beam search. The covering algorithm induces a list of rules that cover all the examples in the learning set. Roughly, the covering algorithm starts by finding a rule, then it removes from the set of learning examples those examples that are covered by this rule, and adds the rule to the set of rules. This process is repeated until all the examples are removed.

There are two versions of CN2: one induces ordered list of rules, and the other unordered list of rules. Our algorithm in this paper is based on the second version of CN2. In this case, the covering algorithm consists of two procedures, CN2unordered and CN2ForOneClass. The first procedure iteratively calls CN2ForOneClass for all the classes in the domain, while the second induces rules only for the class given. When removing covered examples, only examples of this class are removed [3]. Essentially, CN2ForOneClass is a covering algorithm that covers the examples of the given class.

3.2.1 ABCN2: Covering algorithm

The first requirement for ABML is that an induced hypothesis explains argumented examples using given arguments. In rule learning, this means that for each argumented example, there needs to be at least one rule in the set of induced rules that AB-covers this example. This is achieved simply by replacing covering in original CN2 with AB-covering.

Replacing the “covers” relation in CN2 with “AB-covers” in ABCN2 ensures that both argumented and non-argumented examples are AB-covered. However, in addition to simply AB-covering all

Algorithm 1 Covering algorithm of ABCN2 algorithm that learns rules from examples ES for given class T

Procedure ABCN2ForOneClass(Examples ES, Class T)

Let RULE_LIST be an empty list.

Let AES be the set of examples that have arguments; $AES \subseteq ES$
Find splits for arguments where threshold not specified (type $X >$, etc.)

Evaluate arguments (as if they were rules) of examples in AES and **sort** examples in AES according to quality of their best argument.

while AES is not empty **do**

 Let AE1 be the first example in AES.

 Let BEST_RULE be *ABFind_best_rule*(ES,AE1,T)

 Add BEST_RULE to RULELIST.

 Remove from AES examples AB-covered by BEST_RULE.

end while

for all RULE in RULE_LIST **do**

 Remove from ES examples AB-covered by RULE.

end for

 Add rules obtained with *CN2ForOneClass*(ES,T) to RULE_LIST

the examples, we would prefer also explaining as many as possible non-argumented examples by arguments given for the argumented examples. Therefore, we propose a change in the covering algorithm, where CN2ForOneClass is changed into ABCN2ForOneClass (see Algorithm 1). The procedure starts by creating an empty list of rules, and makes a separate set AES of argumented examples only. Then it looks for “unfinished” arguments - arguments that have some of the reasons unspecified ($X >$ and $X <$) and finds the best splits for these reasons. Arguments in examples AES are then evaluated², and examples in AES are sorted according to the “best” given argument. Then, the procedure induces a rule, using *ABFind_Best_rule*, to cover the first argumented example. *ABFind_Best_rule* is a modified beam search procedure that accepts examples, an argumented example and a target class, where the resulting rule is guaranteed to AB-cover the given argumented example. This rule is added to the rule set, and the procedure removes from AES argumented examples AB-covered by this rule. The removal of all positive examples is not necessary, as each of the argumented examples differently constrains the search and thus prevents ABCN2 from inducing the same rule again. When all argumented examples are covered, all positive examples AB-covered by rules are removed, and the remaining rules are learned using classical CN2ForOneClass.

3.2.2 ABCN2: Search Procedure

Algorithm 2 shows AB search procedure. The procedure takes a set of examples to learn from, an argumented example that needs to be AB-covered by the induced rule and a target class. In Algorithm 2 the underlined parts emphasize the differences between the original search procedure in CN2 and AB-search procedure:

Initial value of set STAR are positive arguments of example E.

A rule induced from an argumented example must AB-cover this example, therefore it will have to contain the reasons of at least one of positive arguments. The easiest way to ensure this is to start learning from them.

² Evaluation function in CN2 is Laplace’s rule of succession. However, many alternatives were proposed to improve learning. In this document we assume that Laplace is always used unless is specified differently.

Algorithm 2 Algorithm that finds best rule that AB-covers example E from a set of argumented examples. The “quality” of a complex is evaluated by user-defined evaluation function.

Procedure ABFind_Best_Rule(Examples ES, Example E, Class T)

Let the set STAR contain positive arguments of E (written as complexes).

Evaluate complexes in STAR (using quality function).

Let BEST_CPX be the best complex from STAR.

Let SELECTORS be the set of all possible selectors that are TRUE for E

Let ARG_REASON be the set of all reasons in positive arguments of E (union of reasons).

while STAR is not empty **do**

{Specialize all complexes in STAR as follows}

Let NEWSTAR be the set

$\{x \wedge y \mid x \in \text{STAR}, y \in \text{SELECTORS}\}$

Remove from NEWSTAR all complexes that are consistent with any of negative arguments of E.

for every complex C_i in NEWSTAR **do**

if C_i is statistically significant(ES,T) and quality(C_i) > quality(BEST_CPX) **then** {Statistical significance function is inherited from CN2}

replace the current value of BEST_CPX by C_i

end if

end for

Let STAR be best N complexes from NEWSTAR; N is a user-defined size of STAR (usually N=5).

Let ABNEWSTAR be such subset of NEWSTAR,

that complexes in ABNEWSTAR contain only conditions from ARG_REASON.

Let ABSTAR be best N complexes from ABNEWSTAR.

Let STAR be STAR merged with ABSTAR.

end while

return rule: "IF BEST_CPX THEN T."

Specialize with selectors that are satisfied by argumented example.

This ensures the coverage of the seed example by the induced rule.

Remove all complexes that are consistent with negative arguments.

Again, rules must AB-cover argumented example, therefore can not be consistent with any of negative arguments.

Let ABSTAR be best N complexes from ABNEWSTAR Rules that contain only conditions that are present in positive arguments are likely to be consistent with domain knowledge. Thence, these rules are deemed promising, although at the moment they are not among first N best rules according to quality.

It should be noted that argument based ML is not limited to CN2. Various standard ML techniques can be extended in a similar way to their argument-based variants. This document shows only one of possible implementations.

3.3 Identifying critical examples

Giving arguments to all examples is obviously not feasible. We developed a method to automatically find “problematic” examples, that is examples where arguments would be likely to have a significant effect on learning. So the “commentator” of examples (expert who provides arguments) is asked to concentrate on these “problematic” cases. This idea is realised by the following iterative procedure:

1. *Induce a hypothesis without arguments (using classical CN2).*
2. *Find a critical example that needs to be argumented.* This step involves a search for the most problematic example (e.g. outlier) in the learning set. For this task we propose a k-fold cross-validation repeated n times (e.g. n = 4, k = 5), so that each example is tested n times. The example that was misclassified in most of the cases is chosen as the example that needs to be argumented. If there are several such examples, then the algorithm picks a random one.
3. *If problematic example was not found (in step 2), then stop the iteration.*
4. *An expert gives arguments to the selected example.* Two things can happen here: in the preferred case the expert finds argumenting this example easy; in the undesired case, the expert finds this to be hard. The second case may be due to different reasons (deciding attributes are not available, the example is indeed an outlier, or argumenting may be hard in the chosen representation of arguments). Each of these cases can be mended in different ways, which still needs to be explored. In the extreme, this example can simply be discarded from the learning set.
5. *Induce rules on the learning set using ABCN2 and new argumented example.*
6. *Return to step 2.*

4 EXPERIMENTS WITH ABCN2

In this section we will show a simple example to illustrate how ABCN2 works in practice. A larger experiment with ABCN2, an application to law, is described in [6].

4.1 ZOO Data Set

ZOO data set [7] contains descriptions of 101 animals (instances) with 17 attributes: *hair, feathers, eggs, milk, predator, toothed, domestic, backbone, fins, legs, tail, catsize, airborne, aquatic, breathes, venomous, and type*, which is the class attribute. *Type* has seven possible values: *mammal, bird, reptile, fish, amphibian, insect, and other*. The main advantage of this data set is that, using encyclopedia, we can give good arguments to examples. With arguments we expect to increase comprehensibility and classification accuracy of rules.

The set was split to learning set (70%) and test set (30%), evaluation function was m-estimate of probability [2] with $m = 2$, and statistical significance threshold was set to 1.0. The values were obtained with internal-cross validation (only on learn set) to maximize the classification accuracy. Without arguments (classic CN2), the following rules were induced:

IF milk=yes THEN type=Mammal
IF fins=yes AND breathes=no THEN type=Fish
IF feathers=yes THEN type=Bird
IF legs=6 AND breathes=yes THEN type=Insect
IF legs=4 AND hair=no AND predator=yes THEN type=Amphibian
IF legs=0 AND venomous=yes AND catsize=no AND toothed=yes THEN type=Reptile
IF toothed=no AND legs=4 AND hair=no THEN type=Reptile

Considering learning data alone, the induced rules fit perfectly. However, classification accuracy on the test set is only slightly over 90%. Now, according to our method of involving argumented examples (section 3.3), we have to find the most problematic example using the

learning set only. The internal (on learning set only) cross-validation procedure found that the most frequently misclassified example was a reptile, the tortoise. Notice that the rules covering reptiles split reptiles in two subgroups; in the first group are legless, poisonous, small, and toothed reptiles (snakes) and in the other are toothless, with four legs, and hairless reptiles (turtles). A problem with these two rules is that there also exist four-legged reptiles with teeth (crocodile, tuatara, etc. - tuatara was misclassified in the test set). A good argument for tortoise to be a reptile is that it has the backbone and it lays eggs (tortoise is reptile because backbone=yes AND eggs=yes). Using that argument for tortoise in ABCN2, the two rules for reptiles were replaced by the following two rules:

```
IF backbone=yes AND eggs=yes AND aquatic=no AND
feathers=no THEN type=Reptile
IF eggs=no AND breathes=no THEN type=Reptile
```

Naturally, our argument is not a perfect general rule for recognizing reptiles, so it was extended by ABCN2 with attributes *aquatic* and *feathers*. The first attribute separates reptiles from fishes and the second from birds, as both, fishes and birds, have backbone and lay eggs. It is interesting that our argument did not only affect the rule that was learned from this argument, but also the other rule for reptiles.

The next problematic example found was a sea snake (a reptile). A sea snake is an air-breathing snake that lives underwater. According to encyclopedia, a sea snake should be correctly classified with the above rule, however we noticed that, in the data, sea snake is characterized as a non-breathing reptile and that it does not lay eggs. It is obviously a mistake in data and is also the reason for the induction of the second rule.

The next problematic example found in the learn set was a newt. The argument was provided that the newt is an amphibian because it has backbone, lays eggs and is related to water. This resulted in the rule:

```
IF backbone=yes AND aquatic=yes AND eggs=yes AND legs=4
THEN type=Amphibian
```

After adding these arguments to the two examples, ABCN2 induced a perfect set of rules for the ZOO data set. There were no misclassified examples in the test set.

This example clearly illustrates the effectiveness of our method for choosing critical examples (both identified examples were really critical) and shows how arguments can be used to learn concepts that are otherwise very hard to learn. The example also nicely illustrates that it is much easier to give arguments only to an individual example (e.g why tortoise is a reptile), than it would be to articulate general rules that correctly classify the animals. Moreover, the rules learned from arguments are consistent with prior knowledge. Pazzani [9, 8] argued that induced models are more comprehensible if they are consistent with prior knowledge, even if this makes them more complex. Accordingly, we believe that the new set of rules is more comprehensible to an expert.

5 CONCLUSION

In this paper we have described a novel approach to machine learning that draws on some concepts of argumentation theory. We introduced a new type of examples, argumented examples. Arguments are used to constrain the search among possible hypotheses.

We implemented ABCN2, an argument based extension of CN2. We have shown several advantages of argument based approach to learning rules:

- The capture of expert knowledge in the form of arguments for individual examples is easier for the expert than providing general theories.
- The critical examples whose arguments are needed to improve rules, are automatically identified by our method.
- ABCN2 produces more comprehensible rules than CN2, because it uses expert-given arguments to constrain learning.
- On our test data set ZOO, ABCN2 achieved higher classification accuracy than classical CN2. Although this might not be true for all domains, we can expect that arguments will, in general, improve accuracy of hypotheses, if arguments given by experts are better than pure guessing.

There are two main issues about ABML that still need to be researched. The first is a large-scale experimental quantitative assessment of the benefits of argumented examples. For this task we plan to experiment on several larger domains with the help of experts and compare results of ABML to ML. The second issue is to determine how does the quality of arguments given by experts affect learning. This involves experiments with arguments of different quality (for instance expert given vs. random arguments), and a comparison of experts' arguments with slightly changed version of the same arguments. Such experiment could, for instance, discover that experts (for a certain domain) usually give over-specified arguments.

A Real generalization of discrete AdaBoost

Richard Nock¹ and Frank Nielsen²

Abstract. Scaling discrete AdaBoost to handle real-valued weak hypotheses has often been done under the auspices of convex optimization, but little is generally known from the original boosting model standpoint. We introduce a novel generalization of discrete AdaBoost which departs from this mainstream of algorithms. From the theoretical standpoint, it formally displays the original boosting property; furthermore, it brings interesting computational and numerical improvements that make it significantly easier to handle “as is”. Conceptually speaking, it provides a new and appealing scaling to \mathbb{R} of some well known facts about discrete (ada)boosting. Perhaps the most popular is an iterative weight modification mechanism, according to which examples have their weights decreased iff they receive the right class by the current discrete weak hypothesis. Our generalization to real values makes that decreasing weights affect only the examples on which the hypothesis’ *margin* exceeds its average margin. Thus, while both properties coincide on the discrete case, examples that receive the right class can still be reweighted higher with real-valued weak hypotheses. From the experimental standpoint, our generalization displays the ability to produce low error formulas with particular cumulative margin distributions, and it provides a nice handling of those noisy domains that represent Achilles’ heel for common Adaptive Boosting algorithms.

1 Introduction

In supervised learning, it is hard to exaggerate the importance of *boosting* algorithms. Loosely speaking, a *boosting* algorithm repeatedly trains a moderately accurate learner, gets its *weak* hypotheses, combines them, to finally output a *strong* classifier which boosts the accuracy to arbitrary high levels [9, 10]. (discrete) *Adaboost*, undoubtfully the most popular provable boosting algorithm [5], uses weak hypotheses with outputs restricted to the discrete set of classes that it combines via leveraging coefficients in a linear vote. Strong theoretical issues have motivated the extension of this *discrete* AdaBoost [6] to handle real-valued weak hypotheses as well [6, 11, 15, 18]. Even when only few of them are true generalizations of discrete AdaBoost [11, 18], virtually all share a strong background in convex optimization originally rooted in a “key” to boosting in AdaBoost: a strictly convex exponential loss integrated into a weight update rule for the examples, loss which upperbounds the error and approximates the expected binomial log-likelihood. However, very little is often known for these algorithms from the seminal boosting model standpoint [10, 9, 16], a model which roughly requires conver-

gence to reduced true risk under very weak assumptions (with high probability).

In this paper, we propose a new real AdaBoost, a generalization of discrete AdaBoost that handles arbitrary real-valued weak hypotheses. With respect to former real AdaBoosts, the weight update is fundamentally different as it does not integrate anymore the convex exponential loss; also, the leveraging coefficients for the weak hypotheses differ in the output; finally, these leveraging coefficients are given in closed form and their computation can now easily be delayed until the end of boosting, which is not the case for conventional real AdaBoosts [6, 11, 18]. The major theoretical key feature of this algorithm is that it is a provable boosting algorithm in the original sense. Another point is that it saves computation time with respect to previous generalizations of discrete AdaBoost, that need to approximate the solution of a convex minimization problem at each boosting iteration [11, 18]. From the experimental standpoint, the weight update rule, which does not require anymore the approximation of logarithms or exponentials, is less prone to numerical errors. Finally, it prevents or reduces some numerical instabilities that previous generalizations [11, 18] face when the weak hypotheses reach perfect, or perfectly wrong, classification.

As a matter of fact, it is quite interesting that our algorithm is indeed a generalization of discrete AdaBoost, as when the weak hypotheses have outputs constrained to the set of classes, both algorithms coincide. From this standpoint, our paper also brings a relevant *conceptual* contribution to boosting. Indeed, we give a complete generalization to \mathbb{R} of popular (discrete) boosting properties, and this is sometimes clearly not trivial. For example, discrete AdaBoost is very often presented as an algorithm that reweights lower the examples that have received the right class. Scaled to \mathbb{R} , *this is not true anymore*: lower reweighting occurs **only** for examples on which the classifier’s *margin* exceeds its average margin. Only on the discrete prediction framework do these two properties coincide. Furthermore, this scaling property does not hold for previous real AdaBoosts [6, 11, 15, 18]. For some reasons, our scaling smoothes predictions, and it might explain why experiments clearly display that our algorithm handles noise more efficiently than discrete or real AdaBoosts. Noise handling has soon be described as AdaBoost’s potential main problem [1].

Section 2 presents some definitions, followed by a Section on our generalization of discrete AdaBoost. Section 4 presents and discusses experimental results, and a last Section concludes the paper.

2 Definitions

Our framework is rooted into the original weak/strong learning and boosting frameworks, and Valiant’s PAC model of learnability [5, 10, 19]. We have access to a *domain* \mathcal{X} of observations, which could be $\{0, 1\}^n$, \mathbb{R}^n , etc. . Here, n is the number of description

variables. More precisely, we collect *examples*, that is, couples (observation, class) written $(\mathbf{x}, y) \in \mathcal{X} \times \{-1, +1\}$. “+1” is called the *positive* class (or label), and “-1” the *negative* class. In this paper, we deal only with the two-classes case. Well known frameworks exist that allow its extension to multiclass, multilabel frameworks [18]. In this paper, boldfaces such as \mathbf{x} denote n -dimensional vectors, calligraphic faces such as \mathcal{X} denote sets and blackboard faces such as \mathbb{S} denote subsets of \mathbb{R} , the set of real numbers. Unless explicitly stated, sets are enumerated following their lower-case, such as $\{\mathbf{x}_i : i = 1, 2, \dots\}$ for vector sets, and $\{x_i : i = 1, 2, \dots\}$ for other sets (and for vector entries). We make the assumption that examples are sampled independently, following an unknown but fixed distribution D over $\mathcal{X} \times \{-1, +1\}$. Our objective is to induce a classifier or *hypothesis* $H : \mathcal{X} \rightarrow \mathbb{S}$, that matches the best possible the examples drawn according to D .

For this objective, we define a *strong* learner as an algorithm which is given two parameters $0 < \varepsilon, \delta < 1$, samples according to D a set \mathcal{S} of examples, and returns a classifier or *hypothesis* $H : \mathcal{X} \rightarrow \mathbb{S}$ such that with probability $\geq 1 - \delta$, its true risk is bounded as follows:

$$\Pr_{(\mathbf{x}, y) \sim D}[\text{sign}(H(\mathbf{x})) \neq y] = \epsilon_{D, H} \leq \varepsilon. \quad (1)$$

Here, $\text{sign}(a)$ is +1 iff $a \geq 0$, and -1 otherwise. The time complexity of the algorithm is required to be polynomial in relevant parameters, among which $1/\varepsilon, 1/\delta, n$. To be rigorous, the original models [19, 10] also mention dependences on concepts that label the examples. Examples are indeed supposed to be labeled by a so-called *target* concept, which is unknown but fixed. Distribution D is in fact used to retrieve the examples from this target concept, and the time complexity of the algorithm is also required to be polynomial in its size. Hereafter, we shall omit for the sake of clarity this notion of target concept, which is not important for our purpose, since our analysis may also be fit to handle it as well.

A *weak* learner (*WL*) has basically the same constraints, with the notable exception that (1) is only required to hold with $\varepsilon = 1/2 - \gamma$ for some $\gamma > 0$ a constant or inverse polynomial in relevant parameters, and this still has to be verified regardless of D . Since predicting the classes at random, such as with an unbiased coin, would yield $\Pr_{(\mathbf{x}, y) \sim D}[\text{sign}(\text{random}(\mathbf{x})) \neq y] = 1/2, \forall D$, it comes that a weak learner is only required to perform slightly better than random prediction. In the original models, it is even assumed that δ is also an inverse polynomial in relevant parameters, which makes that the constraints on *WL* are somehow the lightest possible from both the statistical and the computational standpoints. The (discrete) *Weak Learning Assumption* (*WLA*) assumes the existence of *WL* [9, 16]. Simple simulation arguments of *WL* [8] allow to show that the weakening on δ is superficial, as we can in fact weak learn with the same arbitrary δ as for strong learning. However, the conditions on ε are dramatically different, and the question of whether weak and strong learning are equivalent models has been a tantalizing problem until the first proof that there exists *boosting* algorithms that strong learn under the *sole* access to *WL* [16], thus proving that these models are indeed equivalent. This first boosting algorithm outputs a large tree-shaped classifier with majority votes at the nodes, each node being built with the help of *WL*. The point is that it is not easy to implement, and it does not yield classifiers that correspond to familiar concept representations.

AdaBoost [5] has pioneered the field of easily implementable boosting algorithms, for which $\mathbb{S} = \{-1, +1\}$. After [5], we refer to it as *discrete* AdaBoost. Basically, AdaBoost uses a weak learner as a subprocedure and an initial distribution \mathbf{w}_1 over \mathcal{S} which is repeatedly skewed towards the hardest to classify examples. After T rounds

Input: sample $\mathcal{S} = \{(\mathbf{x}_i, y_i), \mathbf{x}_i \in \mathcal{X}, y_i \in \{-1, +1\}\}$

$\mathbf{w}_1 \leftarrow \mathbf{u}$;

for $t = 1, 2, \dots, T$ **do**

 Get $(h_t : \mathcal{X} \rightarrow \mathbb{S}) \leftarrow WL(\mathcal{S}, \mathbf{w}_t)$;

 Find $\alpha_t \in \mathbb{R}$;

 Update: $\forall 1 \leq i \leq m$,

$$w_{t+1, i} \leftarrow w_{t, i} \times \exp(-\alpha_t y_i h_t(\mathbf{x}_i)) / Z_t; \quad (2)$$

end

Output: $H_T(\mathbf{x}) = \sum_{t=1}^T \alpha_t h_t(\mathbf{x})$

Algorithm 1: An abstraction of AdaBoost

of boosting, its output, H_T , is a linear combination of the weak hypotheses. Algorithm 1 gives a useful abstraction of AdaBoost, in which \mathbf{u} is the uniform distribution, Z_t is the normalization coefficient, the elements of \mathcal{S} are enumerated $s_i = (\mathbf{x}_i, y_i)$ and their successive weight vector is noted \mathbf{w}_t , for $t \geq 1$. In discrete AdaBoost, we would have:

$$\alpha_t = \frac{1}{2} \ln \frac{1 - \epsilon_{\mathbf{w}_t, h_t}}{\epsilon_{\mathbf{w}_t, h_t}}, \quad (3)$$

where “ln” denotes the natural logarithm. The two key steps in AdaBoost are the choice of α_t and the weight update rule. They are strongly related and follow naturally if we seek to minimize the following observed *exponential loss* [6, 18] through the induction of H_T :

$$\epsilon_{\mathbf{w}_1, H_T}^{\text{exp}} = E_{(\mathbf{x}, y) \sim \mathbf{w}_1}(\exp(-y H_T(\mathbf{x}))), \quad (4)$$

with E the mathematical expectation. Since $I[\text{sign}(H_T(\mathbf{x})) \neq y] \leq \exp(-y H_T(\mathbf{x}))$ (with I the indicator function), $\epsilon_{\mathbf{w}_1, H_T} \leq \epsilon_{\mathbf{w}_1, H_T}^{\text{exp}}$, and so minimizing the exponential loss amounts to minimizing the empirical risk as well [6, 11, 15, 17], and it turns out that it brings a boosting algorithm as well [5, 17]. There are other excellent reasons to focus on the exponential loss instead of the empirical risk: it is smooth differentiable and it approximates the binomial log-likelihood [6]. Its stagewise minimization brings both the weight update in (2), and the following choice for α_t :

$$\alpha_t = \arg \min_{\alpha \in \mathbb{R}} E_{(\mathbf{x}, y) \sim \mathbf{w}_t}(\exp(-\alpha y h_t(\mathbf{x}))) \quad (5)$$

$$= \arg \min_{\alpha \in \mathbb{R}} Z_t. \quad (6)$$

One more reason, and not the least, to focus on the exponential loss, is that it brings a stagewise maximization of *margins*. While the empirical risk focuses only on a *binary* classification task (the class assigned is either good or bad), margins scale it to *real* classification, as they integrate both the binary classification task *and* a real magnitude which quantifies a “confidence” in the label given. Large margin classification can bring very fast true risk minimization [17]. Margins justify to scale $\mathbb{S} = \{-1, +1\}$ to an interval such as $[-1, +1]$ [6, 18]; in this case, the sign of the output gives the class predicted. Whenever we still enforce $h_t : \mathcal{X} \rightarrow \{-1, +1\}$, (5) admits a closed-form solution, which is naturally (3), and the boosting algorithm is discrete AdaBoost [6, 5]. Relaxing \mathbb{S} to $[-1, +1]$ yields *real* AdaBoost [6, 11, 18]. Unfortunately, (5) does *not* have a closed-form solution in this case [18]. Iterative techniques exist for its fast approximation [13], but they have to be performed at *each* boosting iteration (which buys overall a significant load increase), and it may be the case that the solution found lies *outside* the boosting regime if the number of approximation steps is too small.

Many other extensions have been proposed to scale $\mathbb{S} = \{-1, +1\}$ up to $[-1, +1]$ or even \mathbb{R} in AdaBoost, but virtually very few of those that do not generalize discrete AdaBoost have been proven so far to be boosting algorithms in the original sense. For space considerations, we focus our comparison only on very few of them that bear at least close similarities with true real generalizations of discrete AdaBoost [6, 11, 15, 18]. These algorithms, that fit to Algorithm 1, mainly differ on the choice of the leveraging coefficient α_t . For example, [6, 15] pick $\alpha_t = 1$, a choice for which the boosting property is not shown to hold.

3 Our Real generalization of AdaBoost

We now give up with the direct minimization of (4), and scale $\mathbb{S} = \{-1, +1\}$ up to \mathbb{R} itself; suppose we replace the weight update (2) and eq. (5) by what follows:

$$w_{t+1,i} \leftarrow w_{t,i} \times \left(\frac{1 - (\mu_t y_i h_t(\mathbf{x}_i)/h_t^*)}{1 - \mu_t^2} \right) . \quad (7)$$

$$\alpha_t = \frac{1}{2h_t^*} \ln \frac{1 + \mu_t}{1 - \mu_t} . \quad (8)$$

Here, we have fixed $h_t^* = \max_{1 \leq i \leq m} |h_t(\mathbf{x}_i)| \in \mathbb{R}$, the maximal value of h_t over \mathcal{S} , and:

$$\mu_t = \frac{1}{h_t^*} \sum_{i=1}^m w_{t,i} y_i h_t(\mathbf{x}_i) \in [-1, +1] \quad (9)$$

the normalized *margin* of h_t over \mathcal{S} . For the sake of clarity, we suppose in the following subsection that $\forall 1 \leq t \leq T, h_t^* < \infty$. Infinite values for h_t^* can be handled in two ways: either we bias/threshold the output of h_t to make it finite [18], or we code it as ∞ , making $\alpha_t = 0$ and $\mu_t = \sum_{i:|h_t(\mathbf{x}_i)|=\infty} w_{t,i} \text{sign}(y_i h_t(\mathbf{x}_i))$. In both cases, \mathbf{w}_{t+1} is a valid distribution and the properties below are kept. Let us call AdaBoost_R our real generalization of discrete AdaBoost.

3.1 Properties

We first show that AdaBoost_R is indeed a generalization of discrete AdaBoost.

Lemma 1 When $\mathbb{S} = \{-1, +1\}$, AdaBoost_R = discrete AdaBoost.

Proof: In this case, we have $h_t^* = 1$ and $\mu_t = 1 - 2\epsilon_{\mathbf{w}_t, h_t}$, which brings that eq. (8) is also $\alpha_t = (1/2) \ln((1 - \epsilon_{\mathbf{w}_t, h_t})/\epsilon_{\mathbf{w}_t, h_t})$, i.e. like in discrete AdaBoost. Our update rule simplifies to:

$$w_{t+1,i} \leftarrow \frac{w_{t,i}(1 - y_i h_t(\mathbf{x}_i) + 2y_i h_t(\mathbf{x}_i)\epsilon_{\mathbf{w}_t, h_t})}{2\epsilon_{\mathbf{w}_t, h_t}(1 - \epsilon_{\mathbf{w}_t, h_t})} ,$$

i.e.:

$$w_{t+1,i} \leftarrow \begin{cases} w_{t,i}/(2(1 - \epsilon_{\mathbf{w}_t, h_t})) & \text{iff } y_i h_t(\mathbf{x}_i) = +1 \\ w_{t,i}/(2\epsilon_{\mathbf{w}_t, h_t}) & \text{iff } y_i h_t(\mathbf{x}_i) = -1 \end{cases} .$$

This is the same expression for the weight update of discrete AdaBoost. \square

Now, we show that AdaBoost_R is a boosting algorithm for arbitrary real-valued weak hypotheses. In fact, we show a little bit more, and for this objective, we define the *margin* of H_T on example (\mathbf{x}, y) as:

$$\begin{aligned} \nu_T((\mathbf{x}, y)) &= \tanh(y H_T(\mathbf{x})/2) \\ &= \frac{\exp(y H_T(\mathbf{x})) - 1}{\exp(y H_T(\mathbf{x})) + 1} \in [-1, +1] . \end{aligned} \quad (10)$$

This definition of margin extends a previous one for discrete AdaBoost [21], and its choice is discussed in Section 3.2. $\forall \theta \in [-1, +1]$ we also define the classifier's "margin error" as the proportion of examples whose margin does not exceed θ :

$$\nu_{\mathbf{u}, H_T, \theta} = \frac{1}{m} \sum_{i=1}^m I[\nu_T((\mathbf{x}_i, y_i)) \leq \theta] . \quad (11)$$

Clearly, $\epsilon_{\mathbf{u}, H_T} = \nu_{\mathbf{u}, H_T, 0}$, and $\nu_{\mathbf{u}, H_T, \theta}$ generalizes $\epsilon_{\mathbf{u}, H_T}$. We now prove a first Theorem on AdaBoost_R.

Theorem 1 $\forall \mathbb{S} \subseteq \mathbb{R}, \forall \theta \in [-1, +1], \text{ after } T \geq 1 \text{ iterations, we have:}$

$$\nu_{\mathbf{u}, H_T, \theta} \leq \left(\frac{1 + \theta}{1 - \theta} \right) \times \exp \left(-\frac{1}{2} \sum_{t=1}^T \mu_t^2 \right) . \quad (12)$$

Proof: We need the following simple Lemma.

Lemma 2 $\forall a \in [-1, 1], \forall b \in [-1, 1]$,

$$1 - ab \geq \sqrt{1 - a^2} \exp \left(-\frac{b}{2} \ln \frac{1 + a}{1 - a} \right) .$$

Proof: The function in the right-hand side is strictly convex in b for $a \neq 0$, and both functions match for $b = \pm 1$ and $a = 0$. Writing the right-hand side $(1 + a)^{(1-b)/2}(1 - a)^{(1+b)/2}$ implies that its limits when $a \rightarrow \pm 1$ are zero. \square

Consider some example $(\mathbf{x}_i, y_i) \in \mathcal{S}$ and some $1 \leq t \leq T$. The way we use Lemma 2 is simple: fix $a = \mu_t$ and $b = y_i h_t(\mathbf{x}_i)/h_t^*$. They satisfy the assumptions of the Lemma, and we obtain:

$$\begin{aligned} 1 - (\mu_t y_i h_t(\mathbf{x}_i)/h_t^*) \\ \geq \sqrt{1 - \mu_t^2} \exp \left(-\frac{y_i h_t(\mathbf{x}_i)}{2h_t^*} \ln \frac{1 + \mu_t}{1 - \mu_t} \right) . \end{aligned} \quad (13)$$

Unraveling the weight update rule, we obtain:

$$\begin{aligned} w_{T+1,i} \times \prod_{t=1}^T (1 - \mu_t^2) \\ = u_i \times \prod_{t=1}^T (1 - (\mu_t y_i h_t(\mathbf{x}_i)/h_t^*)) . \end{aligned} \quad (14)$$

Using T times (13) on the right-hand side of (14) and simplifying yields:

$$(w_{T+1,i}/u_i) \times \prod_{t=1}^T \sqrt{1 - \mu_t^2} \geq \exp(-y_i H_T(\mathbf{x}_i)) . \quad (15)$$

Since for any real q , $I[q \leq 0] \leq \exp(-q)$, we have:

$$\begin{aligned} I[\nu_T((\mathbf{x}_i, y_i)) \leq \theta] &= I \left[y_i H_T(\mathbf{x}_i) - \ln \frac{1 + \theta}{1 - \theta} \leq 0 \right] \\ &\leq \exp \left(-y_i H_T(\mathbf{x}_i) + \ln \frac{1 + \theta}{1 - \theta} \right) \\ &= \left(\frac{1 + \theta}{1 - \theta} \right) \times \exp(-y_i H_T(\mathbf{x}_i)) \\ &\leq \frac{w_{T+1,i}}{u_i} \left(\frac{1 + \theta}{1 - \theta} \right) \times \prod_{t=1}^T \sqrt{1 - \mu_t^2} , \end{aligned}$$

Where the last line uses ineq. (15). There only remains to sum that last ineq. for all examples of \mathcal{S} , and use the fact that $\sqrt{1 - a^2} \leq$

$\exp(-\alpha^2/2), \forall \alpha \in [-1, 1]$. Given that w_{T+1} is a distribution and $u_i = 1/m$, we immediately obtain the statement of the Theorem. \square

Theorem 1 generalizes a well-known convergence Theorem for AdaBoost's empirical risk [18] ($\theta = 0$). This generalization is important, as it says that virtually *any* margin error is subject to the same convergence rate towards zero, and not simply the empirical risk. Thus, more than a single point, it gives also a complete curve $f(\theta)$ upperbounding the empirical margin distribution as given by (11). To prove that AdaBoost_R is a boosting algorithm, we need a WLA that a real-valued WL should satisfy. Its formulation for real-valued hypotheses follows that for the discrete case [9, 10, 18]: basically, it amounts to say that we want h_t to perform significantly different from *random*, a case which can be represented by $\mu_t = 0$. A natural choice is thus fixing the WLA to be ($\forall t \geq 1$):

(real) WLA $|\mu_t| \geq \gamma$, for the same $\gamma > 0$ as in the discrete WLA.

This, in addition, provides us with a generalization of the discrete WLA [9, 16], since we have in this case $\mu_t = 1 - 2\epsilon_{w_t, h_t}$. This brings that either $\epsilon_{w_t, h_t} \leq (1/2) - \gamma/2$, or $\epsilon_{w_t, h_t} \geq (1/2) + \gamma/2$. It has been previously remarked that this second condition, although surprising at first glance since the empirical risk is worse than random, is in fact equivalent to the first from the boosting standpoint, as it "reverses" the polarity of learning: when h_t satisfies the second constraint, $-h_t$ satisfies the first [6].

Now proving that AdaBoost_R is a boosting algorithm amounts first to using Theorem 1 with $\theta = 0$, to obtain under the WLA that after T iterations of AdaBoost_R, we have $\epsilon_{u, H_T} \leq \exp(-T\gamma^2/2)$. Thus, if we run AdaBoost_R for $T = \Omega((1/\gamma^2) \ln m)$, we get an H_T consistent with S . Since T is polynomial in all relevant parameters, classical VC-type bounds on the deviation of the true risk for linear separators [8, 20] immediately bring the following Theorem.

Theorem 2 $\forall S \subseteq \mathbb{R}$, provided WLA holds, AdaBoost_R is a boosting algorithm.

3.2 Discussion

Perhaps one of the most important difference with discrete AdaBoost and its numerous offsprings [5, 6, 4, 18] lies in the fact that they tend to reweight lower the examples that have received the right class. This property is appealing, and has certainly participated to their spread and use. However, when scaling the binary classification problem ($S = \{-1, +1\}$) to \mathbb{R} , for this property to fully integrate the extended framework, it should rely entirely on margins (classes + confidences) instead of just classes. This becomes true with AdaBoost_R: lower reweighting occurs only for examples on which the current weak classifier's margin exceeds its average margin (when $\mu_t > 0$):

$$y_i h_t(\mathbf{x}_i)/h_t^* \geq \mu_t. \quad (16)$$

Thus, there can be examples that receive the right class by h_t , and that have their weights increased. When $\mu_t < 0$, the polarity of boosting (and reweighting) is reversed in the same way as when $\epsilon_{w_t, h_t} > 1/2$ for discrete AdaBoost. Finally, these properties are true generalization of discrete AdaBoost's, as all coincide again on the discrete case.

Margins. It may be helpful to compare our definition of margin with those recently used for real extensions of AdaBoost [6, 17, 18]. Eq. (10) is generally replaced by:

$$\nu_T((\mathbf{x}, y)) = \frac{y H_T(\mathbf{x})}{\sum_{t=1}^T \alpha_t} \in [-1, +1]. \quad (17)$$

Eq. (17) is almost equivalent to the margin of a classifier that we have used for weak hypotheses (μ_t). However, eq. (10), which defines the margin of an *example*, appears to be more convenient for three reasons. The first is statistical, as our definition is in direct relationship with additive logistic models [6]. Suppose we fit H_T to the additive logistic model :

$$H_T(\mathbf{x}) = \ln \frac{p[y = +1|\mathbf{x}]}{p[y = -1|\mathbf{x}]}, \quad (18)$$

with the probabilities $p[.|\mathbf{x}]$ to be estimated while learning. This brings for (10):

$$\nu_T((\mathbf{x}, y)) = y(2p[y = +1|\mathbf{x}] - 1). \quad (19)$$

The quantity $2p[y = +1|\mathbf{x}] - 1 = p[y = +1|\mathbf{x}] - p[y = -1|\mathbf{x}]$ which replaces $H_T(\mathbf{x})/\sum_{t=1}^T \alpha_t = \ln(p[y = +1|\mathbf{x}]/p[y = -1|\mathbf{x}])/\sum_{t=1}^T \alpha_t$ in (17) is the *gentle* logistic approximation of [6], a quantity which is much more stable than the full logistic model itself. The second reason is more technical. Theorem 1 shows that $\nu_{u, H_T, \theta}$ vanishes under the WLA regardless of the value of $\theta \in (-1, 1)$ with margin definition (10). Upperbounds for $\nu_{u, H_T, \theta}$ with eq. (17) are not as easy to read, as all require to vanish that θ be smaller than fluctuating upperbounds that can be $\ll 1$ [17, 18]. It does not seem that it is the boosting algorithm which is responsible, as in our case, using (17) would *not* yield a vanishing $\nu_{u, H_T, \theta}$ when $\theta \geq \max_t |\mu_t|/2$, a situation identical to previous analyses [5, 17, 18]. The third reason is an experimental consequence of the second. Definition (10) makes cumulative margin distributions easier to read, since there is no fluctuating theoretical upperbound < 1 for "boostable" margins.

Computations and numerical stability. A first difference with previous generalizations of discrete AdaBoosts that do not fix *ad hoc* values for α_t [6, 11, 18] is computational. Eq. (5) has no closed form solution in the general case, so they all need to approximate α_t . The problem is convex and single variable, so its approximation is simple, but it needs to be performed at *each* iteration, which buys a significant additional computation time with respect to AdaBoost_R, for which α_t is exact. Approximating has another drawback: if not good enough, the current iteration may lie outside the boosting regime [6, 11, 18].

The extensions of discrete AdaBoost [6, 11, 18] face technical and numerical difficulties to compute α_t when h_t or $-h_t$ reaches consistency, that is, when ϵ_{w_t, h_t} approaches its extremal values, 0 or 1. On the extreme values, there is no finite solution to eq. (5), and thus theoretically no weight update. In our case, the problem does not hold anymore, as the multiplicative update of eq. (7) is never zero nor infinite if we adopt the convention that $0/0 = 1$. Indeed, a numerator equals zero iff all numerators equal zero iff all denominators equal zero. Thus, zeroing any numerator or denominator, which amounts to making either perfect or completely wrong classification for h_t on S , brings *no weight change* in w_{t+1} .

A second, well known technical difficulty for some extensions of discrete AdaBoost [6, 11, 18], occurs when the empirical risk approaches 0 or 1, regions where $|\alpha_t|$ has extremely large regimes. In this case, the numerical approximations to exponentials in eq. (5), with the approximations of α_t , make the computation of the weights very instable. Clearly, large multiplicative coefficients for the weight update are possible for AdaBoost_R. However, instability is less pronounced, since we have split the computation of the leveraging coefficients and that of the weight update, allowing the computation of *all* α_t to be delayed till the end of boosting.

Figure 1. Estimated true risks on 25 domains, comparing discrete AdaBoost [5] (D), AdaBoost_R (U) and the real AdaBoost of [6, 11, 18] (T). For each domain, we put in emphasis the **best** algorithm(s) and the *worst* algorithm(s) out of the three. The last 3 rows count the number of times each algorithm counts respectively among the **best**, second, and *worst*.

4 Experiments

Experiments were carried out on 25 domains, most of which come from the UCI repository [2]. Domains with more than two classes (indicated 2C) were transformed in a two class problem by grouping all classes but the first into one: sometimes, this brought domains with highly unbalanced classes, thereby complicating even further the learning task. On each domain, we ran discrete AdaBoost [5], AdaBoost_R and the real AdaBoost of [11, 18]. WL is set to a rule (monomial) learner, with fixed maximal rule size (attribute number) r [12, 14]. True risks are estimated using a 10-fold stratified cross validation procedure on the whole data. Since each rule h_t has two possible outputs, y_{ht} has four possible values, and so the analytic solution for α_t of discrete AdaBoost does not apply for real AdaBoost [11, 18]. The true α_t is approximated from (5) using a simple dichotomous search until the relative error does exceed 10^{-6} , using results of [13] to make it faster. Empirically, the execution time for real AdaBoost [6, 11, 18] is on average more than 100 times that of discrete AdaBoost and AdaBoost_R.

General results. We first give some general comments on results that were obtained at early and reasonable stages of boosting, namely after $T = 10$ and $T = 50$ steps of boosting, for a rule learner configured with $r = 2$. Figure 1 summarizes the results obtained. While AdaBoost_R tends to perform the best, interesting patterns emerge from the simulated domains from which we know everything about the concept to approximate. Easy domains such as Monks(1+2) [2] are those on which real AdaBoost performs the best and converges

the fastest. Increasing further T makes that real AdaBoost outstrips even more the two other algorithms. However, as the domain gets complicated, AdaBoost_R becomes the algorithm that beats the other two when T increases. Consider the following domain ordering, from the easiest to the hardest: Monks(1+2) (no noise, no irrelevant attributes), XD6 (10% class noise, one irrelevant attribute), LEDeven (10% attribute noise), LEDeven+17 (LEDeven + 17 irrelevant attributes) [2, 12]. Real AdaBoost beats the other two algorithms on XD6, but another experiment on larger classifiers ($r = 3$; $T = 100$) reveals that AdaBoost_R becomes the winner and approaches Bayes risk with 11.15% error, while discrete and real AdaBoost respectively achieve 11.47% and 12.46% error (statistically worse in that latter case). Winning occurs even sooner on LEDeven ($T = 50$) and LEDeven+17 ($T = 10$). One reason for this phenomenon might be the fact that the reweighting scheme of AdaBoost_R is actually gentler than the others, especially on noisy examples: discrete and real AdaBoost are subject to very large weight update, due to the exponential update rule and the fact that higher reweighting can occur on the sole basis of the binary classification result (good/bad class), even when the classifier has minute confidence on the label it predicts. This cannot happen in our case if the classifier's margin is negative; whenever it is positive, examples that receive the *right* class can still be reweighted higher, counterbalancing higher reweighting for eventual noisy examples. Gentler updating, such as by thresholding, has soon been proposed as a line of research to improve noise handling [4].

Noise handling. In order to shed some more light on noise handling, we have drilled down into the results on domain LEDeven+17 [2]. Its basis is a seven bits problem that describes the ten digits of old pocket calculators. Examples are picked uniformly at random and the ten possible classes and grouped in two: even / odd. Each description variable gets flipped with 10% chances, and seventeen attributes are added, that are irrelevant in the strongest sense [7]. Thus, there is a total of $n = 24$ description variables. Figures 2 and 3 displays cumulative margin distributions that were obtained for couple $(r, T) \in \{2, 4, 6\} \times \{10, 100, 200, 1000\}$. The training margins clearly display that the real AdaBoost of [6, 11, 18] is the fastest to converge to perfect classification, followed by discrete AdaBoost [5], and then by AdaBoost_R (“us”). The testing margins display a completely different pattern: on ten out of twelve results, the estimated true risk is the lowest for AdaBoost_R, and on eight out of ten, the second best is discrete AdaBoost (with a difference best-worst sometimes reaching 6%). Real AdaBoost [6, 11, 18] beats discrete AdaBoost when the classifiers built get complicated: $T \geq 200$ and $r \in \{4, 6\}$. The clear symmetric sigmoid shape (plateau) observed on testing for real AdaBoost on these cases (which is also observable —though less pregnant— for discrete AdaBoost, and almost not observed for AdaBoost_R) indicates that the confidence in classification becomes virtually “infinite” for almost all examples, i.e. for those that receive the right class, and also for those receiving the wrong class. This, we think, indicates a tendency to overfit while trying to model these noisy data. This tendency is clearly less pronounced for AdaBoost_R, and if we look at the margin curves for $\theta \leq 0$, the fact that AdaBoost_R’s curve are almost systematically below both others tends to indicate that AdaBoost_R performs sensibly better than both discrete and real AdaBoosts. This is in accordance with the fact that plotting Bayes rule’s margin curves, following the prediction of the logistic model in (18), seems to always yield a curve shape closer to AdaBoost_R. To see this, Figure 4 plots cumulative margin distributions for Bayes rule’s, for varying amounts of attribute noise in LEDeven+17, ranging from 5% to 50% by steps of 5%. Curves were

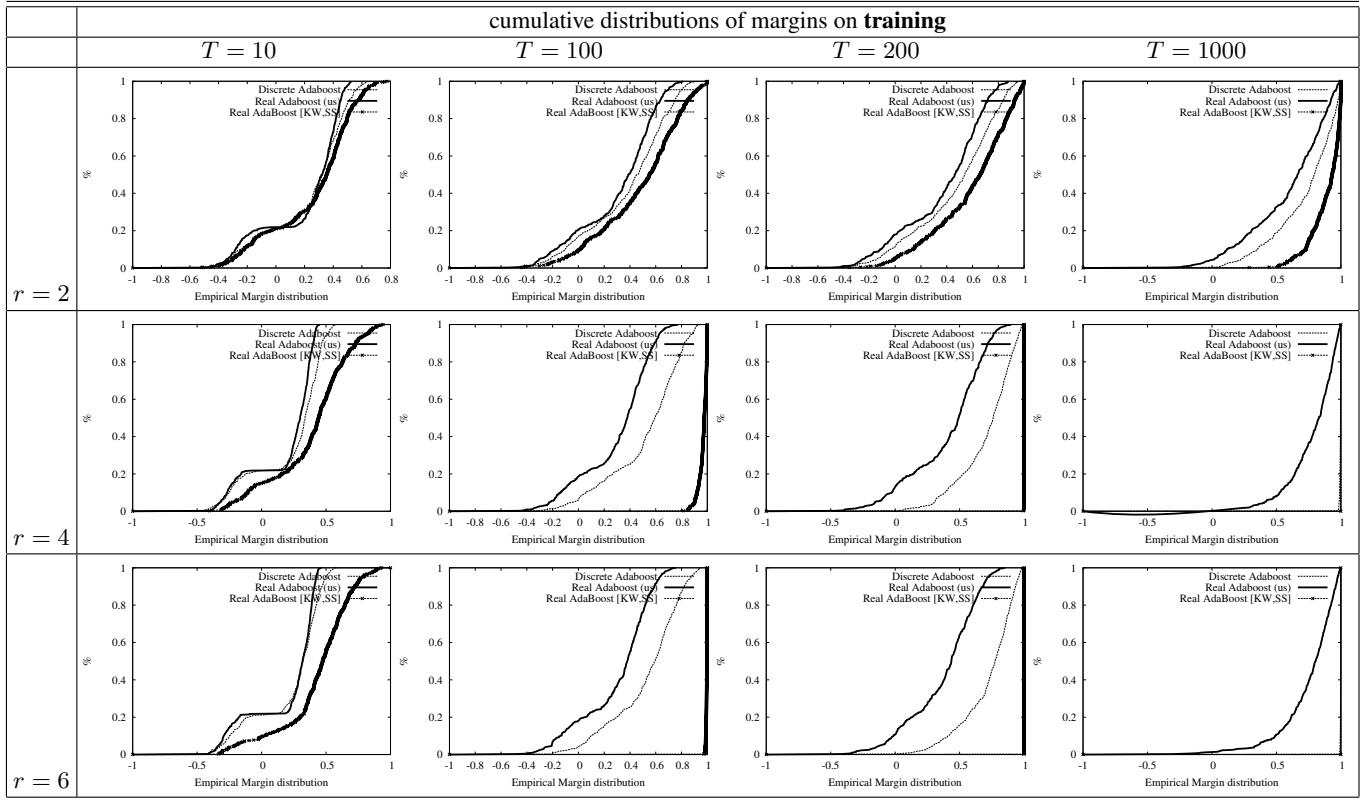

Figure 2. Empirical margin distributions on domain LEDeven+17. An algorithm is as better than another one as its margin distribution is located below the other for negative margin values. The empirical risk of an algorithm is approximately the intersection between its margin distribution and the line $x = 0$.

generated by applying the logistic prediction to random samples containing 300 examples each. It is clear from these curves that the shape that exhibits real AdaBoost as T or r increase, with many examples badly classified with very large confidence, is absent from the logistic prediction. Bayes rule's, along with AdaBoost_R, seem to be more conservative in their predictions. Since the logistic model is fit by discrete and real AdaBoosts [6], this suggests that real AdaBoost, followed by discrete AdaBoost, seem to rapidly overfit the model.

5 Conclusion

In this paper, we have proposed a new generalization of discrete AdaBoost to handle weak hypotheses with real values. Our algorithm, AdaBoost_R, departs from usual generalizations as it does not rely explicitly on the exact minimization of the exponential loss, a loss that upperbounds the empirical risk. While we formally prove that our generalization is a boosting algorithm in the original sense, it provides interesting computational and numerical features with respect to former real extensions of discrete AdaBoost, as well as a generalization of well-known facts about discrete boosting. Among future works, we plan to investigate further the boosting model of learning, and boosting algorithms in a somehow stronger approach. The classical weak and strong learning frameworks are discrete frameworks, as the accuracy of a classifier solely relies on classes. When dealing with real-valued predictions, an accurate framework should take into account both the sign (class), *and* the magnitude (confidence) of the prediction, as a good classifier should basically obtain large confidences with right classes, and not simply right classes. The margin error definition in (11) could be accurate to capture both notions, in

a model that would basically replace $\epsilon_{D,H}$ in (1) by $\nu_{D,H,\theta}$ in (12), with $0 < \theta < 1$ user-fixed, like ε and δ . We believe that strong results are possible: indeed, Theorem 1 shows that all margin errors at fixed $\theta < 1$ vanish with T under the WLA. It should thus be possible to obtain not only classifiers whose true risk is as reduced as desired, *but also* whose confidences are as large as desired. Finally, Theorem 1 does not integrate (the empirical) Bayes risk. A careful integration of this risk, or directly the margin error of Bayes rule, should help to see the way the algorithm behaves on hard problems, and perhaps the way it converges to Bayes rule [3].

ACKNOWLEDGEMENTS

The authors would like to thank the reviewers for insightful comments on the paper. R. Nock would like to warmly thank Sony Computer Science Laboratories Inc., Tokyo, for a visiting grant during which part of this work was done.

Discovery of Entailment Relations from Event Co-Occurrences

Viktor Pekar¹

Abstract. Lexical entailment is knowledge that may prove very useful for a variety of applications that deal with information implicit in a text. In this paper we address the problem of automatic discovery of pairs of verbs related by entailment. A specific challenge in this task is recognition of the direction of entailment in a pair. We model entailment by a number of linguistic cues as to local coherence between clauses. We first investigate the effect of these cues on the quality of the model and then evaluate it against human judgements. Our evaluation reveals that the model is capable of correctly identifying the direction in entailment-related pairs, although their separation from bidirectional pairs proves a more difficult task.

1 INTRODUCTION

The ability of language to express the same content in a variety of forms creates a great challenge for any attempt at deep understanding of natural language text. To deal with this problem at the lexical level, Natural Language Processing (NLP) research has been developing ways to automatically construct resources that describe how various lexical forms can express the same meaning. Many NLP applications can benefit from such a resource: in Question Answering, for example, it can help to make the connection between a question and an answer contained in a corpus, and in Relation Extraction, between an extraction pattern and an actually occurring expression that describes the relevant relation.

Automatic acquisition of paraphrases, expressions that have equivalent meaning, has received significant attention recently. In a paraphrase pair, two expressions (typically, verbs along with their argument structures) denote the same kind of semantic relations between entities. For example, the verbs *buy* and *purchase* both describe the same kind of event, a purchase, as well as the same set of roles different entities play in this event. Occurrence of one verb from this pair in a text signals the same semantic relations between entities as the other verb.

Entailment relations between verbs can also be very helpful in recognizing the same meaning expressed through different lexical forms. However, while in a paraphrase two verbs are semantically equivalent, entailment is a directional, or asymmetric, relation: one verb entails the other, but the converse does not need to hold. For example, *buy* entails *own*, but *own* does not entail *buy* (one can own an object without having bought it). Therefore, to make use of such verb pairs within an NLP application, it is crucial to know the direction of entailment in the pair.

The present paper is concerned with the problem of automatic discovery of entailment relations between verbs from text. In the next section we set the background for the study by describing previous

work. We then define the goal of the study and describe our method for entailment discovery. After that we present results of its experimental evaluation, where we first investigate parameters of the proposed method and then assess the quality of its output against human judgements. Finally, we draw conclusions and outline future work.

2 BACKGROUND

The overall task of entailment acquisition has much in common with that of paraphrase acquisition (e.g., [12], [13], [16]). In both tasks the goal is to discover pairs of related verbs and identify mappings between their argument structures. However, because entailment is an asymmetric relation, similarity between two verbs, an inherently symmetrical relation often used for the discovery of paraphrases, cannot be used for the recognition of the direction of entailment.

To account for the asymmetric character of entailment, a popular approach has been to use lexico-syntactic patterns indicative of entailment. In [4] different types of semantic relations between verbs are discovered using surface patterns (like "*X-ed* by *Y-ing*" for enablement) and assessing the strength of asymmetric relations as mutual information between the two verbs. Similar approaches are adopted by [17] and [8] for the discovery of entailment between verbs and by [6] for causal relations between nouns. Although these techniques achieve high precision, their reliance on surface patterns limits their coverage in that they address only those relations that are regularly made explicit through concrete natural language expressions, and only within sentences.

In tasks involving recognition of relations between entities such as Question Answering and Information Extraction, it is crucial to encode the mapping between the argument structures of two verbs. Pattern-matching often imposes restrictions on the syntactic configurations in which the verbs can appear in the corpus: the patterns employed by [4] and [17] derive pairs of only those verbs that have identical argument structures, and only those that involve a subject and a direct object. The method for discovery of inference rules based on distributional similarity proposed by [12] obtains pairs of verbs with highly varied argument structures, which also do not have to be identical. While the inference rules seem to encompass pairs related by entailment, these pairs are not distinguished from paraphrases and the direction of entailment in such pairs is not recognized.

3 ENTAILMENT RELATIONS

With the view of potential applications, we adopt an operational definition of entailment. We define it to be a semantic relation between verbs where one verb, termed premise p , refers to event e_p and at the same time implies event e_q , typically denoted by the other verb, termed consequence q .

¹ University of Wolverhampton, UK, email: v.pekar@wlv.ac.uk

The goal of entailment acquisition is then to find two linguistic templates each consisting of a verb and slots for its syntactic arguments. In the pair, (1) the verbs are related in accordance with our definition of entailment above, (2) there is a mapping between the slots of the two templates and (3) the direction of entailment is indicated explicitly. For example, in the template pair "*buy(obj:X)* \Rightarrow *belong(subj:X)*" the operator \Rightarrow specifies that the premise *buy* entails the consequence *belong*, and *X* indicates a mapping between the object of *buy* and the subject of *belong*.

As opposed to logical entailment, we do not require that lexical entailment holds in all conceivable contexts and view it as a relation that may be more plausible in some contexts than others. For each verb pair, we therefore wish to assign a score quantifying the likelihood of its satisfying entailment in some random context.

4 APPROACH

The key assumption behind our approach is that the ability of a verb to imply an event typically denoted by a different verb manifests itself in the regular co-occurrence of the two verbs inside locally coherent text, i.e. a set of sentences ordered in a pragmatically relevant manner. This assumption is not arbitrary; as discourse investigations show [1], lexical entailment plays an important role in determining the local structure of discourse. We expect this co-occurrence regularity to be equally characteristic of any pair of verbs related by entailment, regardless of its type and the syntactic behavior of verbs.

The method consists of three major steps. First, it identifies pairs of clauses that are related in the local discourse. We chose a clause rather than a sentence as the unit of analysis, since, as previous work has shown (e.g., [17]), two events related by entailment are often described in the same sentence. From the related clauses, our method then creates templates by extracting pairs of verbs along with relevant syntactic argument positions. Third, the method scores each verb pair in terms of plausibility of entailment by measuring how strongly the premise signals the appearance of the consequence inside the text segment at hand. In the following sections, we describe these steps in more detail.

4.1 Identifying discourse-related clauses

While there is extensive research into ways to instantiate theories of discourse in natural language processing and generation systems (e.g., [3] [10], [9]), in this study we are using a number of surface indicators that might help identify pairs of discourse-related clauses, without trying to build a full discourse representation of text.

Textual proximity. We start by parsing the corpus with a dependency parser, treating every verb with its dependent constituents as a clause. For two clauses to be discourse-related, we require that they appear close to each other in the text. Adjacency of sentences has been previously used to model local coherence [11]. To capture related clauses within larger text fragments, we experiment with windows of text of various sizes around a clause. Since locally related sentences tend to be grouped into paragraphs, we additionally require that the two clauses appear within the same paragraph.

Common event participant. Entity-based theories of discourse such as Centering Theory ([7]) claim that a coherent text segment tends to focus on a specific entity. This intuition has been formalized by [2], who developed an entity-based statistical representation of local discourse and showed its usefulness for assessing coherence between sentences. We also impose this as a criterion for two clauses to be discourse-related: their arguments need to refer to the same

participant, henceforth, **anchor**. We identify the anchor as the same noun lemma appearing as an argument to the verbs in both clauses, considering only subject, object, and prepositional object arguments.

Pronouns as anchors. Studies into local discourse also suggest that salient entities within a discourse segment are frequently referred to with anaphoric expressions, rather than with the same noun or noun phrase. Thus, one can expect that clauses that share the same pronoun are likely to be discourse-related. On the other hand, it seems quite probable that identical pronouns may refer to different entities, especially if the pronouns appear at a large distance from each other and/or there are more than one salient entity in the text segment. We investigate the effect of using identical pronouns as anchors that appear at different distances from each other in the text.

4.2 Constructing templates

Once relevant clauses have been identified, we create pairs of syntactic templates, each consisting of a verb and a label specifying the syntactic role the anchor occupies near the verb. For example, given a pair of clauses *Mr Brown was appointed as a new chief executive*, and *Mr Brown became a chief executive*, the method will extract two pairs of templates: $\{\text{appoint}(\text{obj}:X), \text{become}(\text{subj}:X)\}$ and $\{\text{appoint}(\text{as}:X), \text{become}(\text{comp}:X)\}$

Before templates are constructed, we automatically convert complex sentence parses to simpler, but semantically equivalent ones so as to increase the amount of usable data and reduce noise. We convert passive constructions into active, phrases with past and present participles are turned into predicate structures, coordinated nouns and verbs are separated and treated as separate phrases. If a verb has been used in negative clauses, the particle *not* is appended in front of it in order to distinguish between postulated and negated events.

The output of this step is $V \in P \times Q$, a set of pairs of templates $\{p, q\}$, where $p \in P$ is the premise, consisting of the verb v_p and r_p – the syntactic relation between v_p and the anchor, and $q \in Q$ is the consequence, consisting of the verb v_q and r_q – its syntactic relation to the anchor.

4.3 Measuring asymmetric association

To score the pairs for asymmetric association, we use a procedure similar to the method for learning selectional preferences of verbs proposed by [14].

Each template in a pair is tried as both a premise and a consequence. We quantify the ‘preference’ of the premise p for the consequence q as the contribution of q to the amount of information p contains about its consequences seen in the data. First, we calculate Kullback-Leibler Divergence [5] between two probability distributions, u – the prior distribution of all consequences in the data and w – their posterior distribution given p , thus measuring the information p contains about its consequences:

$$D_p(u||w) = \sum_n u(x) \log \frac{u}{w} \quad (1)$$

where $u(x) = P(q_x|p)$, $w(x) = P(q_x)$, and x ranges over all consequences in the data. Then, the score for template $\{p, q\}$ expressing the association of q with p is calculated as the proportion of q ’s contribution to $D_p(u||w)$:

$$\text{Score}(p, q) = P(q|p) \log \frac{P(q|p)}{P(p)} D_p(u||w)^{-1} \quad (2)$$

In each pair we compare the scores in both directions, taking the direction with the greater score to indicate the most likely premise and consequence and thus the direction of entailment.

In the following two sections we first describe the results of a study of the parametrization of the method and then evaluation of the output generated by its most optimal configuration.

5 PARAMETERS OF THE METHOD

5.1 Task

To explore the effects of different parameter settings for the method, we designed a recognition task similar to that of pseudo-word disambiguation [15]. The task was, given a certain premise, to select its correct consequence out of a pool with several artificially created incorrect alternatives. The advantage of this evaluation design, in comparison with manual evaluation of the direct output of the system, is that it requires minimal human involvement and makes it possible to conduct large-scale experiments.

5.2 Data

The experimental material was created from the BLLIP corpus, a collection of texts from the Wall Street Journal (years 1987-89). We chose 15 transitive verbs with the greatest corpus frequency and used a pilot run of our method to extract 1000 highest-scoring template pairs involving these verbs as a premise. From them, we manually selected 129 template pairs that satisfied entailment.

For each of the 129 template pairs, four false consequences were created. This was done by randomly picking verbs with frequency comparable to that of the verb of the correct consequence. A list of parsed clauses from the BLLIP corpus was consulted to select the most typical syntactic configuration of each of the four false verbs. The resulting five template pairs, presented in a random order, constituted a test item. Figure 1 illustrates such a test item.

```
9.1 * buy(subj X,obj Y) => own(subj X,obj Y)
9.2 buy(subj X,obj Y) => approve(subj X,obj Y)
9.3 buy(subj X,obj Y) => reach(subj X,obj Y)
9.4 buy(subj X,obj Y) => decline(subj X,obj Y)
9.5 buy(subj X,obj Y) => compare(obj X,with Y)
```

Figure 1. An item from the test dataset. The template pair with the correct consequence is marked by an asterisk.

The entailment acquisition method was evaluated on entailment templates acquired from the British National Corpus. Even though the two corpora are quite different in style, we assume that the evaluation allows conclusions to be drawn as to the relative quality of performance of the methods under consideration.

5.3 Recognition algorithm

During evaluation, we tested the ability of the method to select the correct consequence among the five alternatives. Our entailment acquisition method generates association scores for one-slot templates. In order to score the double-slot templates in the evaluation material, we used the following procedure.

Given a double-slot template, we divide it into two single-slot ones such that matching arguments of the two verbs along with the verbs themselves constitute a separate template. For example, "send

(*obj*:X, *to*:Y) \Rightarrow go (*subj*:X, *to*:Y)" will be decomposed into "send (*obj*:X) \Rightarrow go (*subj*:X)" and "send (*to*:Y) \Rightarrow go (*to*:Y)". The scores of these two templates are then looked up in the generated database and averaged. In each test item, the five alternatives are scored in this manner and the one with the highest score was chosen as containing the correct consequence.

The performance was measured in terms of accuracy, i.e. as the ratio of correct choices to the total number of test items. Ties, i.e. cases when the correct consequence was assigned the same score as one or more incorrect ones, contributed to the final accuracy measure proportionate to the number of tying alternatives.

This experimental design corresponds to a random baseline of 0.2, i.e. the expected accuracy when selecting a consequence randomly out of 5 alternatives.

5.4 Results

We first examined the following parameters of the model: the window size, the use of paragraph boundaries, and the effect of the shared anchor on the quality of the model.

5.4.1 Window size and paragraph boundaries

As was mentioned in Section 4.1, a parameter in our model is a threshold on the distance between two clauses, below which the clauses are taken to be discourse-related. We evaluated different values of *k*, the size of the window of clauses around a given clause. We also looked at the effect paragraph boundaries have on the identification of related clauses. Figure 2 shows two curves depicting the accuracy of the method as a function of the window size: the first one describes performance when paragraph boundaries are taken into account (PAR) and the second one when they are ignored (NO_PAR).

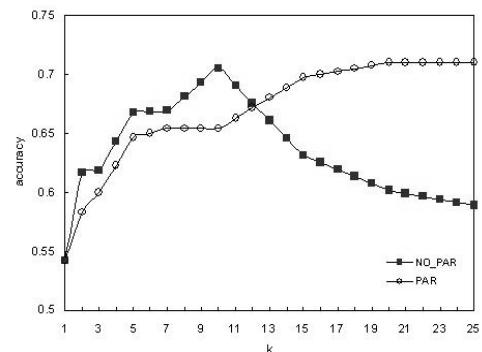

Figure 2. Accuracy of the algorithm as a function of window size, with and without paragraph boundaries used for delineating coherent text.

One can see that both curves rise steeply until *k* = 7, indicating that many entailment pairs are discovered when the two clauses appear close to each other. The rise is the steepest between *k* being 1 and 3, suggesting that entailment relations are most often explicated in clauses appearing very close to each other.

PAR reaches its maximum at *k* = 15, where it levels off. Considering that 88% of paragraphs in BNC contain 15 clauses or less, we take this as an indication that a segment of text where both a premise and its consequence are likely to be found indeed roughly

corresponds to a paragraph. NO_PAR's maximum is at 10, then the accuracy starts to decrease, suggesting that evidence found deeper inside other paragraphs is misleading to our model.

We tested the difference between the maxima of PAR and NO_PAR using the sign test, the non-parametric equivalent of the paired t-test. The test did not reveal any significance in the difference between their accuracies (6-, 7+, 116 ties: $p = 1.000$).

5.4.2 Common anchor

We further examined how the criterion of the common anchor influenced the quality of the model. We compared the configuration that used this criterion (ANCHOR) against the one that did not (NO_ANCHOR), i.e. considering only co-occurrence of verbs concatenated with specific syntactic role labels. Additionally, we included into the experiment a model that looked at plain verbs co-occurring inside a context window (PLAIN). Figure 3 compares the performance of these three models (paragraph boundaries were taken into account in all of them).

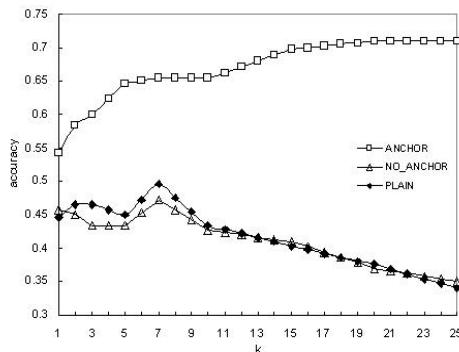

Figure 3. The effect of the common anchor on the accuracy of the method.

Compared with ANCHOR, the other two models achieve considerably worse accuracy scores. The differences between the maximum of ANCHOR and those of the other two models are significant according to the sign test (ANCHOR vs NO_ANCHOR: 44+, 8-, 77 ties: $p < 0.001$; ANCHOR vs PLAIN: 44+, 10-, 75 ties: $p < 0.001$). Their maxima are also reached sooner (at the window of 7) and thereafter their performance quickly degrades. This indicates that the common anchor criterion is very useful, especially for locating related clauses at larger distances in the text.

5.4.3 Pronouns as anchors

Figure 4 compares the performance of the method with and without pronouns being used as anchors for the discovery of template pairs. We see that the two curves are very similar. The use of pronouns offers improvement at $k < 5$, though it is quite small (max. 4% at $k = 3$). With the further increase of k , the performance curve generally stays below the one when pronouns are not used as anchors.

The observed effect of pronouns is consistent with the expectation that identical pronouns occurring close to each other typically refer to the same entities, thus signifying relatedness between clauses. At greater distances, they tend to refer to different entities.

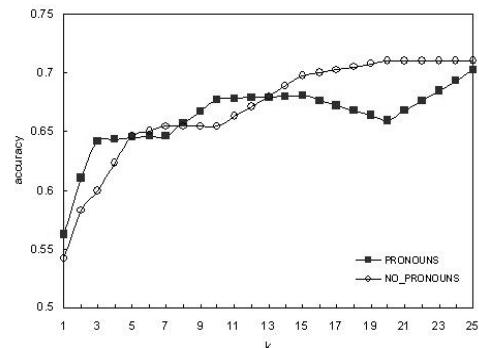

Figure 4. The effect of pronouns used as anchors on the accuracy of the method.

6 HUMAN EVALUATION

6.1 Design

In order to directly evaluate the quality of entailment patterns discovered by our model, we elicited judgements from humans. We randomly selected 300 pairs from the top 1000 scoring pairs generated by the optimized configuration of the model from the BNC data, that was determined in the previous set of experiments (i.e., using a window of 20 verbs, paragraph boundaries and the common anchor criterion; pronouns were not used as anchors).

To examine the ability of the model to capture the direction of entailment relations, from each of the 300 pairs we created a similar one by swapping the premise and the consequence, so that the resulting pair was identical to the original one except that its direction was the opposite. This produced an evaluation set with 600 verb pairs.

Presented with the pairs in a random order, five paid subjects were asked to mark in each pair whether or not the verb on the left implied the one on the right. They were specifically instructed to pay attention to the order of the templates in a pair and mark highly probable, but not necessarily certain implications.

The obtained judgements were then analyzed to arrange the initial 300 pairs into four groups:

- CORRECT, where entailment held in the predicted direction, i.e. the premise implied the consequence, as assigned by the method;
- OPPOSITE, where entailment was found in the direction opposite to the predicted one, i.e. the intended premise was in fact a consequence and vice versa;
- BIDIRECTIONAL, where entailment held in both directions, i.e. the two templates were paraphrases of each other; and
- NO_RELATION, where entailment existed in neither direction.

Table 1 shows 20 randomly selected verb pairs that were present in the CORRECT category with at least three subjects.

6.2 Results

Table 2 shows the mean number of pairs for each of the four groups of verb pairs, standard error as well its proportion in the entire sample.

These results indicate that the model discovers a greater number of pairs with correctly identified direction of entailment in them, than pairs where entailment holds in the opposite direction. A two-tailed

sell X to Y \Rightarrow Y own X	ask X for Y \Rightarrow X have Y
sell X to Y \Rightarrow Y accept X	X eat Y \Rightarrow X get Y
X grant Y \Rightarrow X have Y	X exceed Y \Rightarrow X reach Y
appoint X as Y \Rightarrow X become Y	X play in Y \Rightarrow involve X in Y
X win Y \Rightarrow X hold Y	X prevent Y \Rightarrow X reduce Y
X achieve Y \Rightarrow X have Y	identify X in Y \Rightarrow Y have X
X explain Y \Rightarrow X understand Y	send X to Y \Rightarrow X go to Y
entitle X to Y \Rightarrow X claim Y	X pick_up Y \Rightarrow X take Y
X publish Y \Rightarrow X produce Y	X live in Y \Rightarrow X come to Y
X win Y \Rightarrow X get Y	X wear Y \Rightarrow X have Y

Table 1. A sample of system-generated verb pairs evaluated by the majority of subjects as satisfying entailment.

	Mean	Std. error	%
CORRECT	48.8	3.35	16.26
OPPOSITE	26.4	4.7	8.8
BIDIRECTIONAL	71.4	15.96	23.8
NO_RELATION	153.4	22.26	51.13

Table 2. Four types of system-discovered pairs created on the basis of judges' responses.

paired t-test between CORRECT and OPPOSITE shows the difference is significant ($p = 0.001$). However, the model has difficulty distinguishing between pairs with the correct direction and those with bidirectional relations. The difference between the means is not significant ($p > 0.1$). The evaluation also shows that in about half of the pairs output by the model, neither verb was perceived as implying its counterpart.

6.3 Error analysis

Manual examination of pairs appearing in groups other than CORRECT revealed the following most common types of errors.

Pairs with bidirectional relations made up a large proportion of the system output. They included pairs that would normally be classified as paraphrases (e.g., X cause $Y - X$ lead to Y , X help $Y - X$ encourage Y , X develop $Y - X$ promote Y) and conversives (e.g., X receive $Y - send Y to X$, X buy $Y - sell Y to X$, X buy $Y - X$ pay for Y). This shows that these lexical relations can frequently be found in discourse-related clauses. If the co-occurrence rate for such pairs is high compared with the frequency of one of the verbs, the association score for such pairs turns out to be high. A possible way to filter out such pairs might be to additionally score pairs using a method for discovery of symmetrical relations, such as one that measures distributional similarity between the templates ([12]).

Among pairs in the NO_RELATION group, there is a considerable number of antonyms, such as X reject $Y - X$ approve Y , X lose $Y - X$ win Y , and X reduce $Y - X$ increase Y . Manual inspection suggests there are around 30 antonymous pairs (10%) in the 300 pairs used for the experiment. Because antonymy is a symmetrical relation, the number of output antonyms might also be reduced by a method that discovers symmetrically related verb pairs.

A considerable number of pairs that seem to satisfy entailment ended up in the NO_RELATION category, because of ambiguity of verbs and the insufficiency of information as to the context in which they should be interpreted. For example, X obtain $Y - X$ apply for Y found to be unrelated by 3 out of 5 subjects. However, considering this pair in the context of some legal procedure, entailment does seem

to hold. Similar examples of this kind are X encourage $Y - X$ increase Y , X receive $Y - X$ claim Y , X maintain $Y - X$ build Y . It should also be noted that some pairs that appear in the CORRECT category would normally be judged to be paraphrases in some contexts, such as X regard as $Y - X$ call Y , X approve $Y - X$ pass Y .

7 CONCLUSION

We have proposed a method for automatic discovery of entailment relations from text, a task that is of potential benefit for many AI applications. The central assumption behind the method is that entailment relations manifest themselves in the regular co-occurrence of two verbs inside locally coherent text. We examined the effect on the quality of our model produced by a number of surface cues as to discourse relatedness between clauses, finding that the distance between clauses, paragraph boundaries, and shared arguments of the verbs are good indicators of entailment relations. A direct evaluation of entailment pairs found by the proposed method demonstrated that it provides a promising approach for discovery of the asymmetric relations of entailment.

Efficient Knowledge Acquisition for Extracting Temporal Relations

Son Bao Pham and Achim Hoffmann¹

Abstract. Machine learning approaches in natural language processing often require a large annotated corpus. We present a complementary approach that utilizes expert knowledge to overcome the scarceness of annotated data. In our framework KAFTIE, the expert could easily create a large number of rules in a systematic manner without the need of a knowledge engineer. Using KAFTIE, a knowledge base was built based on a small data set that outperforms machine learning algorithms trained on a much bigger data set for the task of recognizing temporal relations. Furthermore, our knowledge acquisition approach could be used in synergy with machine learning algorithms to both increase the performance of the machine learning algorithms and to reduce the expert's knowledge acquisition effort.

1 Introduction

Recent years have seen a growing interest in Natural Language Processing applications. Machine learning became the method of choice for building domain specific text analysis systems. Statistical NLP proved very popular as shallow approaches to language understanding appear more promising than previously thought. However, limitations of what those techniques can achieve are on the horizon: machine learning approaches are limited by the available tagged data, in particular, where supervised learning is involved.

There has been an increasing demand for temporal analysis. A number of approaches have addressed temporal processing: identification and normalization of time expressions [6], time stamping of event clauses [4], temporally ordering of events [5], recognizing time-event relations in TimeML [1]. At a higher level, these temporal expressions and their relations are essential for the task of reasoning about time, for example, to find contradictory information [3]. In this emerging domain, there is a clear lack of a large annotated corpus to build machine learning classifiers for detecting temporal relations.

We present our incremental knowledge acquisition approach that utilizes expert's knowledge (almost any competent speaker of the relevant language) to overcome the scarceness of annotated data. We demonstrate the effectiveness of our approach as we have quickly developed a large knowledge base (KB) based on a small data set that performs better than machine learning (ML) approaches trained on a much bigger data set on the task of recognizing temporal relations.

We further show how ML algorithms can be used in synergy with our approach when annotated data is available to both increase the performance of the ML algorithms and reduce the knowledge acquisition effort. This work is based on [7, 8].

Our knowledge acquisition framework builds on the idea of Ripple Down Rules (RDR) [2] which allows one to add rules to the given KB

incrementally while automatically ensuring consistency with previously seen cases i.e the KB's performance is continuously improved. Let us consider simple examples in the task of assigning a positive or negative class to sentences. Given the following sentence:

Our approach has a good performance.

the user could assign the positive class to the sentence due to the word *good* by creating the following rule:

if the text contains "good" then assign positive class (1)

The following sentence:

The approach's performance is not good.

will be assigned with the positive class by rule (1). Suppose the user disagrees as the presence of the word *not* negates the effect of having the word *good*. He or she can in turn create an exception to rule (1):

if the text contains "not" then assign negative class (2)

This rule is potentially applicable only in the context where rule (1)'s condition is satisfied i.e. it is an exception of rule (1). Effectively, the above two rules are equivalent to:

**if the text contains "good" then assign positive class
except if the text contains "not" then assign negative class**

For the sentence:

The work does not follow traditional approaches.

rule (1)'s condition is not satisfied. Rule (2) will therefore not be considered either. However, the sentence

This approach is good and does not suffer from existing problems.

will be labeled incorrectly with the negative class by rule (2). This is probably not the intention of the user when creating the exception rule (2) as the word *not* does not modify the meaning of the word *good*. The user could add another exception rule to refine rule (2):

if "not" appears after "good" then assign positive class (3)

The above examples use a very simple pseudo rule language to illustrate how the knowledge acquisition process works. The actual rule language description used is presented in detail in section 3.1.

In section 2 we present a short overview of RDR. This is followed by a description of KAFTIE in section 3. Section 4 reports experimental results on recognizing temporal relations which demonstrates the success of our approach. Section 5 discusses how ML could be utilized in KAFTIE. The conclusions follow in section 6.

2 Knowledge Acquisition Methodology

In this section we present the basic idea of Ripple-Down Rules (RDR) [2] which inspired our approach. RDR allows one to add rules to a knowledge base incrementally without the need of a knowledge engineer. A new rule is only created when the KB performs unsatisfactorily on a given case. The rule represents an explanation for why the conclusion should be different from the KB's conclusion on the case at hand.

A *Single Classification Ripple Down Rules* (SCRDR) tree is a binary tree with two distinct types of edges. These edges are typically called *except* and *if-not* edges. See figure 1. Associated with each node in a tree is a *rule*. A rule has the form: *if* α *then* β where α is called the *condition* and β the *conclusion*.

Cases in SCRDR are evaluated by passing a case (an object to be classified) to the root of the tree. At any node in the tree, if the condition of a node N 's rule is satisfied by the case, the case is passed on to the exception child of N using the *except* link if it exists. Otherwise, the case is passed on to the N 's *if-not* child. The conclusion given by this process is the conclusion from the last node in the RDR tree which *fired* (satisfied by the case). To ensure that a conclusion is always given, the root node typically contains a trivial condition which is always satisfied. This node is called the *default* node. We will show how a more complex *default* rule can improve the knowledge acquisition process in section 5.

A new node is added to an SCRDR tree when the evaluation process returns the wrong conclusion. The new node is attached to the last node in the evaluation path of the given case with the *except* link if the last node is the *fired* rule. Otherwise, it is attached with the *if-not* link.

With the structure of RDR tree, it is possible that redundancy is present as one rule could appear in multiple places. Reorganizing RDR structure was reported in [11]. However, this is not crucial as the structure of the KB is transparent to the users.

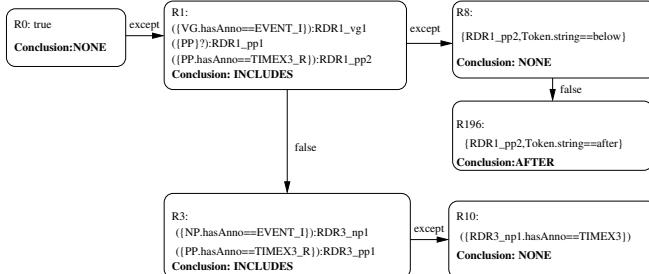

Figure 1. An extract of a KB for recognizing TLINK between an EVENT and a TIMEX3. Note that SCRDR is different from a decision tree: rules in internal nodes can be used to give conclusions to input cases.

3 Our KAFTIE framework

We use SCRDR for building knowledge bases in the KAFTIE (Knowledge Acquisition Framework for Text classification and Information Extraction) framework. Some levels of abstraction in the rule's condition is desirable to make the rule expressive enough in generalizing to unseen cases. To realize this, we use the idea of annotations where phrases that have similar roles (belong to the same concept) are deemed to belong to the same annotation type. Annotations contain the annotation type, the character locations of the beginning and ending position of the annotated text in the document, and a list of feature value pairs.

3.1 Rule description

A rule is composed of a condition part and a conclusion part. A condition is a regular expression pattern over annotations. It can also post new annotations over matched phrases of the pattern's sub-components. The following is an example of a pattern which posts an annotation over the matched phrase:

$\{\{\text{Noun}\}\{\text{VG.type==FVG}\}\{\text{Noun}\}\}:\text{MATCH}$

This pattern would match phrases starting with a Noun annotation followed by a VG, which must have feature *type* equal to FVG, followed by another Noun annotation. When applying this pattern on a piece of text, MATCH annotations would be posted over phrases that match this pattern. As annotations have feature value pairs, we can impose constraints on annotations in the pattern by requiring that a feature of an annotation must have a particular value.

The rule's conclusion contains the classification of the input text. In the task of recognizing temporal relations between a pair of temporal expressions (event or time), the conclusion is either the relation type or NONE.

3.2 Annotations and Features

Built-in annotations: As our rules use patterns over annotations, the decision on what annotations and their corresponding features should be are important for the expressiveness of rules. The following annotations and features make patterns expressive enough to capture all rules we want to specify for various tasks.

We have Token annotations that cover every token with *string* feature holding the actual string, *category* feature holding the POS and *lemma* feature holding the token's lemma form.

As a result of the Shallow Parser module, which is a cascade of finite state transducers, we have several forms of noun phrase annotations ranging from simple to complex noun phrases, e.g. NP (simple noun phrase), NPL (list of NPs) etc. There are also VG (verb groups) annotations with *type*, *voice*, *headVerbPos*, *headVerbString* etc. features and other annotations e.g. PP (prepositional phrase), SUB (subject), OBJ (object). The Shallow Parser used in this work is not geared towards the task.

Every rule that has a non-empty pattern would post at least one annotation covering the entire matched phrase. Because rules in our knowledge base are stored in an exception structure, we want to be able to identify which annotations are posted by which rule. To facilitate that, we number every rule and enforce that all annotations posted by rule number x have the prefix RDR x _. Therefore, if a rule is an exception of rule number x , it could use all annotations with the prefix RDR x _ in its condition pattern.

Apart from the requirement that an annotation's feature must have a particular value, we define extra annotation constraints: *hasAnno*, *hasString*, *underAnno*, *endsWithAnno*. For example, *hasAnno* requires that the text covered by the annotation must contain the specified annotation:

$\text{NP.hasAnno == TIMEX3}$

only matches NP annotations that have a TIMEX3 annotation covering their substring. This is used, for example, to differentiate a TIMEX3 in a noun group from a TIMEX3 in a verb group.

Custom annotations: Users could form new named lexicons during the knowledge acquisition process. The system would then post a corresponding annotation over every word in those lexicons. Doing this makes the effort of generalizing the rule quite easy and keeps the KB compact.

3.3 The Knowledge Acquisition Process in KAFTIE

The knowledge acquisition process goes through a number of iterations. The user gives a text segment (e.g. a sentence) as input to the KB. The conclusion (e.g. classification) is suggested by the KB together with the *fired* rule R that gives the conclusion. If it is not the default rule, annotations posted by the rule R are also shown (see section 4.3) to help the user decide whether the conclusion is satisfactory.

If the user does not agree with the KB's performance, there are two options: adding an exception rule to rule R or modifying rule R if possible. In either case, user's decision will be checked for consistency with the current KB before it gets committed to the KB. To create a new exception rule, the user only has to consider why the current case should be given a different conclusion from rule R . This effort does not depend on the knowledge base size. The level of generality of the new rule is not crucial as this process can be supported by the work reported in [9].

4 Experiments

We build a knowledge base using KAFTIE to recognize TLINK relations between an EVENT and a TIMEX3 in the TimeBank corpus. According to the specification of TimeML [10], TIMEX3 marks up explicit temporal expressions such as times, dates, durations etc. EVENT covers elements in a text describing situations that occur or happen while TLINK is a temporal link representing a relation between an event and a time or between two events.

4.1 The TimeBank corpus

The TimeBank corpus is marked up for temporal expressions, events and basic temporal relations based on the specification of TimeML. Currently, the TimeBank corpus has 186 documents.

Excluding TIMEX3s in document's meta-data (doc creation time), the majority of TLINKs are between EVENTS and TIMEX3s within the same sentence. Hence, in all experiments, we focus on recognizing intra-sentential temporal relations.

The TimeBank annotation guidelines suggest distinctions among TLINK types between two EVENTS but do not explicitly specify how those types are different when it comes to relations between an EVENT and a TIMEX3. In fact, some of the TLINKs types between an EVENT and a TIMEX3 are hard to distinguish and a number of cases of inconsistency are observed in the corpus. We group similar types together: BEFORE and IBEFORE are merged, AFTER and IAFTER are merged and the rest is grouped into INCLUDES.

4.2 KAFTIE for extracting Temporal Relations

For the task of extracting EVENT-TIMEX3 temporal relations, we consider all pairs between an EVENT and a TIMEX3 in the same sentence and build a knowledge base to recognize their relations. The sentence containing the pair is used as the input to the knowledge base. As there could be more than one EVENT or TIMEX3 in the same sentence, we change the EVENT and the TIMEX3 annotations in focus to EVENT_I (instance) and TIMEX3_R (related_to) annotations respectively. This enables our rule's pattern to uniquely refer to the pair's arguments. For each pair, the KB's conclusion is the type of its temporal relation if there exists a relation between the pair's arguments or NONE otherwise.

Apart from this, there was no prior design required to adapt KAFTIE to the task of recognizing temporal relations.

4.3 How to build a Knowledge Base in KAFTIE

The following examples are taken from the actual knowledge base discussed in section 4.4 and shown in figure 1. Suppose we start with an empty KB for recognizing temporal relations between an EVENT and a TIMEX3 within the same sentence. I.e. we would start with only a default rule that always produces a *NONE* conclusion. When the following sentence is encountered:

```
Imports of the types of watches [VG [EVENT_I totaled EVENT_I] VG]
[PP about $37.3 million PP] [PP in [NP [TIMEX3_R 1988 TIMEX3_R]
NP] PP], ...
```

our empty KB would use the default rule to suggest the relation between EVENT_I and TIMEX3_R is *NONE* i.e. no relation exists. This can be corrected by adding the following rule to the KB:

Rule 1:
 $((\{VG.\text{hasAnno} == \text{EVENT_I}\}):RDR1_vg1$
 $(\{\text{PP } ?\}:RDR1_pp1$
 $(\{\text{PP}.\text{hasAnno} == \text{TIMEX3_R}\}):RDR1_pp2$
 $):RDR1_$
Conclusion: INCLUDES

Each of the component in the rule's pattern is automatically assigned a tag which will effectively post a new annotation over the matched token strings of the component if the pattern matches a text. New tags of rule i always start with $RDRi_$. This rule would match phrases starting with a VG annotation which covers the EVENT_I annotation, followed by an optional PP annotation followed by a PP annotation covering the TIMEX3_R annotation. When the sentence containing the pair EVENT_I-TIMEX3_R is matched by this rule, the pair is deemed to be of INCLUDES relation type. Once matched, new annotations RDR1_vg1, RDR1_pp1 and RDR1_pp2 will be posted over the first VG, the first PP and the last PP in the pattern respectively. This is to enable exception rules to refer to the results of previously matched rules. Notice here that the first PP component is specified optional. It could be that the expert already *anticipates* future cases and makes the current rule more general. Alternatively, experts always have a choice of modifying existing rule to cover new cases.² When we encounter this pair:

```
The company's shares [RDR1_vg1 [VG are [EVENT_I wallowing
EVENT_I] far VG] RDR1_vg1] [RDR1_pp2 [PP below [NP their
[TIMEX3_R 52-week TIMEX3_R] NP] PP] RDR1_pp2] high....
```

Rule **R1** fires suggesting that the pair has INCLUDES relation with the newly posted annotation highlighted in bold face. This is incorrect as there is no relation. The following exception rule is added to fix the misclassification:

Rule 8:³
 $(\{RDR1_pp2.\text{Token.string} == \text{below}\}):RDR8_$
Conclusion: NONE

This rule says that if the second PP matched by Rule 1 (RDR1_pp2) starts with a token string *below* then there is no relation between the pair. Notice that the sentence could have different PP annotations. As each rule posts unique annotations over the matched phrases, we can unambiguously refer to relevant annotations.

² Automatic recommendation on which existing rules and how to modify to cover new cases is reported in [9].

³ We only select some rules to show as examples, hence indices of rules are not consecutive

4.4 Experimental results

Out of 186 documents in the TimeBank corpus with approximately 1350 intra-sentential TLINK instances, we randomly took half of that as training data and keep the remaining half for testing. Using our KAFTIE framework, we built a knowledge base of 229 rules to recognize relations between an EVENT and a TIMEX3 in the same sentence using the training data.⁴ The knowledge base uses NONE as its default conclusion. In other words, by default and initially when the KB is empty, all EVENT-TIMEX3 pairs are deemed not to have any TLINK relations.

The overall results are shown in table 1 for two settings: *3 types* (BEFORE, INCLUDES and AFTER see section 4) and *without typing* - collapsing all TLINK types into one type, effectively detecting if the pair has a TLINK relation regardless of the type. While the accuracy reflects performance on the test data across all types including NONE, the F-measure is based on only TLINKs types, i.e. excluding NONE.⁵ On the *without typing* setting, the built knowledge base achieved an F-measure of more than 75% and an accuracy of 86.7%.

Methods	3 types		w/o typing	
	F-m	Acc.	F-m	Acc.
KAFTIE	71.3%	86.1%	75.4%	86.7%
J48 (5-folds)	62.3%	78.7%	66.4%	81.2%
SMO (5-folds)	61.4%	77.4%	63.1%	78.7%

Table 1. Results on recognizing TLINKs for 3 types and *without typing* settings.

For comparison with standard machine learning approaches, we use Weka's J48 and SMO [12] as implementations for C4.5 and support vector machine algorithms respectively. To adapt machine learning algorithms to the task of extracting relations, we define the following feature representation which is capable of capturing the relation arguments (EVENTs and TIMEX3s) and the surrounding context. We break up the sentence containing the EVENT-TIMEX3 pair into five segments namely: spans of the two arguments (EVENT and TIMEX3), the span between the two arguments and spans to the left/right of the left/right arguments. From each segment, we use token strings, token lemmas, parts-of-speeches, bigrams of parts-of-speeches and all annotations from the Shallow Parser as features.

J48 and SMO are run using 5-fold cross validation. As the result could vary depending on the seed used for the cross validation, we report results averaged over 100 runs with different random seeds. As can be seen in table 1, the knowledge base built using our framework significantly outperforms standard J48 and SMO. In fact, our knowledge base with the initial 60 rules (as the result of seeing roughly 60 misclassified TLINK pairs) already outperforms J48 and SMO (see figure 2).

Figure 2 shows the performance of our knowledge base on the test data as rules are incrementally added. Given the upwards trend of the graph as more rules are added, it is plausible that our KB would get to even higher performance had we used 80% of the available data for building the KB.

⁴ To evaluate the TLINK recognition task alone, we use the EVENT and TIMEX3 annotations in the TimeBank corpus.

⁵ The NONE type occurs approximately 2.5 times more often than the TLINK types.

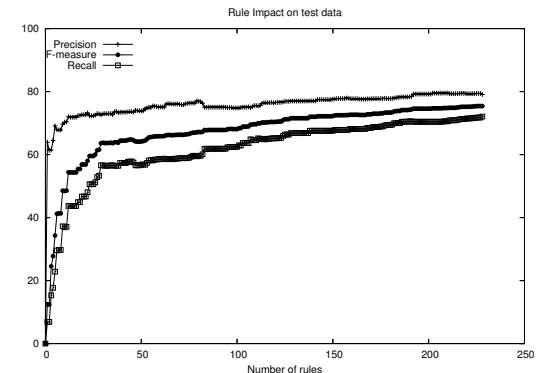

Figure 2. Impact of incrementally adding rules to the KB.

5 Combining ML with KA

In this section, we investigate how machine learning could be used in synergy with our knowledge acquisition approach to both improve the machine learning algorithms' performance and reduce the required knowledge acquisition effort.

A knowledge acquisition (KA) session corresponds to the creation of a new rule as a result of the KB performing incorrectly on a particular case. Notice that the KB's default rule is quite simple. It always returns the default conclusion which is *NONE* for the task of recognizing temporal relations. We conjecture that if we start with a better default rule then the number of knowledge acquisition sessions can be reduced. One way of doing it is to take some training data to train a classifier as the default rule.

We carry out the following experiment: We focus on the task of recognizing temporal relation in the *without typing* setting and use the exact training and test data from the previous section to build and test a KB respectively. The difference is that we now split the training data into two parts i.e. *ML data* and *KB data*. The *ML data* is used to train a classifier as the default rule in a KB while the *KB data* is used to add exception rules to the KB.

Instead of having real experts involved in the process of creating exception rules, we simulate it by consulting the KB built from the previous section, called *oracleKB*.⁶ For each example in the *KB data* that is misclassified by the current KB, we use the *fired* rule for the example from the *oracleKB* i.e. the rule that the *oracleKB* would use on the example.

Table 2 shows the results of using J48 and SMO which are trained on varying portions of the training data. Specifically, it shows the f-measure of the classifier alone, the KB with the classifier as the default rule on the test data as well as the number of rules in the KB. The number of rules in the KB reflects the number of KA sessions required for building the KB. All figures are averaged over 20 different runs using different seeds on splitting the training data into *ML data* and *KB data*.

In all situations, machine learning algorithms can always be augmented with more rules using our knowledge acquisition approach to achieve a significantly better performance, see figure 3.

As we increase the percentage of *ML data*, the number of KA sessions required gets smaller. Ideally, we want to minimize the number of KA sessions while maximizing the f-measure. When the *ML data* is empty (0% of the training data), we effectively rebuild a KB in

⁶ Every rule in this KB is made independent of other rules by incorporating all of its context e.g. the rule it is an exception of.

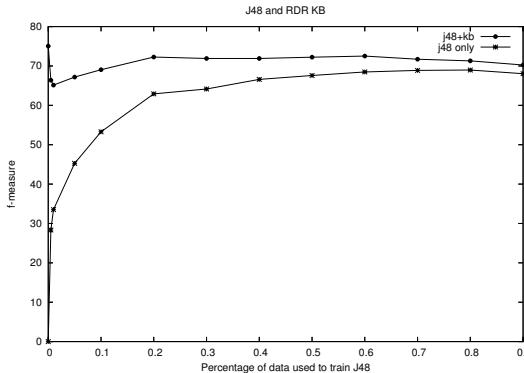

Figure 3. F-measures of J48 and J48 with KB.

the same fashion as in the previous section with different orders of examples. The f-measure of 75.1% suggests that the performance of our approach is independent of the order of examples presented to the experts.

As can be seen from table 2, the f-measures of the KBs with SMO or J48 as the default rule follow the same trend. It first degrades as we start giving some data to the classifier and improves as more data is used to train the classifier. After certain thresholds, the f-measures start degrading again as we get less data for experts to add exception rules while the classifiers do not improve their performance.

Depending on the task and the classifier used, we can choose an appropriate amount of data to train a classifier as the default rule in order to substantially reduce the number of KA sessions involved while still achieve a reasonable performance. For example with J48 the best performance is at 72.5% when we use 60% of the training data for training J48 and the rest to add exceptions rules. This reflects a 4% improvement in f-measure to the raw machine learning classifier. Compared to a fully manual approach (using 0% data for the classifier), we achieve a 60% reduction in the number KA sessions.

As the *oracleKB* is built with the assumption that the default rule always returns *NONE*, all of the exception rules at level 1 (exception rules of the default rule) are rules covering *INCLUDES* instances. Even though rules at level 2 cover *NONE* instances, they have limited scopes because they were created as exceptions to level 1 rules. When the default rule gives an incorrect *INCLUDES* conclusion, it is likely that we would not be able to consult the *oracleKB* for an exception rule to fix this error.⁷ It therefore suggests that if we use real experts, we could achieve a better result.

6 Discussion and Conclusions

We have shown that with our unconventional Knowledge Acquisition approach using KAFTIE, we could quickly build a knowledge base that performs better than the classifiers built by existing machine learning approaches while requiring much less data.

It took 7 minutes on average to create one rule, independent on the current size of the KB. This includes the time needed to read the sentence to understand why there is a certain relation between the pair of an EVENT and a TIMEX3 as well as the time required to test the new rule before committing it to the KB. If the users have to classify the pair's relation from scratch, when we do not have annotated data,

%	j48	j48 +kb	#rules	smo	smo +kb	#rules
0%	0	75.1	173	0	75.1	173
0.5%	28.4	66.4	146	27	68.6	151
1%	33.5	65.2	143	27.3	71.6	158
5%	45.3	67.2	138	54.3	71.9	142
10%	53.3	69	131	61.7	72.4	133
30%	64.2	71.9	103	65.6	72.7	108
50%	67.6	72.2	78	66.6	71.8	84
60%	68.5	72.5	65	67	71.7	70
90%	68	70.3	22	66	68.5	25

Table 2. Results of using j48/SMO as the default rule for KBs averaged over 20 random seeds.

then the actual time spent on creating a rule would be much less, as understanding the sentence takes most of the time.

We further demonstrated how ML algorithms could be used together with our approach to reduce the knowledge acquisition effort. This also results in performance improvement to the ML algorithms.

In future work, we will investigate the application of our framework KAFTIE to tasks in a different language other than English.

Efficient Learning from Massive Spatial-Temporal Data through Selective Support Vector Propagation

Yilian Qin and Zoran Obradovic¹

Abstract. In the proposed approach, learning from large spatial-temporal data streams is addressed using the sequential training of support vector machines (SVM) on a series of smaller spatial data subsets collected over shorter periods. A set of representatives are selected from support vectors corresponding to an SVM trained with data of a limited spatial-temporal coverage. These representatives are merged with newly arrived data also corresponding to a limited space-time segment. A new SVM is learned using both sources. Relying on selected representatives instead of propagating all support vectors to the next iteration allows efficient learning of semi-global SVMs in a non-stationary series consisting of correlated spatial datasets. The proposed method is evaluated on a challenging geoinformatics problem of aerosol retrieval from Terra satellite based Multi-angle Imaging Spectro Radiometer instrument. Regional features were discovered that allowed spatial partitioning of continental US to several semi-global regions. Developed semi-global SVM models were reused for efficient estimation of aerosol optical depth from radiances with a high level of accuracy on data cycles spanning several months. The obtained results provide evidence that SVMs trained as proposed have an extended spatial and temporal range of applicability as compared to SVM models trained on samples collected over shorter periods. In addition, the computational cost of training a semi-global SVM with selective support vector propagation (SSVP) was much lower than when training a global model using spatial observations from the entire period.

1. INTRODUCTION

With recent advances in remote sensing technologies, scientists collect a much larger volume of spatial-temporal observations than previously. For example, since 2000, the Multi-angle Imaging SpectroRadiometer (MISR) instruments onboard Terra satellite of NASA's Earth observing system have been used to observe solar radiation through nine cameras each in four spectral bands with 1.1 km spatial resolution and global coverage of Earth in about 9 days [1]. Such a resolution results in quick accumulation of terabytes of high dimensional spatial-temporal observation data. The objective of learning nonlinear relationships from such non-stationary data can in principle be addressed by artificial neural networks (ANN) and support vector machines (SVM) [2]. While theoretically such prediction models are more

accurate with large training datasets, the computational cost of learning from high volume data prohibits the training and retraining of global models using the entire historical data.

In a recent study [3], a neural network ensemble procedure was developed to learn ANN models from massive datasets. In this project, neural networks of low complexity were learned from small datasets first, and the component networks were incrementally combined into an ensemble while progressively increasing the size of the training dataset. This allowed for a regulation of the computational costs of developing nonlinear regression models from large datasets through an automated identification of an appropriate number of component networks, their complexity and a sample size for training the component.

For learning nonlinear relationships in high dimensional data, SVM are frequently preferred when both stability and high accuracy are required [4]-[6]. However, the training and prediction time of SVM increases with the increased number of support vectors. Therefore, both training and prediction time may be prohibitively long when learning with an SVM for massive spatial-temporal datasets that typically require a large number of support vectors. Approaches considered to address this situation include reducing the size of datasets [7], improving the performance of SVM through incorporating known invariance of the problems [8], approximating the decision surface and reformulation of the training problem that yields the same decision surface using a smaller number of basis functions [9][10], using a proximal SVM [11], and exploiting partial/merge k-mean method with parallel computation [12]. Nevertheless, as long as the time-consuming kernel matrix operations are required, it is prohibitively costly to develop a global SVM for massive spatial-temporal datasets. An efficient method uses SVMs trained locally with a small number of instances [13]. However, such an SVM is only valid locally while in many cases global and semi-global properties that are difficult to capture with local models are of primary interest.

Inspired by previous projects, we propose efficient development of semi-global SVM models valid within extended spatial regions and usable over a longer time span than those of local models. This approach is based on the observation that regional features frequently exist in spatial-temporal datasets over certain areas due to a large number of factors such as vegetation, topology, air pollution, humidity, snow, ice, and cloud coverage. Such factors are also strongly time dependent, and consequently induce semi-stationary temporal features within certain time intervals. Therefore, sub-models developed from regional datasets might remain

¹ Temple University, USA, email: zoran@ist.temple.edu

accurate for a reasonably long time or over a large area, and so can be frequently reused for reduced computational cost. The proposed method for training and reusing the semi-global SVM models will be discussed first followed by a summary of the experimental evaluations and discussion.

2. METHODOLOGY

In the simplest case where the patterns are linearly separable, an SVM looks for a separation plane which maximizes the margin. For linearly non-separable patterns, the attributes are nonlinearly mapped to a higher dimensional space such that the patterns in the new feature space are linearly separable [6]. An SVM is represented by a kernel matrix, or equivalently a set of support vectors and parameters specifying the kernel functions. A kernel matrix in a quadratic size of the number of support vectors is involved in the SVM training processes.

The support vectors of an SVM are the most important instances in the datasets from which the SVM is trained. Therefore, merging the support vectors of an SVM trained using dataset one with raw examples of another dataset results in a merged dataset which to some extent carries the properties of both datasets. The number of instances in the merged dataset would be much smaller than the total number of instances in the combined raw datasets. This observation, the starting point in this project, is aimed at the construction of semi-global training datasets of limited size for efficient learning of a series of SVMs on large spatial-temporal data series.

In spatial-temporal situations, data properties often remain semi-stationary over certain space and time intervals. Therefore, SVMs trained from neighboring local spatial datasets in a time series might frequently be similar. In such cases, merging the support vectors of a previous SVM to the adjacent raw data might be sufficient to learn a new SVM that preserves statistical properties of both regions. Based on this idea, a coarse-grained pseudo code of the proposed algorithm for learning SVMs with selective support vector propagation (SSVP) is presented below:

1. S is initialized to an empty support vector set
2. For each spatial dataset D_i , $i=1,2,\dots$, in a series
3. $D = \text{Union of } S \text{ and } D_i$
4. Train a support vector machine M_i with D
5. $S' = \text{support vector set of } M_i$
6. $S'' = \text{set of instances in } S' \text{ misclassified by } M_i$
7. $S = \text{set of instances in } S' \text{ but not in } S''$
8. End For

While the number of support vectors in each individual dataset D_i can be small, propagating all support vectors for merging with new data is likely to enlarge the merged data in time because of the inclusion of outliers that are considered support vectors. With a support vector selection method described in lines 5, 6, and 7 in the above pseudo code, the number of support vectors propagated to the next stage will be reduced significantly. More specifically, in each iteration of the training process, all the misclassified support vectors of

the resulting SVM are excluded from the support vector set to be propagated to the next training step. The effectiveness of this method will be demonstrated and discussed in the experimental results section below.

3. DATA DESCRIPTION

3.1 Synthetic Data

A series of simple synthetic datasets were generated with four cluster centers, namely $(0, 1)$, $(1, 0)$, $(0, -1)$, and $(-1, 0)$ on the 2-D plane. For each dataset, the first two clusters are labeled as positive and the other two are negative. Using different noise levels, we generated a low noise and a high noise dataset. For the low noise dataset, a randomly generated noise of normal distribution with a standard deviation of 0.1 was added to the dataset. Each dataset in the low noise series contained 100 instances with 25 instances drawn from each of four clusters. While the properties of the series, such as the location of cluster centers and the standard deviations, did not vary with time, the dataset may still be considered a spatial-temporal one in that the noise is injected in time. For the high noise dataset, the same configuration of the datasets was adopted with a standard deviation of 0.3 in noise level. A series of 500 datasets were generated for low noise and high noise cases respectively.

3.2 MISR Data

The spatial-temporal data are obtained from the MISR instrument aboard the Terra satellite of NASA's Earth observation system. MISR views Earth with nine cameras pointed at different viewing angles, each with four spectral bands. Terra orbits the Earth about 15 times per day and completes a data cycle in 16 days. For each 16-day cycle, there are 233 distinct MISR paths (orbits) [<http://eosweb.larc.nasa.gov/MISRBR>]. We analyzed four such cycles covering the entire continental U.S. from 07/17/2002 to 01/08/2003 where each cycle consisted of data over 47 paths.

The MISR Level 1B2 radiance and Level 2 aerosol optical depth (AOD) data were used for SVM model learning. We extracted 36 radiances and supplemented these with additional 82 geometric parameters resulting in 118 dimensional patterns. The learning target was the green band regional mean AOD, which was converted to binary classes of low (thin) vs. high (thick) aerosol situations as compared to the mean AOD (0.18) for the entire datasets. So, the problem of aerosol estimation from radiances was reduced to a classification problem of identifying low vs. high aerosol situations given two classes of about the same size.

The observations under cloudy conditions were removed since the existence of cloud would significantly affect the correctness of the AOD retrieval. Cases with low-quality radiance (radiometric data quality index less than 2) and with missing AOD were also removed. Therefore, the number of remaining instances used in our experiments is space and time dependent. The total number of instances in the constructed dataset of each cycle is shown in Table 3.1.

Table 3.1. Cloud-free MISR radiance and aerosol data over entire continental US (period and number of instances).

Cycle	Start Time	End Time	# of Instances
1	07/17/2002	08/01/2002	76449
2	08/01/2002	08/17/2002	65620
3	08/18/2002	09/02/2002	51869
4	12/24/2002	01/08/2003	30451

4. RESULTS AND DISCUSSION

The method of combining and reusing the SVM proposed in Section 2 was applied to both synthetic and MISR dataset series described in Section 3. A linear classifier was used for experiments on synthetic datasets and RBF classifier with unity cost of constraint violation and width parameter for experiments with MISR datasets.

4.1 Results from Synthetic Data

The first objective was to explore the rate at which the number of support vectors might accumulate in time if all vectors were propagated to the next stages. For this experiment, the proposed method for merging relevant support vector representatives with new arriving data was applied without the proposed vector selection step by setting “S” to be an empty set in line 6 of the algorithm in Section 2. The algorithm was applied to 50,000 data points partitioned into a series of 500 spatial datasets each consisting of 100 instances. The experiment was performed for low as well as for high noise synthetic data described in Section 3.1.

For a low noise situation, very few support vectors were propagated for merging with the newly arriving data independent of time. At the final 500-th time step, 10 support vectors were propagated for merging with 100 newly arrived data points and the resulting SVM was almost 100% accurate. In contrast, for high noise data, the number of propagated support vectors increased in time and soon became excessively large. In particular, unless pruned properly, about 2,200 support vectors were collected throughout the SSVP process of the initial 499 stages and they dominated over the newly arriving 100 data points. The number of the support vectors propagated at each of the 500 stages for merging with the next dataset is plotted at the top panel of Fig. 4.1. The linear trend of support vectors accumulation in this experiment was due to outliers identified as support vectors.

The selection step proposed for pruning support vectors (lines 5-7 of the algorithm described at Section 2) resolved this problem as shown at the bottom panel of Fig. 4.1. The simple selection method eliminated propagation of outliers as they were produced such that the number of propagated support vectors was much smaller (less than 140 throughout the entire process) as necessary for efficient applications in large spatial-temporal data series. While the accuracies of the final SVM obtained with and without support vector pruning on the entire dataset were similar (98.3% and 98.2%, respectively) the training and prediction with the pruning step was much faster than that without pruning.

At the bottom panel of Fig. 4.1, the slope of the curve corresponding to the number of propagated support vectors as a function of the time step is typically larger when the number of support vectors is smaller. This is expected since the position of the separation plane of an SVM is affected by the fraction of support vectors propagated from previous SVMs. The “inertia” of the separation plane, or the influence of previous datasets, increases with the fraction of propagated support vectors. On the other hand, the probability that a support vector from an earlier dataset is removed increases monotonically with time, such that the effect of a previous dataset becomes less important in the training process with the addition of new datasets. Therefore, the time interval, in which an SVM can be validly trained with the SSVP method, is determined by the competition of these two effects.

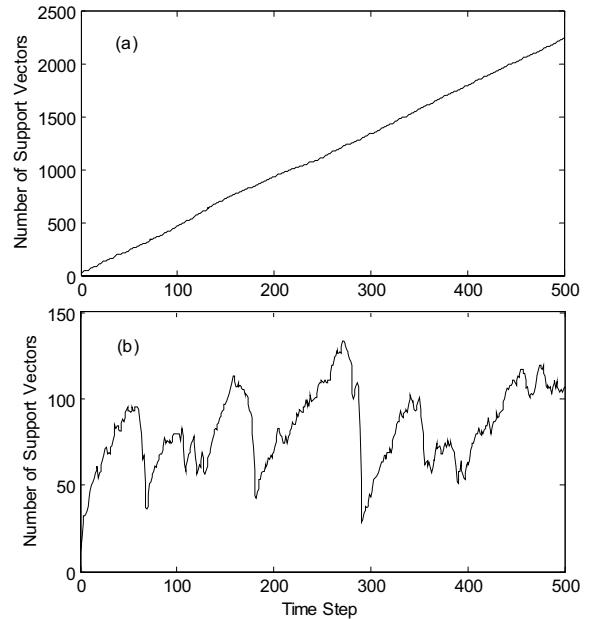

Figure 4.1. Effect of SSVP on the size of the combined datasets for high noise synthetic data. Without pruning the number of propagated support vectors in each of 500 time steps monotonically increased (top panel) while it stays small when the proposed selection step is used (bottom panel).

4.2 Results from MISR Data

The proposed method with SSVP was then applied to the MISR AOD retrieval described in Section 3. In this challenging test data properties vary both spatially and temporally with highly complex regional and temporal features. To isolate the effect of regional features of the dataset on the training of SVMs, the first set of experiments was carried out using cycle 1 aerosol data over continental U.S. (Table 3.1).

First, 47 SVMs were trained using 47 individual paths without SSVP. Each SVM was applied to predict out-of-sample AOD at all 47 paths of cycle 1. It was evident that the SVMs trained on the Eastern region (paths 4 to 27) were not applicable to Western region (paths 28 to 50) and vice versa, whereas SVMs trained on a single path on one coast were

somewhat applicable for out-of-path prediction over the same region. In particular, the average accuracy for 24 SVMs trained on a single eastern path when tested on out-of-sample data over the entire eastern region was 66%. Similarly, a single western-path-based SVM achieved 67% out-of-sample average accuracy on 23 region paths.

Next, the proposed method was applied to cycle 1 data by learning SVMs on training data corresponding to individual paths supplemented with SSVP from previously learned SVMs. In this experiment the training started from the western most path (number 50 which is California data) and proceeded east (to finish at path number 4 which is East Coast U.S. data). Again, 24 East Coast predictors were tested for out-of-sample accuracy on the entire eastern region while each of 23 West Coast predictors was tested on the entire western region. The average out-of-sample accuracy of the SVMs with SSVP on the eastern and western regions was 77% and 72% respectively, which is significantly higher than the accuracy obtained without SSVP.

The result of the first two sets of experiments provide evidence that SSVP is also beneficial for improving the prediction accuracy when data is high dimensional and the spatial relationship is complex. The next set of experiments on the MISR dataset was designed to explore the applicability of the proposed methods for modeling temporal variation in the properties of spatial-temporal datasets. For prediction on all cycles, we first applied the final predictor of the previous experiment obtained by learning local SVMs starting from the western most path (50) and moving east with SSVP. The accuracy of this predictor on all paths at all cycles is summarized at the top panel of Fig. 4.2.

As already observed, cycle 1 accuracy of this predictor was much better on the eastern region corresponding to path numbers lower than 28 (accuracy 73% vs. only 38% at west). The same predictor also had good accuracy on the eastern region when predicting at cycle 2 and 3 data (71% and 64%). The prediction accuracy on cycle 4 was consistently much worse (40%) since this data corresponds to a completely different season as compared to training period (cycle 1). The identified temporal semi-stationary property of the MISR datasets provides opportunities for developing semi-global SVM models for periods covering multiple time cycles without discarding older observations of the same region.

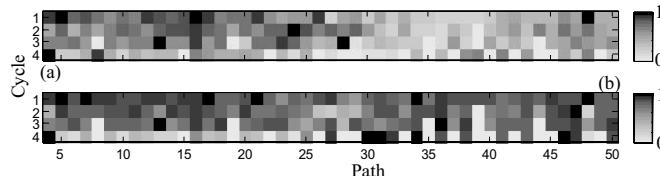

Figure 4.2. Out-of-sample classification accuracy (darker is more accurate) on Cycles 1-4 when trained on Cycle 1 data. Application of a single SVM obtained with SSVP (top panel) is compared to using 47 path-specific SVMs also constructed with SSVP (bottom panel).

Dependence of temporal semi-stationary behavior on the regional features is further examined in the experiments summarized at the bottom panel of Fig. 4.2. Here, an SVM trained on path k data of cycle 1 with SSVP from path $k+1$ at cycle 1 is used for out-of-sample classification at path k in all

four cycles. So, instead of applying a single predictor for out-of-sample prediction, 47 path-specific predictors were trained with SSVP. The resulting accuracy was much improved as can be seen by comparing top and bottom panels of Fig. 4.2. In particular, for East Cost data (paths 4-27) average accuracy in cycle 1 and 3 is improved from 73%, 71% and 64% to 85%, 73% and 75%. In addition, West Coast (paths 28-50) accuracy was 80%, 71%, 71% and 82% for cycle 1-4, respectively. Therefore, model reuse in the MISR datasets was possible both spatially and temporally.

The performed experiments suggest that the SVMs trained with SSVP should only be extended to a spatial and temporal vicinity of the training datasets and not to extremely remote spatial regions or time periods. As a result, we developed a scheme for constructing a sequence of semi-global SVMs applicable for accurate prediction to moderately large spatial and temporal regions in an efficient way (such that the number of SVMs to cover the entire dataset is minimized).

By analyzing in more details cycle 1 classification accuracy of the predictor summarized at the top panel of Fig. 4.2, it can be seen that it was highly accurate in an East Coast region covering about 10 paths followed by deteriorated accuracy as it was applied west (see Fig. 4.3). Accuracy of the global SVM trained on cycle 1 and semi-global SVMs with SSVP over shorter regions was compared next. The results over 4 cycles and propagation over 47, 24, 16, 8 and 4 paths are reported in Fig. 4.4 (propagation over 47 paths at cycle 1 corresponds to Fig. 4.3 results). The overall highest accuracy, which was even slightly better than that of the global SVM, was achieved by SSVP over blocks of 8 neighboring paths. In these experiments, SVMs trained with SSVP after every 8 paths are applied for out-of-sample prediction at the corresponding 8 adjacent paths. Consequently, only six semi-global SVMs were required to cover each data cycle.

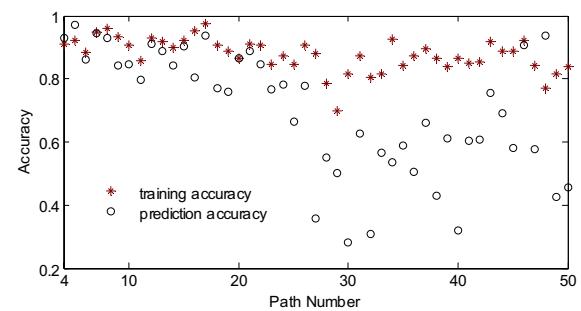

Figure 4.3. Path-specific training vs. prediction accuracy of the SVM trained with SSVP on Cycle 1. SSVP was from West to East (paths 50 to 4).

Finally, the computational efficiency of SVM training and prediction in a sequence of paths of MISR datasets with SSVP was compared to that of training a single SVM on the corresponding data. Time comparison experiments were performed on Cycle 1 data with the least number of missing values and the most balanced number of instances per path (see Table 3.1). A fixed number of 1500 instances were randomly sampled with replacement from each path (i.e. each instance may be included more than once). Both the training and the prediction CPU time was insensitive to the length of the data stream when learning in a series of local steps with

SSVP as proposed here. In contrast, for training a regular global model with merged data, the training time was a quadratic function of the number of paths N , and the prediction time increased linearly with N due to the increased size of training data (see Fig. 4.5).

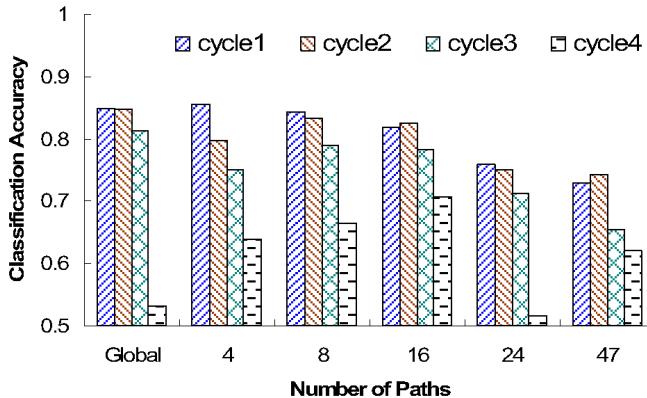

Figure 4.4. Classification accuracy on cycles 1 to 4 with global and semi-global SVMs trained on cycle 1 with SSVP over blocks of 4, 8, 16, 24 and 47 paths. Global SVM was trained with 70% instances of cycle 1.

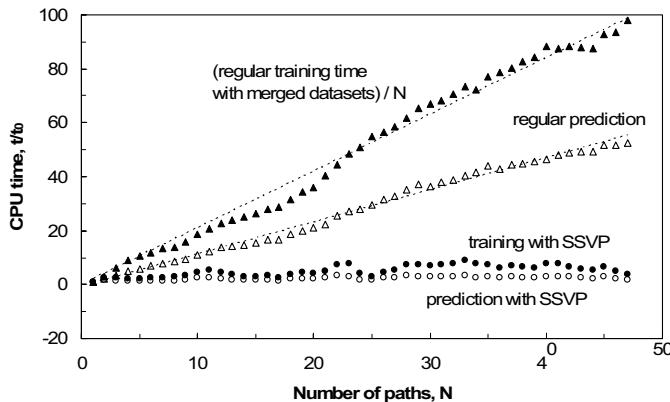

Figure 4.5. Comparison of normalized training and prediction CPU time, as a function of the number of paths N covered in training, for SVMs trained with SSVP vs. regular SVM trained using merged raw data from all paths. Training was from west to east (path 50 to 4) using the data of Cycle 1, and prediction was for each individual path only. CPU time for regular training with merged data is presented normalized by the number of paths as to show a quadratic growing curve together with a linear growing CPU time curve of regular prediction and near-constant curves obtained when training and testing with SSVP.

5. CONCLUSIONS

The proposed method of sequential SVM training with SSVP was developed for supervised learning in a non-stationary series consisting of correlated spatial datasets. The objective was to obtain accurate semi-global prediction models with low computation cost. A simple support vector selection method was applied at each propagation step to prevent monotonic growth of the number of propagated support vectors over long sequences. The validity of the proposed method was demonstrated on simple synthetic and

challenging geoinformatics spatial-temporal datasets. It was found that to predict within larger spatial and temporal neighborhoods, the SVM trained on a sequence of local spatially correlated datasets with SSVP from a neighboring region can be superior to reusing local models trained with individual datasets.

Regional features discovered using the proposed approach allowed spatial partitioning of MISR aerosol data over the continental U.S. to western and eastern regions that provided more accurate prediction results. Furthermore, regional features were also found to be semi-stationary in time, such that the regional models trained on previous datasets were reusable for accurate regional predictions at future times. The proposed model reuse method was also demonstrated as a cost-effective alternative to merging raw data when learning SVMs from large spatial-temporal data streams.

Automatic term categorization by extracting knowledge from the Web

Leonardo Rigutini, Ernesto Di Iorio, Marco Ernandes, Marco Maggini¹

Abstract. This paper addresses the problem of categorizing terms or lexical entities into a predefined set of semantic domains exploiting the knowledge available on-line in the Web. The proposed system can be effectively used for the automatic expansion of thesauri, limiting the human effort to the preparation of a small training set of tagged entities. The classification of terms is performed by modeling the contexts in which terms from the same class usually appear. The Web is exploited as a significant repository of contexts that are extracted by querying one or more search engines. In particular, it is shown how the required knowledge can be obtained directly from the snippets returned by the search engines without the overhead of document downloads. Since the Web is continuously updated "World Wide", this approach allows us to face the problem of open-domain term categorization handling both the geographical and temporal variability of term semantics. The performances attained by different text classifiers are compared, showing that the accuracy results are very good independently of the specific model, thus validating the idea of using term contexts extracted from search engine snippets. Moreover, the experimental results indicate that only very few training examples are needed to reach the best performance (over 90% for the F1 measure).

1 Introduction

Term categorization is a key task in the Text Mining research area. In fact, the availability of complete and up-to-date lexical knowledge bases is becoming a central issue for automatic text processing applications, especially when dealing with rich and fast changing document collections like the Web. The maintenance of thesauri, gazetteers, and domain-specific lexicons usually requires a large amount of human effort to track changes and new additions of lexical entities. The expansion of domain-specific lexicons consists in adding a set of new and unknown terms to a predefined set of domains. In other words, a lexicon or even a more articulated structure, like an ontology [3], can be populated by associating each unknown lexical entity to one or more specific categories. Thus, the goal of term categorization is to label a lexical entity using a set of semantic themes (i.e. disciplines, domains). Domain-specific lexicons have been used in *word-sense disambiguation* [8], *query-expansion* and *cross-lingual text categorization* [10]. Several proposals to face the problem of the *automatic expansion of ontologies and thesauri* are proposed in the literature [5, 11]. In [2], the *exogenous* and the *endogenous* categorization approaches are proposed for training an automatic term classifier. The exogenous classification of lexical en-

tities is inspired by corpus-based techniques for Word Sense Disambiguation [12]. The idea is that the sense of a term can be inferred by the context in which it appears. On the other side, the endogenous classification relies only on the statistical information embedded within the sequence of characters that constitute the lexical entity itself. In [1], the authors approach this problem as the dual of text categorization. They use a set of unlabeled documents to learn associations between terms and domains and then to represent each term in the space of these documents. However, the use of a predefined collection of documents to extract knowledge can be quite limitative in highly dynamical and rich environments, like the Web, where the lexical entities involved are extremely variable, since different languages, cultures, geographical regions, domains and times of writing may coexist.

In this paper we propose an approach to term categorization that exploits the observation that the Web is a complete knowledge base that is updated continuously and is available on-line through search engines. Many recent attempts to extract the information embedded in Web documents for human-level knowledge handling are reported in the literature, such as [4] in the field of Web-based Question Answering. Nevertheless, as far as we are concerned, none of these systems is oriented to term categorization. Search engines as Google™ answer user queries returning a list of Web links along with a brief excerpt of the documents directly related to the queries. These passages, called *snippets*, represent a condensed and query-relevant version of the document contents and are designed to convey sufficient information to guide the selection of the appropriate results. Thus, snippets can provide a relevant textual context related to the lexical entities used in the query: the words in the snippets can be used to obtain a set of features for representing the query term and this representation can be used to train a classifier. The experimental results show that the information provided by the snippets is effective to attain very good classification performances, thus avoiding the overhead due to the downloads of the referred documents. Interestingly, the choice of appropriate classifier models and feature selection schemes allows us to use only few examples per class in the learning phase. Hence, the Web and, in particular, search engines can be profitably used as sources of textual corpora to automatically generate domain-specific and language-independent thesauri. This approach is general and admits any granularity in the classification. In addition, the self-updating nature of the Web can help to face the problem of thesaurus maintenance in fast evolving environments.

The paper is structured as follows. In the next section the architecture of the system is described in detail, explaining the different models used in the experiments. Section 3 reports the configuration and the results of the experiments that were aimed at assessing the system performance and at comparing the possible design choices.

Finally, in section 4 the conclusions and the directions for future research are presented.

2 System description

The system for term categorization is composed of two main modules as sketched in Figure 1. The *training module* is used to train the classifier from a set of labeled examples, whereas the *entity classification module* is applied to predict the appropriate category for a given input entity. Both modules exploit the Web to obtain an enriched rep-

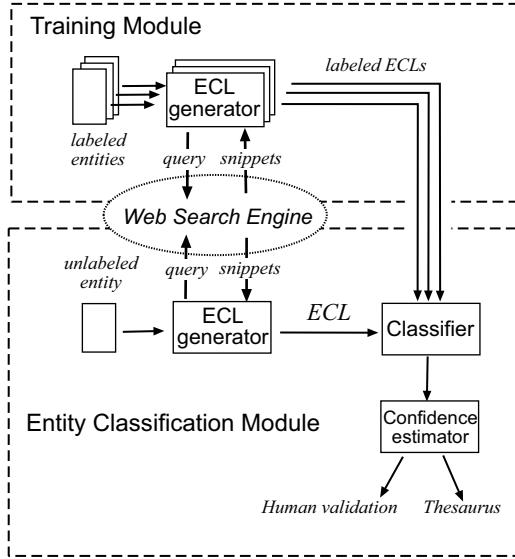

Figure 1. Block diagram of the term categorization system.

resentation of each entity. Basically the entities are transformed into queries and then the snippets obtained by one or more search engines are analyzed to build the *Entity Context Lexicon* ECL_e of each entity e :

$$e \xrightarrow{\text{Search Engine}} ECL_e.$$

In the training step, a set of labeled entities is used to train an automatic classifier to assign an ECL to one category out of a pre-defined set of classes $C = C_1, C_2, \dots, C_k$. For each labeled entity e_l , its ECL_l is computed and provided to the classifier as a training example.

To classify an unknown entity e_u , the corresponding ECL_u is obtained by querying the selected Web search engines. Then, the classifier is used to assign the resulting ECL_u to one class of the category set C . The confidence of the classifier output is evaluated to decide if the category assignment is reliable or if a human judgment is required. In the latter case, the human feedback can be used to expand the training set.

2.1 The ECL generator

This module builds the *Entity Context Lexicon* for a given entity e by analyzing the set of snippets $SN_e = \{snip_1(e), \dots, snip_s(e)\}$ obtained by issuing a query Q_e to one or more search engines. In the current implementation Q_e contains only the terms that compose the entity (e.g. Q_e is the string “New York”). Query expansion techniques will be evaluated in the future developments of the system.

The number S of snippets is a system parameter and allows us to include a different number of independent sources of entity contexts. Usually we would like to keep S as small as possible in order to include only the top-ranked results, assuming that the ranking algorithm exploited by the search engines is reliable enough to provide the most relevant and significant results in the top positions of the ranking list. By exploiting more search engines we can enforce this property since the S snippets can be obtained by exploring only the very top-ranked results. However, this advantage is achieved at the cost of a more complicated preprocessing to eliminate duplicate results. Hence, in the current implementation of the system we decided to exploit only one search engine (i.e. Google).

The ECL_e of a given entity e is simply the set of the context terms extracted from the snippets SN_e . For each word $w_k \in ECL_e$, the following statistics are stored:

- the *word count* $wc_{k,e} = \#\{w_k \in SN_e\}$;
- the *snippet count* $sc_{k,e}$ is the number of snippets in SN_e containing the word w_k , i.e. $sc_{k,e} = \#\{snip(e) \in SN_e | w_k \in snip(e)\}$.

In order to avoid the inclusion of insignificant terms, we can filter the set of the selected terms by means of a *stop-words* list. This list must be properly constructed in order to consider all the languages that are managed by the system.

2.2 The classifier module

In the system each entity e is characterized by the corresponding set of context terms, ECL_e . Hence, the term categorization task can be viewed as a text classification problem where a feature vector is associated with the ECL_e to be classified. Different term weighting schemes and classifier models can be exploited in this module. In this work, several models commonly used in text classification tasks have been tested: *Support Vector Machine (SVM)*, *Naive Bayes (NB)* and *Complement Naive Bayes (CNB)*. Moreover, we propose a prototype-based model particularly suited for this task called *Class-Context-Lexicon (CCL) classifier*, which performs the classification of each entity by evaluating the similarity between the entity and the prototype lexicons.

Support Vector Machine (SVM). The *SVM* model [6] assumes to use a mapping function Φ that transforms the input vectors into points of a new space, usually characterized by a higher number of dimensions than the original one. In this new space, the learning algorithm estimates the optimal hyperplane that separates the positive from the negative training examples for each class. The model does not require an explicit definition of the mapping function Φ , but exploits a *kernel function* $K(x_1, x_2)$ that computes the scalar product of the images of the points x_1 and x_2 , i.e. $K(x_1, x_2) = \langle \Phi(x_1), \Phi(x_2) \rangle$. The choice of an appropriate kernel function is the basic design issue of the *SVM* model. The training algorithm selects a subset of the training examples, the *support vectors*, which define the separation hyperplane with the maximum margin between the class and its complement.

A different *SVM* is trained for each class C_j using the ECL_e of the entities labeled with class C_j as positive examples and a subset of the other training entities as negative examples. Each ECL_e is mapped to a feature vector by adopting a specific term weighting function as described in the following. When an entity ECL_u has to be categorized, each model returns the distance between ECL_u

and its separation hyperplane. This value ranges in $[-1, 1]$ and can be considered as the similarity score between ECL_u and the class represented by the model.

Naive Bayes. The Naive Bayes classifier estimates the posterior probability of a category given the ECL . Using the Bayes rule, this value can be evaluated by estimating the likelihood of the ECL given the class:

$$P(C_j|ECL_i) = \frac{P(ECL_i|C_j)P(C_j)}{P(ECL_i)}.$$

$P(ECL_i)$ is a normalization factor constant for all categories and it can be ignored. Considering the words in the ECL as independent events, the likelihood of an unknown ECL_u can be evaluated as:

$$P(ECL_u|C_j) = \prod_{w_k} P(w_k|C_j)^{\#\{w_k \in ECL_u\}}.$$

In the training phase, each $P(w_k|C_j)$ can be estimated from the frequency of the term w_k in the class C_j .

Complement Naive Bayes. This classifier [9] estimates the posterior probability as $P(C_j|ECL_i) = 1 - P(\overline{C_j}|ECL_i)$, where \overline{C} indicates the complement of C . In this way, the probability $P(\overline{C_j}|ECL_i)$ can be easily estimated similarly as in the Naive Bayes model:

$$P(\overline{C_j}|ECL_i) = \frac{P(ECL_i|\overline{C_j})P(\overline{C_j})}{P(ECL_i)}.$$

Each $P(w_k|\overline{C_j})$ is approximated by the frequency of the term w_k in the complement class $\overline{C_j}$. This approach is particularly suited when only few labeled examples are available for each category C_j .

CCL classifier. Following the idea that similar entities appear in similar contexts, we exploited a new type of profile-based classifier. An independent classifier is trained to model each class. The profile of a given class is obtained by merging the $ECLs$ of the training entities associated with that class. Each term in the profile is associated with a weight evaluated using a given weighting function W . The profile represents the lexicon generated by all the training entities for the j^{th} class C_j and we indicate it as *Class Context Lexicon* (CCL). The CCL is simply the set of the context terms extracted from the $ECLs$ associated with the entities labeled with the corresponding class. Similarly to the case of the $ECLs$, for each word $w_k \in CCL_j$ the following statistics are stored:

- the *word count* $w_{c_{k,j}}$ counts the occurrences of w_k in the class C_j , i.e. $w_{c_{k,j}} = \#\{w_k \in CCL_j\}$. It is the sum of the $w_{c_{k,e}}$ of the $ECLs$ used to build the CCL ;
- the *snippet count* $s_{c_{k,j}}$ is the number of snippets in class C_j containing the word w_k , i.e. $s_{c_{k,j}} = \#\{snip \in CCL_j | w_k \in snip\}$. It is the sum of the $s_{c_{k,e}}$ of the $ECLs$ used to build the CCL .

When an unlabeled ECL_u is to be classified, each classifier returns a score indicating the membership degree of the ECL_u with respect to the corresponding class. First, the weights of the terms in ECL_u are evaluated using the weighting function W and then the similarity between ECL_u and each CCL_j is computed using a given similarity function.

The CCL model (as also the *SVM* classifier) exploits a function $WECL[w]$ that assigns a weight to each component w of an ECL

(or CCL). In the experiments, we tested the most commonly used weighting schemes: *binary*, *term frequency* (tf) and *term frequency-inverse document frequency* ($tfidf$). Moreover, we defined another weighting function, called *snippet frequency-inverse class frequency* ($sficf$), which combines the frequency in the snippets of each term with its distribution in each class. Being L a lexicon (ECL or CCL), $sc_{k,L}$ the snippet count of the term w_k in L and sCL the total number of snippets associated with L , the weighting function is defined as:

$$sficf(w_k, L) = \left(\frac{sc_{w,L}}{sCL} \right) \cdot \frac{1}{\#\{C | w_k \in C\}}.$$

When evaluating weights of an ECL , $sc_{w,L} = sc_{w,ECL}$ whereas in weighting terms of a CCL , $sc_{w,L} = sc_{w,CCL}$. As reported in section 3, this weighting scheme yields better performances especially when used with the CCL classifier.

Finally, the CCL classifier requires the definition of a similarity function. This function is used to compare an ECL with a CCL and yields high values when the two sets are considered similar. The most commonly used functions in automatic text processing applications are the *Euclidean similarity* and *Cosine similarity*. We also introduced a new similarity function called *Gravity*. These functions are defined as follows.

- *Euclidean similarity function.* It derives from the Euclidean distance function for vectorial spaces.

$$E(ECL_e, CCL_j) = \frac{1}{\|ECL_e - CCL_j\|}.$$

- *Cosine similarity function.* It measures the cosine of the angle formed by the two vectors.

$$C(ECL_e, CCL_j) = \frac{\langle ECL_e, CCL_j \rangle}{\|ECL_e\| \cdot \|CCL_j\|}.$$

- *Gravity similarity function.* It combines the Euclidean function, which is sensitive to the terms not shared by the two vectors, and the cosine correlation, which mainly depends on the shared terms. This function performs better when the number of terms is small (i.e. when the training set used to build the $CCLs$ contains few entities).

$$G(ECL_e, CCL_j) = \frac{\langle ECL_e, CCL_j \rangle}{\|ECL_e - CCL_j\|^2}.$$

In the previous expressions, the euclidean distance and the cosine values are computed as

$$\|ECL_e - CCL_j\| = \sqrt{\sum_w (W_{ECL_e}[w] - W_{CCL_j}[w])^2}$$

and

$$\langle ECL_e, CCL_j \rangle = \sum_w W_{ECL_e}[w] \cdot W_{CCL_j}[w],$$

where $W_{ECL_e}[w]$ and $W_{CCL_j}[w]$ are the weights of the term w in ECL_e and CCL_j , respectively.

The CCL classifier, being a prototype-based model, guarantees the modularity of the classifier when adding new categories in the domain set. In fact, each class is modeled by a CCL that is built independently of the examples in the other classes. When a new category is added, it is simply required to learn the CCL of the new class without modifying the previously computed $CCLs$. Also the Naive Bayes classifier guarantees this kind of modularity, but the experimental results showed that the CCL classifier is able to attain better performances. All the others models, instead, use negative examples in the learning phase and, therefore, they require a new training step for all the categories when a new domain is added.

3 Experimental results

We selected 8 categories (*soccer*, *music*, *location*, *computer*, *politics*, *food*, *philosophy*, *medicine*) and for each of them we searched for predefined gazetteers on the Web. Then, we randomly sampled these lists of terms in order to collect 200 entities for each class². The *soccer*, *music* and *politics* classes contain many proper names of players, coaches, teams, singers, musicians, bands, politicians, and political parties. The *location* category collects names of cities and countries, while the *computer* category mainly lists brands of computer devices and software. The *food* class contains names of dishes and typical foods, whereas in the *philosophy* category, there are the terms for various philosophical currents and concepts (e.g. casualism, illuminism and existentialism). Finally, in the *medicine* class, there are terms related to pathologies and treatments (e.g. dermatitis).

The dataset was split into two subsets, both composed by 100 randomly sampled entities: a learning collection and a test set. For each experiment we randomly partitioned the learning collection into 5 distinct training sets in order to average the results with a five-fold-validation.

The precision and recall measures were used to evaluate the system performance. Given a class C_j , the corresponding precision and recall values are defined as

$$Pr_j = \frac{TP_j}{TP_j + FP_j} \quad Re_j = \frac{TP_j}{TP_j + FN_j},$$

where TP_j is the number of the examples correctly assigned to C_j (the true positives), FP_j is the number of wrong assignments to C_j (the false positives), and FN_j is the number of examples incorrectly not assigned to C_j (the false negatives). Since the test sets for each class are balanced, we averaged these values over the set of classes (i.e. we report the *Micro Average*). Precision and recall were combined using the classical F_1 value ($F_1 = \frac{2 \cdot Pr \cdot Re}{Pr + Re}$).

We performed a preliminary set of experiments to determine the optimal number S of snippets to be used in the construction of the *ECLs*. We found that there is no significant improvement for $S > 10$, thus we decided to perform the following tests using $S = 10$.

Using the entities in the learning collection we extracted different training sets with an increasing number of entities. We indicate as LS_M the training set containing M entities per category (i.e. a total of $8M$ entities).

The first test aimed at comparing the performances of the *CCL*-based classifier using the different weighting and similarity functions and at evaluating the influence of the size of the training set. Figure 2 reports the plots of the F_1 value for the three best configurations (we decided to report only these cases in order to improve the plot readability). The best performing model is the one that exploits the *Gravity similarity function* and the *sficf* weighting scheme. In fact, the gravity similarity shows a slightly better behavior for small learning sets. Using this configuration for the *CCL* classifier, we obtain about 90% for the F_1 value using just 5–10 examples per class. No evident improvement is achieved by adding more examples, and this result is probably due to the presence of some intrinsically ambiguous entities in the dataset. However, the system performance is very satisfactory and validates the effectiveness of the proposed approach. Table 1 collects the words with the highest score in the profile of each class using the best classifier configuration, *CCL**. It can be noticed that words in different languages (English and Italian) appear in the

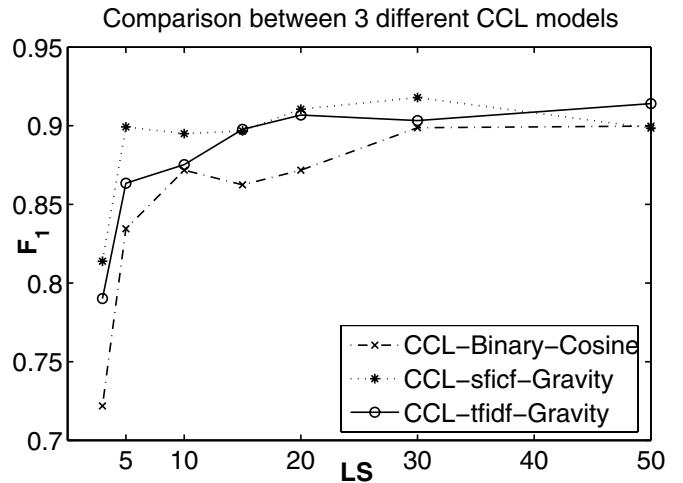

Figure 2. Plot of the F_1 values with respect to the training set size for different weighting and similarity functions in the *CCL* classifier. Each value is the average on 5 different runs exploiting different training sets.

same set, thus showing that the system can naturally adapt its behavior to a multi-lingual context.

Philosophy:	searches, empiricus, definition, outlines, theory, knowledge, philosophical, doctrine

Table 1. The top scored words for each *CCL* in the best performing classifier.

After we individuated the best configuration for the *CCL* classifier, we compared it with the *Naive Bayes*, *Complement Naive Bayes* and *Support Vector Machine*. We used *SVM-light*³ as implementation of the SVM classifier [7] and we exploited the linear kernel that has been shown to be the best performing one in text classification tasks. In the figure 3, we notice that the *CNB* classifier attains the best performances, although they are very similar to those of the *CCL*-based classifier. Moreover, the SVM classifier shows worse performances than the other models. This model, in fact, requires a great number of support vectors to locate the best separation hyperplane. In this application, the size of training sets is quite small thus reducing the effectiveness of this model. In fact, from figure 3 we can notice that the SVM model obtains significant performance improvements when increasing the learning set size.

Globally, the performance saturates when increasing the learning

set size, showing that the system is able to attain good precision and recall values even with a quite limited set of examples. In particular, we individuated $M = 20$ as the best compromise between performance and learning set cardinality, there being no significant increase in the performance for larger sets.

4 Conclusions and future work

In this work we proposed a system for Web based term categorization, oriented to automatic thesaurus construction. The idea is that “terms from a same semantic category” should appear in very similar contexts, i.e. that contain approximately the same words. Based on this assumption, the system builds an *Entity Context Lexicon* (*ECL*) for each entity, which is the vocabulary composed by the words extracted from the first 10 snippets returned by Google submitting e as a query. Each *ECL* can be considered as the representation of the *term* in a feature space and an automatic classifier can be trained to categorize it into one category out of a predefined set of classes. In this work, we compared some popular classification models and we also proposed a new profile-based model that exploits the concept of class lexicon (*Context Class Lexicon*, *CCL*). The new model performs well especially when a small number of training examples is provided and it does not require a global retraining step if a new domain is added to the category set. Even if the Complement Naive Bayes model (*CNB*) yields the best performances, it does not have these two positive features. The experiments proved that with just 20 training examples per class, the system averages with over 90% of the F_1 measure. These results are very promising and we expect a further improvement after a tuning of the system design. Additional tests have been planned considering a multi-label classification of each entity and to verify the robustness of the system in “out of topic” cases, i.e. when the correct category is not present in the taxonomy.

Strategic Foresighted Learning in Competitive Multi-Agent Games

P.J. 't Hoen and S.M. Bohte and J.A. La Poutré¹

Abstract. We describe a generalized Q-learning type algorithm for reinforcement learning in *competitive* multi-agent games. We make the observation that in a competitive setting with adaptive agents an agent's actions will (likely) result in changes in the opponents policies. In addition to accounting for the estimated policies of the opponents, our algorithm also adjusts these future opponent policies by incorporating estimates of how the opponents change their policy as a reaction to ones own actions. We present results showing that agents that learn with this algorithm can successfully achieve high reward in competitive multi-agent games where myopic self-interested behavior conflicts with the long term individual interests of the players. We show that this approach successfully scales for multi-agent games of various sizes, in particular to the social dilemma type problems: from the small iterated Prisoner's Dilemma, to larger settings akin to Harding's Tragedy of the Commons. Thus, our multi-agent reinforcement algorithm is foresighted enough to correctly anticipate future rewards in the important problem class of social dilemmas, without having to resort to negotiation-like protocols or pre-coded strategies.

1 Introduction

More and more opportunities are arising where smart software agents can perform useful tasks for their owners. With these agents representing individual stakeholders, they will naturally strive to act such as to maximize the extracted utility for the stakeholder.

It is well known however that in many cases, greedy, selfish behavior by individual agents may harm the reward gained by a collective of agents as a whole, and importantly, ultimately decrease the payoff of the individual agents. This class of problems is known as 'social dilemmas', with the classic iterated Prisoner's Dilemma [15] being an example in the smallest – two player – setting, and Harding's Tragedy of the Commons [6] embodying the same problem instantiated with many players. In both cases the most valuable immediate action that a selfish agent can take lowers the value extracted by all agents collectively. The selfish agent however reaps a higher immediate reward. When all agents take this immediately most rewarding action, the resulting collective joint action has an individual payoff that is (much) worse for each individual agent than some other joint actions. Thus, in repeated play of these games, myopic selfish behavior leads for all individuals to (very) poor outcomes. The challenge is to design adaptive algorithms for individual agents that are smart and foresighted enough to allow them to quickly learn how to extract the most individual utility in repeated play of these deceptive competitive multi-agent games.

Recent work in Multi-Agent Reinforcement Learning (MARL) has proposed a number of extensions from the single agent setting to

the competitive multi-agent domain (see [3, 10, 13] for an overview). State-of-the-art MARL algorithms improve on single-agent RL approaches by incorporating models of the current opponent agents' behavior. This allows an agent to model the current "environment" including opponents, against which it has to optimize its own behavior by playing a best-response. Unfortunately, this approach encourages detrimental outcomes for social-dilemma type games.

We observe that an important aspect of competitive multi-agent games is largely ignored in MARL algorithms: the policy that maximizes payoff will typically depend on the *changing* actions of adversaries. Importantly, the adaptations of adversaries are likely to be reactions to *ones own* actions. Strategic reasoning about the expected adaptations of the adversaries can be paramount when an agent is repeatedly interacting with the same opponents, and earlier actions influence the future behavior of these adapting adversaries. As noted above, ignoring the consequences of ones actions on the development of the opponent policies can lead to detrimental outcomes, especially for settings with a social dilemma at its core.

In general, social dilemmas can be modeled by the generalized n-player iterated Prisoner's Dilemma, or nIPD [15]. In the nIPD game, every agent has a unilateral incentive to defect. However, if all agents follow this policy, then the individual reward received is lower than if all agents cooperated.

The two-player Prisoner's Dilemma (iPD) is illustrative in that in repeated play the optimal policy differs from playing the myopic best response, and it can be profitable to have a good estimation of the opponents' reactions to ones own play. In a single game, two competing agents can each choose from actions 'Cooperate' or 'Defect' (C or D), and the maximum *joint* payoff is achieved when both agents choose to Cooperate. However, an individual agent obtains a larger payoff by playing Defect, provided that the other agent plays Cooperate. From a game-theoretic perspective, playing $\{D, D\}$, the joint action with the lowest joint and individual payoff, is the dominant strategy and a Nash-Equilibrium in the single shot game.

In iterated play of the Prisoner's Dilemma game, there is no longer a clear dominant strategy, as both agents can achieve a higher aggregated and individual reward by cooperating and playing the joint action $\{C, C\}$, provided each agent has some strategic incentive to rarely unilaterally defect.

It is important to realize that this strategic incentive in Prisoner's Dilemma type games can consist of the predictable counter-moves of opponents: an intelligent adaptive adversary will react to ones own actions. The question thus becomes: which moves should one play to maximize the individual reward given the *dependent* adaptive behavior of the adversary? How will the opponents react to selfish or cooperative actions and what are good moves to play?

Strategies developed by people like Tit-For-Tat for iPD [1] enforce

¹ CWI, The Netherlands Centre for Mathematics and Computer Science, email: hoen@cwi.nl,sbohte@cwi.nl,hlp@cwi.nl

cooperative play with (smart-enough) adversaries by predictably “punishing” a defecting opponent. Defecting as a strategy is discouraged by the likely *negative future* reaction of the opponent (see also the Folk Theorem discussed in Section 2). For larger and/or less predictable games, such fixed strategies may not exist (or may be hard to determine). It may however still be beneficial for an agent to reason about the impact of its actions on the aggregated behavior of the other agents, and how this will affect the possible rewards that can be gained in future play.

We argue that current state-of-the-art MARL algorithms (reviewed in for example [13]) do not incorporate a sufficient notion of the longer term impact of their actions on the dynamics of the environment. This environment includes other adaptive agents that react to moves of their opponents as well. For example, current MARL algorithms that play the two-player iPD will universally converge to the worst possible outcome of $\{D, D\}$ when an agent plays against an opponent that uses the same MARL algorithm (self-play) [3].

The one exception we are aware of is the M-Qubed algorithm [3], which successfully learns to play $\{C, C\}$ in self play for the two-player iPD. M-Qubed adaptively switches between playing a best-response strategy and the fixed pre-coded strategy of playing one action consistently. The problem with using such pre-coded strategies is that they can be exploited [14], and in general such an approach can be expected to be unsuitable for more complex multi-agent games.

In fact, we are not aware of any state-of-the-art MARL algorithms that scale well to larger, n-player IPD games. Myopic best-response type strategies become woefully inadequate, and no current MARL algorithm has sufficient foresightedness to detect how its own behavior changes future payoffs due to other agents’ adaptive behavior.

In this paper, we make a number of important contributions: first, we refine the foresighted StrOPM MARL framework developed in [14]. This StrOPM framework builds on multi-agent Q-leaning type ideas and includes the crucial element of estimating ones opponents’ reactions into the forward reward estimations. The StrOPM algorithm in [14] successfully solves two-player two-action matrix games, including the two-player iPD. Here, we generalize the StrOPM framework such that it can be applied to games with more than two players. We develop an instantiation of this refined and generalized framework that is capable of scaling to larger size nIPD games. To deal with nIPD games, we additionally develop a generalized description of aggregate opponent policies, which we use to circumvent the state-space explosion by enabling a description of the nIPD problem in a much reduced, linear state space. We show that this approach successfully scales the StrOPM framework for the nIPD, and our StrOPM algorithm is shown to achieve a high degree of cooperation (and thus reward) even for the 9-player IPD, which was the maximum feasible game-size that ran within reasonable time. We thus argue that our generalization of the StrOPM framework is foresighted enough to correctly anticipate future rewards in the important problem class of social dilemmas, without having to resort to negotiation-like protocols or pre-coded strategies.

This result is of particular importance, as the generalized n-player iterated Prisoners Dilemma (nIPD) is a matrix game of particular interest, as noted [6]. Although the familiar 2-player iPD is a special case of the nIPD, it has been argued , that the nIPD is ‘qualitatively different’ from 2 player iPD, and that ‘... certain strategies that work well for individuals in the [2-player] iPD fail in large groups’ [2, 4, 5]. Even more than the 2-player iPD, the nIPD game is also notoriously hard for existing MARL approaches. Thus, we believe the successful generalization of the StrOPM framework to the nIPD matrix game is an important step forward for MARL algorithms.

2 Agents and Matrix games

We define the assumptions and terminology for multi-agent Reinforcement Learning in iterated play of matrix games. We refer to [2] for some well-known terms from Game Theory (GT) such as a **Nash Equilibrium** (NE), a **dominant** strategy, **pareto optimal** or **deficient** strategies, and **best-response**.

Let S denote the set of states in the game and let A_i denote the set of actions that agent/player i may select in each state $s \in S$. Let $a = (a_1, a_2, \dots, a_n)$, where $a_i \in A_i$ be a joint action for n agents, and let $A = A_1 \times \dots \times A_n$ be the set of possible joint actions.

A **strategy (or policy)** for agent i is a probability distribution $\pi_i(\cdot)$ over its actions set A_i . Let $\pi_i(S)$ denote a strategy over all states $s \in S$ and let $\pi_i(s)$ (or π_i) denote a strategy in a single state s . The generalized strategy is a **mixed strategy**, and lists for each state the probability of selecting each available action. A **joint strategy** played by n agents is denoted by $\pi = (\pi_1, \dots, \pi_n)$. Let a_{-i} and π_{-i} refer to the joint action and strategy of all agents except agent i .

We consider **matrix games**, where the payoff for each agent is defined by a set of matrices $R = \{R_1, \dots, R_n\}$. Let $R(\pi) = (R_1(\pi), \dots, R_n(\pi))$ be a vector of expected payoffs when the joint strategy π is played. Also, let $R_i(\pi_i, \pi_{-i})$ be the expected payoff for agent i when it plays strategy π_i and the other agents play π_{-i} . Let $R_i(\begin{bmatrix} a_i \\ a_{-i} \end{bmatrix})$ be the payoff for agent i playing action a_i while the other agents play action a_{-i} .

A **stage game** is a single iteration of a matrix game, and a **repeated game** is the indefinite repetition of the stage game between the same agents. While matrix games do not have state, agents can encode the previous w joint actions taken by the agents as state information, as for example illustrated in [12].

In this work, we assume that an agent can observe its own payoffs as well as the actions taken by all agents in each stage game, but only after the fact. All agents concurrently choose their actions. Adaptation of the agents’ policy, i.e. learning as a result of observed opponent behavior, only takes effect in the next stage game. Repeated games are modeled as a series of stage games with the same opponent(s). Each agent then aims to maximize its reward from iterated play of the same matrix game.

2.1 The n-player iterated Prisoner’s Dilemma

In the nIPD game, each player has a choice of two operations: either **cooperate** (C) with the other player or **defect** (D). A matrix game can be classified as a nIPD game if it has the following three properties: 1) Each player can choose between playing cooperation (C) and defection (D); 2) The D option is dominant for each player, i.e. each has a better payoff choosing D than C no matter how many of the other players choose C ; 3) The dominant D strategies intersect in a deficient equilibrium. In particular, the outcome if all players choose their non-dominant C -strategies is preferable from every player’s point of view to the one in which everyone chooses D , but no one is motivated to deviate unilaterally from D . The natural outcome of agents playing myopic Best-Response in nIPD is Defection by all agents, which is stable (a NE) but obviously Pareto-deficient.

The nIPD payoff matrix is shown in Table 1; C_i denotes the reward for cooperating with i cooperators and D_i the reward for defecting with i cooperators and $n - i - 1$ other defectors. The following conditions hold for the respective payoffs are [15]: (1) $D_i > C_i$ for $0 \leq i \leq n - 1$; (2) $D_{i+1} > D_i$ and $C_{i+1} > C_i$ for $0 \leq i < n - 1$; (3) $C_i > \frac{(D_i + C_{i-1})}{2}$ for $0 \leq i \leq n - 1$ (the payoff matrix is symmetric for each player).

		Number of cooperators among the other n-1 players				
		0	1	2	...	n - 1
player A	C	C ₀	C ₁	C ₂	...	C _{n-1}
	D	D ₀	D ₁	D ₂	...	D _{n-1}

Table 1. Structured payoffs for the (symmetrical) n-player PD

Most multi-agent learning algorithms to date have focused on an individual agent learning a (myopic) Best Response to the *current* strategies of the other agents. Play between such agents using this approach often converges, and has as a goal to converge, to a one-shot NE. However, a famous result from game theory (the **folk theorem**) suggests that the goal of reaching a one-shot NE may be inappropriate in repeated games.

The folk theorem implies that, in many games, there exists NEs for repeated games, repeated Nash-Equilibria (rNEs), that yield higher individual payoffs to all agents than do one-shot NEs, i.e. the rNE Pareto dominates the NE. Hence, in repeated games, a successful set of agents should learn to play profitable rNEs. However, since many repeated games have an infinite number of rNEs, the folk theorem does little to indicate which one the agents should play. [8] present an algorithm for computing rNEs that satisfies a set of desiderata, but how to learn these strategy online is unknown. Additionally, an agent may have preferences between rNEs and play one above the other, if allowed by its opponents.

3 The StrOPM Framework

Here, we refine the StrOPM framework of [14] and generalize it to apply to games with more than two players. In the StrOPM framework, an agent applies reinforcement learning to a state-based policy as described in Algorithm 1. At each epoch of learning, the agent adapts its policy along the gradient of increasing reward. The gradient of reward is calculated including the expected changing behavior of the opponent, as a reaction of the agent's own actions. The StrOPM algorithm tracks the changes in observed opponent policy, on a state by state basis, over time. It is assumed that these changes in the opponent behavior, at least in part, reflect reaction to actions chosen by the StrOPM algorithm. The policy of the StrOPM is then optimized with expected future reactions taken into account.

We describe the StrOPM algorithm from the perspectives of an agent i and its opponents, agents $-i$, we use this notation with subscripts to indicate policy, states, action, etc ... of the two types of agents. E.g., a_i and a_{-i} are actions of agents i and $-i$ respectively.

States. The set of states that an agent i can visit, S_i , fulfills the unichain assumption [11]: One set of “recurrent” class of states. Starting from any state in the class, the probability of visiting all the states in the class is 1. We introduce a **transition function** $T : S_i \times A_i \times A_{-i} \rightarrow S_i$ to return the next state of agent i upon playing a (joint) action from the current state.

Policies. For a state $s \in S_i$, $\pi_i(s)$ is the state-based policy of agent i , and $\pi_{-i}(s)$ is the estimate of the opponent $-i$ policies when agent i is in state s . The opponent policy is estimated online using Exponential Moving Average (EMA). The estimate of $\pi_{-i}(s)$ after observing action a_{-i} is adjusted according, for action a_i :

$$\pi_{-i,t+1}(s)(a_{-i}) = (1 - \alpha_{EMA1})\pi_{-i,t}(s)(a_{-i}) + \alpha_{EMA1}. \quad (1)$$

After this update, the policy $\pi_{-i,t+1}(s)$ is normalized to retain $\pi_{-i}(s)$ as a probability distribution.

We introduce **policy update actions**. A policy update action $pua_i(s)$ dictates whether the likelihood of an action a_i should be in-

creased for state s . Additionally, we introduce the *null* policy update action $pua_{null}(s)$ to indicate that the policy should not be changed.

Let $\pi_i(s)^{pua_i}$ be the policy achieved by applying the policy update action $pua_i(s)$ to $\pi(s)_i$. The policy $\pi(s)_i$ of agent i given $pua_i(s)$ not equal to the null action is updated according to:

$$\pi_{i,t+1}(s)^{pua_i} = (1 - \alpha_{LEARN})\pi_{i,t}(s)(a_i) + \alpha_{LEARN}, \quad (2)$$

where α_{LEARN} is the learning rate. The probabilities $\pi_i(s)(\cdot)$ for actions $a_j \neq a_i$ are then normalized to retain $\pi_i(s)$ as a probability distribution.

We wish to select policy update action $pua_i(s)^*$ in (2) that maximizes a measure of expected future payoff of the changed policy. Below, we explain how to compute this.

We introduce $\xi(\pi_{-i}(s), a_i)$ to estimate the impact of an agent i playing an action a_i on the development of the policies $\pi_{-i}(s)$ of the opponent. This function predicts the change in policy of the opponents upon playing action a_i ; i.e.

$$\pi_{-i,t+1}(s) = \xi(\pi_{-i,t}(s), a_i). \quad (3)$$

As a first implementation of this function, we take the approach that the changes in the opponent policy are, at least in part, caused by an agent's own actions. Our StrOPM implementation estimates the change in policy as a continuation of the change in policy from estimation of the opponent policy N epochs in the past, i.e. how was the opponent policy at time $t - N$? This is done for each state: for state s reached after playing action joint action $\begin{bmatrix} a_i \\ a_{-i} \end{bmatrix}$ and $T(s', a_i, a_{-i}) = s$ transitions from the current state s' to s , the change in policy for this new state is estimated as a linear extrapolation of the change in the estimated opponent policy:

$$\xi(\pi_{-i,t}(s), a_i) = \frac{\pi_{-i,t}(s) - \pi_{-i,t-N}(s)}{N} + \pi_{-i,t}(s), \quad (4)$$

where we limit ξ to $[0, 1]$. As states can encode a history of play, we judge how an opponent changes its behavior based on our choice of actions.

Thus estimating the change in opponent policies, the question becomes how to compute the value of proposed policy updates. Here, we make use of the unichain assumption that says we only need to consider loops starting from and returning to the current state to compute this value. The algorithm then updates the policy for the possible loops to increase the expected average reward.

From a state s_0 , a single loop $L(s_0)$ is defined as:

$$L(s_0) = s_0, \begin{bmatrix} a_{i,0} \\ a_{-i,0} \end{bmatrix}, s_1, \begin{bmatrix} a_{i,1} \\ a_{-i,1} \end{bmatrix}, s_2, \dots, s_{(n-1)}, \begin{bmatrix} a_{i,(n-1)} \\ a_{-i,(n-1)} \end{bmatrix}, s_0, \quad (5)$$

for a sequence of joint moves for agent i starting in s_0 , going through s_1, s_2, \dots to s_n and ending again in s_0 . Each next state reached is through a joint move; $T(s_j, \begin{bmatrix} a_{i,j} \\ a_{-i,j} \end{bmatrix}) = s_{j+1}$. All intermediate states reached in the loop are unique, and not equal to s_0 . For brevity, we denote the j -th state s_j in the sequence by $L(s_0)^j$, the j -th action pair $\begin{bmatrix} a_{i,j} \\ a_{-i,j} \end{bmatrix}$ by $L(s_0)_j$, and $L(s_0)_{j+}$ and $L(s_0)_{j-}$ the components of the j -th action pair: $a_{i,j}$ and $a_{-i,j}$. The length of the sequence $L(s_0)$, $|L(s_0)|$, is equal to n ; the number of joint actions played before the considered state is reached again.

Let $Bag(s, n) = \{L(s) | |L(s)| \leq n\}$, i.e. $Bag(s, n)$ are all the loops starting in state s with length of at most n . The probability of a particular loop $L(s)$ occurring, denoted by $Pr(L(s))$ is:

$$\begin{aligned} Pr(L(s)) = \prod_{0 \leq j < |L|} Pr(L(s)_{j+1} | \pi_{i,j}(L(s)^j)) \\ \times Pr(L(s)_{j-1} | \pi_{-i,j}(L(s)^j)), \end{aligned} \quad (6)$$

where $L(s)_j$ and $L(s)^j$ are the respective elements in the loop as defined above, $\pi_{i,j}$ and $\pi_{-i,j}$ are the respective policies at time j , evolving according to Equation (3), and $Pr(\cdot)$ denotes the probability of a specific transition along the sequence given the respective policies $\pi(s)$.

The expected reward over the possible loops can then be expressed as the weighted expected value of individual loops:

$$E(Bag(s, n)) = \sum_{L(s) \in Bag(s, n)} Pr(L(s)) \times E(L(s)), \quad (7)$$

where $E(L(s))$ is the expected average reward for each joint action of a loop starting in state s :

$$E(L(s)) = \frac{\sum_{0 \leq j < |L(s)|} V(L(s)_j)}{|L(s)|}, \quad (8)$$

where $V(L(s)_j)$ denotes the estimated value of the j -th joint action in the loop, $L(s)_j$, to agent i .

The values $V_i : A_i \times A_{-i} \rightarrow \mathbb{R}$ learns the value of a joint action to agent i ; $V_i\left(\begin{bmatrix} a_i \\ a_{-i} \end{bmatrix}\right)$ learns $R_i\left(\begin{bmatrix} a_i \\ a_{-i} \end{bmatrix}\right)$. The function V_i is updated using EMA similar to Equation 1.

Strategic Updating. Let the opponent changes in policy be estimated by $\xi(\pi_{-i}(s), a_i)$, we can then compute the policy update with highest expected payoff:

$$pua_i(s)^* = \max_i E(Bag(s, n))_{pua_i(s)}^\xi, \quad (9)$$

where $E(Bag(s, n))_{pua_i(s)}^\xi$ denotes the expected average reward for the possible loops of at most length n , starting in state s , after effecting policy update action $pua_i(s)$ and taking $\xi(\pi_{-i}(s), a_i)$ as the estimated opponent adaptation. Our StrOPM algorithm thus obtained is outlined in Algorithm 1.

4 Experiments

We demonstrate StrOPM for nIPD games of different sizes: from the standard two-player IPD to nIPD games with up to nine players.

For the two-player IPD, the payoff matrix is shown in Figure 1a, inset. We let each agent encode as states the last joint action played; $\{C, C\}$, $\{C, D\}$, $\{D, C\}$, $\{D, D\}$.

This type of state representation, along with the detailed modeling of each individual opponent policy, cannot be scaled indiscriminately for an increasing number of agents (for n players the number of states per joint action scales as 2^{n-1}). We observe however that for nIPD with more than two players, we can reduce the state space representation: even though the opponent payoff contributions C_{-i} and D_{-i} in Table 1 can be different for individual opponents $j \in -i$, their contribution to the reward gradient is summed, and each agent playing this game only experiences this summed gradient.

Thus, we can choose a simpler state representation where we model the behavior of the aggregated opponents. We choose policy update actions using the estimates of the aggregated opponent behavior, and determine the reward gradient through the expected global change in behaviors of the opponents as follows: For each agent, we encode as states the number of other agents that have cooperated in

Algorithm 1 StrOPM

```

1: Initialize  $\pi_i(s)$ ,  $\pi_{-i}(s)$  for all  $s \in S_i$  and  $V$  for all joint actions. Set the initial state.
2: Do in each epoch sequentially for each agent  $i$  in state  $s$ :
3: loop
4:   calculate the highest valued  $pua_i(s)^*$  using  $E(Bag(s, n))_{pua_i(s)}^\xi$  as value for the individual policy update actions.
5:   Update policy  $\pi_i(s)$  using the highest valued policy update  $pua_i(s)^*$  action.
6:   Play action  $a_i \in A_i$  based on the chosen policy update action  $pua_i(s)^*$ . StrOPM plays action  $a_i$  for chosen policy update action  $pua_i(s) = pua(s)^*$  if  $pua^*$  is not the null policy update action. Otherwise choose the action according to  $\pi_i(s)$ .
7:   Receive reward  $R_i([a_i a_{-i}])$  for the joint action determined by agents  $-i$ .
8:   Update the estimate of the reward for the joint action  $V([a_i a_{-i}])$  and the opponent policy  $\pi_{-i}$ .
9:   set the current state to  $T(s, \begin{bmatrix} a_i \\ a_{-i} \end{bmatrix})$ .
10: end loop

```

the last epoch; i.e. for n players there are $n - 1$ states that capture whether 0, 1, to $n - 1$ other agents cooperated in the last epoch. For each state s , separately for action C and D , each agent maintains an estimate of aggregate opponent policy $\pi_{-i}(s)$. The function ξ in Equation (4) then effectively captures the likelihood of either i) staying in the same state, ii) going to a state with more cooperators, or iii) moving to a state with less cooperators as a consequence of playing either action.

The function V learns the payoff Table 1. As for the two agent case, $\pi_i(s)$ encodes for each state the probability of agent i playing C in that state. A learning rate of 0.01 was used for all the EMA equations of Section 3. The StrOPM algorithm looks back $N = 10$ epochs in Equation 4. Additionally, an agent using StrOPM had a $\epsilon = 0.01$ probability of taking an exploration move in each epoch to ensure all states are sufficiently sampled in play.

StrOPM in the 2-player IPD. We present results of the StrOPM algorithm for self-play in the two-player IPD (Figure 1a, solid line), and for more myopic agents in self-play (Figure 1a, dashed line). The myopic agents used a restricted version of StrOPM, MOPM, that was constructed by using StrOPM and setting $\xi(\pi_{-i}, a_i) = \pi_{-i}$ (i.e., the agent assumes that its adversaries do not adapt in response to its own actions). MOPM thus mimics the best-response type strategies most state-of-the-art MARL algorithms employ.

As can be seen in Figure 1a, the StrOPM learner in self-play converges to playing the (optimal) Cooperate-Cooperate ($\{C, C\}$) strategy with reward 0.35 (solid line). The full cooperation equilibrium is reached as the StrOPM learner estimates that unilaterally defecting leads to states where more and more defection is expected. Additionally, the full cooperation state is expected to lead to more cooperation. In contrast, agents using MOPM in self-play quickly “learn” that cooperation is risky and move to full defection (dashed line).

A closer study of the state-based policy of the StrOPM players reveals that the agents in self-play exhibit a learned Tit-For-Tat strat-

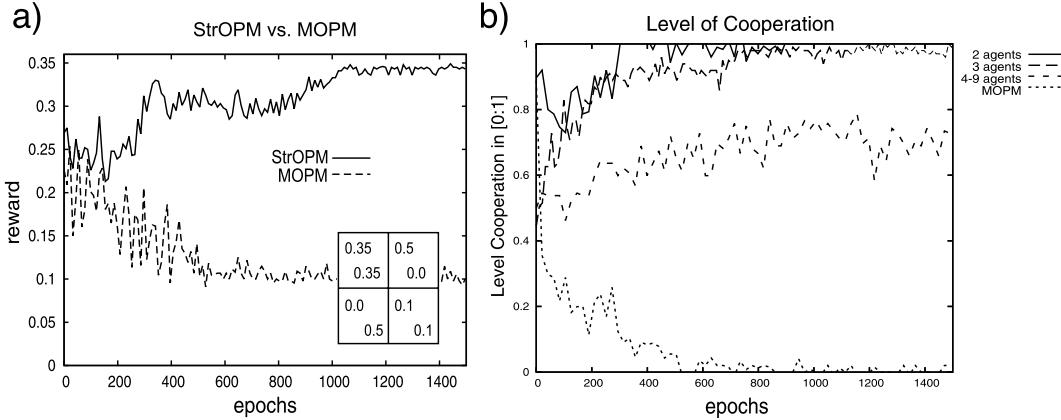

Figure 1. a) Inset: payoff matrix for a two player iPD game. Graph: average payoff for two StrOPM agents and two MOPM agents playing the iPD. b) Cooperation, as % of all agents cooperating, for 3 to 9 players in nIPD using StrOPM.

egy [1]. The Tit-For-Tat algorithm plays C until the opponent defects upon which a D is played followed by again C until the next defection to encourage cooperation. With states encoded as outlined above, the policy is to play C in state $\{C, C\}$, play D from state $\{C, D\}$, and C from $\{D, D\}$. The StrOPM agents learn this strategy and play C to cooperate and reach a good equilibrium, except for occasional exploratory moves. At the same time the StrOPM players also evolve a “threat” state where defection is retaliated in order to guard against exploitation by the opponent. Note that StrOPM also learns to play optimally in less difficult 2-player matrix games, like chicken, rock-paper-scissors, and matching pennies (not shown).

StrOPM playing nIPD. The real challenge for playing strategic games like nIPD, is to successfully learn to cooperate with many players. In Figure 1b, we show results for three and more agents playing the nIPD. The x-axis shows the number of epochs learned, while the y-axis shows the average number of cooperators. For three agents, the StrOPM algorithm learns full cooperation. For four up to nine agents, the nIPD is no longer solved in full. The agents as a collective learn to cooperate approximately 70% of the time. Nine-player IPD was the maximum game-size for which we found it feasible to still compute the loops as defined in Equation 5 for the Bags used in the algorithm.

In Figure 1b, bottom line, we show nIPD results for agents using myopic MOPM described above for three agents, to model agents that do not reflect on the impact of their actions; this short-sighted exploitation of the gradient leads to full defection of the agents. This illustrates that as for the two player iPD, classic MARL algorithms that ignore the impact of ones own actions on other agents will, for each state, increase the probability of playing defect, leading to the well known Tragedy of the Commons: universal defection of all agents.

5 Conclusions

We make a number of contributions in this paper: first, we refine the StrOPM MARL framework developed in [14], and generalize it so that it can be applied to matrix games with more than two players. We show that our implementation of this generalized framework successfully scales to larger size nIPD games. To this end, we develop a generalized description of aggregate opponent policies, which allows us to circumvent the state-space explosion and enables us to describe the nIPD problem in a much reduced, linear state space. We show that using this state-space description, our generalized StrOPM algorithm allows an agent to learn profitable strategies for long term behavior in generalized n-player IPD for games with up to nine players. The

successful scaling of the framework is of particular interest because, as noted earlier, the n-player iterated Prisoners Dilemma is a game that can represent many important and hard real life problems.

One important novel component of this work is the concept of learning the *aggregate* changes in opponents’ policies due to ones own actions. This is an idea that can in fact be incorporated into the quickly growing literature on MARL. One can foresee more and more complex nested opponent models [7] to extract every bit of reward from complex games like nIPD. Although perfectly learning about an opponent while at the same time perfectly learning to adjust oneself is problematic [9], there is still much scope to be “smarter” than your opponents.

MSDA: Wordsense Discrimination Using Context Vectors and Attributes

Abdulrahman Almuhareb¹ and Massimo Poesio^{1,2}

Abstract. We present MSDA (Major Senses Discovery Algorithm) – a development over the context vector approach to (noun) sense discrimination [20, 24] that uses attributes and values instead of word features to cluster contexts, and does not require for the number of senses to be fixed beforehand. The algorithm achieves a precision of 89% on a dataset including both ambiguous and non-ambiguous nouns, twice that of previous algorithms.

1 INTRODUCTION

Arguably, the most difficult part of the task of acquiring lexical and ontological knowledge from text [2, 6–8, 13, 16, 18, 23, 24] is the identification of a word’s senses—i.e. trying to discover that a word such as *palm* can be used to express both the concept “the inner surface of the hand” (WordNet 2 sense 1), henceforth **palm1**, and the concept “any plant of the family Palmae” (WordNet 2 sense 3), henceforth **palm3** [5, 16, 20, 22, 24]. Not the least among the difficulties is the fact that whereas **major sense** distinctions like the one just mentioned can generally be made reliably, other distinctions—e.g. that between **palm1** above and the derived sense of “a linear unit based on the length or width of a human hand” (WordNet 2 sense 2) are more difficult [12].

Our own work on the acquisition of lexical knowledge has been motivated by the consideration that knowing about concept **attributes**³—e.g. knowing that **ships** have **captains**—is an essential aspect of the rep-

resentation of concepts in AI [4, 26], Linguistics [21] and Psychology [15]. We developed methods for extracting from the Web candidate concept attributes, and semantic classifier to select those that fit into a linguistically and philosophically motivated classification of attributes, finding that this leads to improvements at concept clustering.

The motivation for the work discussed in the present paper is the intuition that such information about attributes ought to help with sense discrimination as well, in that different senses of a word ought to be associated with different attributes. Thus, for example, instances of **palm1** are more likely to be connected with a **wrist** than instances of **palm3**; conversely, the latter will be more likely to have **coconuts**. (Of course, there will also be attributes in common. E.g. instances of both **palm1** and **palm3**, being physical objects, will have a length—although we conjectured that these would not be the most distinctive attributes.) In addition, we explicitly focus on the task of identifying major senses instead of all sense distinctions as identified, say, in WordNet.

The structure of the paper is as follows. After a brief overview of relevant literature on sense discrimination and on using attributes for concept clustering, we introduce our new algorithm for sense discrimination, MSDA, and present the experiment we used to evaluate it. Results and discussion follow.

2 BACKGROUND

2.1 Wordsense discrimination with context vectors

The old observation that context is required to determine a word’s meaning led, e.g. Miller and Charles [14] to suggest that similar meanings are often used in similar contexts. Schütze [24] implemented this intuition by extending his earlier vector space model [23] to identify senses of words by using two different types

¹ University of Essex, UK, email: aalmuh & poesio at essex.ac.uk.

² University of Trento, Italy.

³ The term **attribute** is used informally here to indicate the type of relational information about concepts that is expressed using so-called **roles** in Description Logics [4]—i.e. excluding **IS-A** style information (that cars are vehicles, for instance). It is meant to be a more restrictive term than the term **feature**, often used to indicate any property of concepts, particularly in Psychology. We are carrying out a systematic analysis of the sets of features used in work such as [25] (see Discussion).

of vectors: **first-order vectors** representing contexts in terms of neighboring words of the target word, as in his original model; and **second-order vectors**, used to represent a context as the centroid of the first-order vectors for the words occurring in that context—which amounts to using word vectors as features. The context vectors for a word are then clustered using agglomerative clustering in a predefined number of sense clusters. Schütze reported an accuracy of between 72% and 90%, but pointed out that his algorithm should be tested using more natural ambiguous words. Pedersen and Bruce [17] developed a second method for identifying senses, in which contexts were directly represented with first-order vectors, i.e. using words themselves as features. These first-order vectors were then clustered using agglomerative cluster and the EM algorithm.

Purandare and Pedersen [20] (henceforth: P&P) compared these two methods, also looking at different combinations of clustering and features, and concluded that first-order vectors and agglomerative clustering are the best choice when the sample data is large (e.g. about 4,000 contexts per word), while second-order vectors and the Repeated Bisects algorithm are the best when the sample data is small (e.g. around 50-200 contexts per word). P&P [20] also developed a (publicly available) software package called **SenseClusters** implementing a variety of context representation models include first-order and second-order vectors with and without dimensionality reductions. The software also provides several clustering algorithms including agglomerative, partitional, and Repeated Bisects [11] algorithms.

2.2 Mining concept attributes from the Web

As said earlier, most theories of concepts are based on the assumption that concepts are characterized in terms of semantic attributes or, more generally, features, but no previous work on the acquisition of lexical or ontological knowledge by concept clustering attempted to identify such semantic properties. In our own earlier work [2, 18] we developed methods for extracting candidate attributes from the Web using patterns as done, e.g. by Hearst [10] to identify **is-a** relations or Poesio et al. [19] to identify **part-of** relations. For example, Hearst [10] acquired information about hyponymy (**is-a** links) by searching for instances of patterns such as

NP {, NP}* or other NP

(as in, e.g. *bruises broken bones and other INJURIES*). In our own work, we used the pattern

"the * of the C [is|was]"

(suggested by e.g. Woods [26] as a test for ‘attribute-hood’) to search for candidate attributes of concept *C* in the Web (finding e.g. instances such as *the color of the car is*) and a separate pattern for identifying **values** of such attributes (such as *red*). We showed in [3] that using only such attributes and values results in better concept descriptions for the purposes of clustering than collecting all relations in which a concept occurs. We then trained a classifier using morphological information and information from the Web for filtering such candidate attributes by assigning them to one of five classes according to a scheme derived from the work of Pustejovsky [21] and Guarino [9]. We showed in [18] that a binary classifier filtering non-attributes this way (i.e. eliminating attributes not recognized as belonging to one of the five classes) leads to significant improvements in concept clustering.

The conjecture motivating the present work was that such methods for identifying attributes and values could work better as a feature selection mechanism than the methods used by Schütze or P&P for the purposes of identifying distinct context clusters, each representing a separate sense.

3 A NEW SENSE DISCRIMINATION ALGORITHM

Our new sense discrimination algorithm, MSDA (Major Senses Discovery Algorithm) improves over the algorithms implemented in SenseClusters in three respects: (i) it uses attributes and values as semantic features used to identify different senses; (ii) it does not require to predefine the number of senses; and (iii) it returns a flag specifying whether context information provides enough evidence to decide on a number of senses.

The pseudo-code for MSDA is shown in Figure 1. The algorithm begins by computing the set *C* of context vectors *c*. The algorithm is designed to work with large amounts of data such as those that can be extracted from the Web (we use up to 10,000 contexts per word, see below); hence, on the basis of the Purandare and Pedersen results, it uses first-order vectors, one for each occurrence of target noun *w*. After collecting the contexts, an iteration begins. Each loop consists of two phases. In **Phase 1**, the contexts in *C* are clustered into *n* clusters (at the beginning *n* = 2; it is incremented by 1 at each iteration). Against the recommendations of Purandare and Pedersen, we used Repeated Bisects for clustering, with a criterion function that tries to maximize the internal similarity of each cluster [11]. We did not use agglomerative clustering because we found that it produces clusters

with varying sizes: some clusters contain very large number of instances, while other ones a very small number, which is not adequate in our case because we are only looking for major senses, that should be frequent in the data.

Input: A set of contexts C ; the thresholds Φ_1 and Φ_2 ; and m , the number of features to be compared.

$n = 2$; $f \leftarrow \text{true}$;

repeat

Phase 1:

 partition C in n clusters $k_1 \dots k_n$ by repeated bisections;

Phase 2:

foreach $i=1..n$ find the m most frequent attributes and values in cluster k_i ;

$k_i, k_j \leftarrow$ the two clusters such that $\text{sim}(k_i, k_j)$ is max;

if $\text{sim}(k_i, k_j) \geq \Phi_2$ **then**

$n \leftarrow n-1$; **halt**;

if $\Phi_1 < \text{sim}(k_i, k_j) < \Phi_2$ **then**

$n \leftarrow n-1$; $f \leftarrow \text{false}$; **halt**;

$n \leftarrow n+1$;

end repeat

Output: n , the number of the discovered senses; f , a flag indicating if MSDA is certain or not; and the top frequent attributes & values related to each sense.

Figure 1: Pseudo-code for MSDA.

In **Phase 2**, attributes and values are used to discriminate between clusters. They are extracted from the contexts in each cluster k_i using the methods developed in our previous work, and the top m most frequent attributes / values for each cluster are used to decide which clusters k_i and k_j are most similar (using the cosine similarity function on binary values). At this point, a decision is made whether to halt or to try to partition C into more clusters. The decision is made by comparing $\text{sim}(k_i, k_j)$ with two thresholds. If the similarity between the top m features of the two most similar clusters is \geq threshold Φ_2 , MSDA halts, and concludes that there are ($n - 1$) major sense(s). If the similarity is less than or equals a second threshold Φ_1 ($\Phi_1 < \Phi_2$), n is incremented and the next iteration is attempted. If the similarity falls in between these two thresholds, the algorithm reports that it is uncertain about the results, and there are at least ($n - 1$) major sense(s) for the target noun.

The intuition behind the decision procedure is as follows. The higher threshold Φ_2 is used to decide when two sets of attributes / values are similar enough that two senses should be considered the same. Suppose that noun w only has one sense. Then the two initial clusters should share many attributes / values, hence the similarity between them should be $\geq \Phi_2$. The lower threshold Φ_1 is used to decide when two clusters

share so few features that they belong to two different senses. Suppose noun w has two or more clearly distinct senses. Then the sets of most distinctive attributes should be very different, and the similarity should be $\leq \Phi_1$. The algorithm will try to find more distinctive senses (but it will return $n-1$ if it ends up splitting a cohesive cluster). In other words, MSDA continues partitioning the contexts until it finds two very similar clusters. Finally, if the similarity falls in between the two thresholds, the evidence is not strong enough to give a certain conclusion. The algorithm also halts reporting an uncertain conclusion if there are less than m distinct features for any of the clusters in the set.

MSDA compares valid attributes (e.g. qualities, activities, and parts) and valid values (e.g. *fast*, and *slow* for the quality *speed*) only; invalid attributes are filtered out using the 2-way attribute classifier proposed in [18], and invalid values are filtered out using methods described in [1]. Note also that to eliminate the effect of these semantic features on the clustering, these features are hidden in Phase 1, and only used in the comparison in Phase 2.

4 EVALUATION

We now discuss how we evaluated MSDA, and compared it with Purandare and Pedersen's SC.

4.1 Test data

In order to facilitate the comparison with previous work, we tested MSDA using a combination of unambiguous, naturally ambiguous, and pseudo-ambiguous words as done by Schütze and others. Our natural words included two ambiguous nouns used by Schütze (**capital** and **interest**), the one used by Rapp [22] (**palm**), and three nouns that are unambiguous (according to WordNet) and frequent: *brigade*, *hydrogen*, and *ship*. These three unambiguous nouns were also used to create three artificially ambiguous words: *brigade_hydrogen_ship*, *hydrogen_ship*, and *brigade_hydrogen*. ‘Contexts’ for these words were created by replacing e.g. every occurrence of *hydrogen* and of *ship* with *hydrogen_ship*, as done by Schütze.

4.2 Data collection

We collected from the Web about 10,000 contexts of occurrence for each natural noun in the dataset. For the pseudo-ambiguous nouns, we included a balanced number of contexts for each of the natural nouns that make them: e.g. the contexts for *hydrogen_ship* contain 5,000 contexts related to *hydrogen* and 5,000 contexts related *ship*. The context vectors were built using

a window of size 50 around the target noun. In phase 2, attributes and values are extracted from each context using the patterns discussed in our previous work.

We experimented with different values for Φ_1 , Φ_2 , and m (the number of most frequent attributes / values for each cluster). The best results were obtained with $\Phi_1 = 0.15$, $\Phi_2 = 0.30$, and $m = 20$.

4.3 Comparisons

We also used the data collected as above to test SenseClusters on the same dataset using Purandare and Pedersen's [20] recommendations and choices for clustering a large data sample. Again, about 10,000 contexts were used for each noun. The context vectors were constructed using a scope of size 5 and a window of size 40 (i.e. 20 in either side of the target noun). As done by P&P, we fixed the number of clusters to 7, but discarded clusters with few instances, less than 2% of the total number of instances, the threshold used by P&P. (We also tried a higher threshold (20%) and obtained similar results.) First-order contexts were used, and clustered using the agglomerative algorithm. Less frequent neighboring words with overall frequency of less than 2 were ignored. Frequencies were weighted using the log-likelihood function using the threshold 3.841.

4.4 Results

The results using SenseClusters (SC) and MSDA are shown in Table 1. The second column lists the number of major senses found in the literature for the natural ambiguous nouns (and based on WordNet for the unambiguous nouns); the third column shows the number of senses found using SC; the fourth the number of senses found using MSDA.

Noun	Major Senses	SC	MSDA
brigade	1	1 ✓	1 ✓
hydrogen	1	3 ✗	1 ✓
ship	1	1 ✓	1 ✓
brigade_hydrogen	2	2 ✓	2 ✓
hydrogen_ship	2	3 ✗	2 ✓
brigade_hydrogen_ship	3	2 ✗	3 ✓
capital	2	1 ✗	2 ✓
interest	2	1 ✗	1 ✗
palm	2	2 ✓	2 ✓

Table 1: Results with SC and MSDA

As can be seen from the Table, MSDA works very well: it identifies the correct number of senses for 8 out of 9 nouns, 89%. By contrast, SenseClusters only

found the correct number of major senses for 4 out of 9 nouns, 44%.

4.5 Semantic features related to each sense

Table 2 shows the 4 most frequent semantic features (attributes and values) for each sense of the five ambiguous nouns found using MSDA. The features are ordered by frequency. Attribute features are preceded by '[a]', while value features are preceded by '[v]'. The first column in the table shows a manually assigned label for each sense.

Label	Top 4 Frequent Features
brigade_hydrogen	
brigade	[v]fire, [v]Texas, [v]1st, [a]commander
hydrogen	[v]liquid, [v]amide, [v]element, [v]fire
hydrogen_ship	
hydrogen	[v]liquid, [v]amide, [v]element, [v]molecular
ship	[a]captain, [a]name, [a]safety, [a]owner
brigade_hydrogen_ship	
brigade	[v]Texas, [v]1st, [v]3rd, [a]commander
hydrogen	[v]liquid, [v]amide, [v]element, [v]molecular
ship	[v]fire, [a]captain, [a]name, [a]side
capital	
assets	[v]fixed, [v]variable, [a]value, [v]circulating
district	[a]streets, [a]transfer, [a]removal, [a]heart
palm	
hand	[a]size, [v]right, [v]left, [a]base
tree	[v]date, [v]coconut, [v]oil, [v}sago
interest	
Common features: [a]extent, [a]holder, [a]transfer, [a]value, [v]controlling, [v]partnership, [v]security	

Table 2: Top 4 semantic features for each sense found by the MSDA algorithm.

Most of the attributes and values in the table are clearly related to the named sense. For example, the *assets* sense of *capital* includes the attribute *value* and the values *fixed*, *variable*, and *circulating*, which are clearly related to *assets*; while most of the attributes *streets*, *transfer*, *removal*, and *heart* are more related to the *district* sense of *capital* than to the *assets* sense.

The table also shows the data for the noun *interest* where MSDA failed to find the correct number of major senses: In the first iteration of Phase 2, MSDA found 7 common features (shown in the table) among the top 20 features of the two clusters of the *interest* contexts which gives a similarity score of 0.35 that is above the threshold Φ_2 .

5 DISCUSSION AND CONCLUSIONS

This work suggests using semantic features such as

attributes and values is not only a good way to build concept descriptions for the purposes of clustering, but also to discriminate between noun senses. This work however raises a number of questions that we hope to explore in further research, such as whether it is possible to come up with a clear enough repertoire of ‘major senses’ for some words that we will be able to assess whether in fact the algorithm is always successful at the task. (Unfortunately, the distinction between polysemy and homonymy is notoriously difficult to draw – see again Kilgarriff’s paper.)

Integrating Domain and Paradigmatic Similarity for Unsupervised Sense Tagging

Roberto Basili¹ and Marco Cammisa¹ and Alfio Massimiliano Gliozzo²

Abstract. An unsupervised methodology for Word Sense Disambiguation, called Dynamic Domain Sense Tagging, is presented. It relies on the convergence of two very well known unsupervised approaches (i.e. Domain Driven Disambiguation and Conceptual Density). For each target word a domain is dynamically modeled by expanding the its topical context, i.e. a set of words evoking the underlying/implicit domain where the word is located. The estimation of the paradigmatic similarity within such a specific lexicon is assumed as a disambiguation model. The Conceptual Density measure is here used to account for paradigmatic associations, and the top scored senses of the target word are selected accordingly. Results confirm the impact of domain based representation in capturing useful paradigmatic generalizations, especially when small text fragments are available. In addition, the precision/recall tradeoff of the resulting method can be tuned in a meaningful way, allowing us to achieve impressively high precision scores in a purely unsupervised setting.

1 Introduction

Semantic disambiguation is a relevant problem in a number of Artificial Intelligence applications, ranging from Ontology Engineering to Information Retrieval. Any text-driven ontology population or ontology mapping task, for instance, is implicitly a sense disambiguation problem at various degrees of grain and complexity. Another important application is query translation and expansion for cross-language Information Retrieval.

Unfortunately, Word Sense Disambiguation (WSD) is a cornerstone in Natural Language Processing. In fact, the specificity of the target application domains and the involvement of languages different from English do not allow to rely on existing sense tagged resources, without whom state-of-the-art supervised approaches to WSD [6] cannot be adopted. Unsupervised approaches for semantic disambiguation thus play a central role in most of the above scenarios.

Among those approaches, [9] proposes a method to estimate predominant senses via a large untagged corpus, reaching high accuracy on standard WSD benchmarks. The underlying assumption is that predominant senses are not stable across domains and corpora, and that the notion of predominance can be modeled through an unsupervised corpus based analysis. The main limitation of that approach is that the sense distribution is modeled once for all on the basis of the corpus adopted for unsupervised learning, while word senses are first of all disambiguated by local constraints. The concept of predomi-

nance provide only an "a-priory" information about the probability distribution of word senses, that should be anyway refined by looking at a local context.

A possibility to merge both approaches is then to adapt the global information provided by the whole corpus to the local constraints provided by tokens in the surrounding context of the word to be disambiguated. Each sentence in fact suggests a topical context where the semantics of the target word is highly constrained. The modeling of such local domain evidence can thus exploit several sources of semantic evidences. Words w describing a topical contexts of the target word tw can be used to impose tighter constraints to the interpretation of tw . They express indeed a variety of information:

- *Domain information*, as the semantic domain of the context can be used to discriminate among metaphorical sense shifting (e.g. *virus* in Biology vs. Computer science)
- *Paradigmatic information*, as important siblings or synonyms w of tw (e.g. *bugs* vs. *bacteria*) are likely to appear in topical-contexts: class information for sense distinctions is thus made available

In this paper we investigate a disambiguation model that captures the above idea within an unsupervised framework aiming to address the semantic disambiguation problem of classical AI tasks, e.g. query translation and ontology learning. The model, named Dynamic Domain Semantic Tagging (*DDST*), relies on unsupervised learning techniques and Wordnet [11].

The DDST algorithm integrates two well known methodologies, i.e. the Domain Driven Disambiguation (*DDD*) [8] and the similarity metric known as Conceptual Density (*CD*) [1], reflected in the following two steps:

Domain Detection Extract the topical-context for the target word.

Paradigmatic Disambiguation Estimate the paradigmatic cohesion of the domain lexicon and then select the sense maximizing such an association within the topical context .

Details of each individual step will be provided in Section 2 and Section 3, respectively.

The DDST approach solves the main limitations of the CD algorithm: the lack of semantic relations among concepts having different ontological types (e.g. the nouns *athlete* and *sport* are totally unrelated in WordNet, because they belong to the disjointed hierarchies of *life forms* and *act*, respectively). To this aim, the DDST algorithm identifies a wider context (i.e the semantic domain) for the word to be disambiguated. In this way a wider region of WordNet is involved, providing the CD algorithm of a more reliable evidence.

The DDST algorithm is then totally unsupervised, because it does not rely on the availability of sense tagged data and it does not exploit neither a prior estimation of sense frequency distribution [9] nor the

² ITC-irst, Trento, Italy, email: gliozzo@itc.it

sense ordering provided by WordNet (reflecting the sense predominance in Semcor). It can be thus applied to a large set of tasks and languages once a WordNet like lexical database and a large corpus have been provided. It represents a technologically viable solution, uniform across different languages and application scenarios.

The result of the Domain Detection step is a sensible improvement in the accuracy of the overall lexical disambiguation process. To show this, in Section 4 we compared the DDST performances against a classical CD algorithm over the Senseval-3 English all words task [10]. First, the DDST algorithm achieves a substantial improvement against a random baseline. More importantly, its superiority is particularly evident when small contexts of the target word are taken into account, and this confirms its applicability to query disambiguation (expansion or translation). Conclusion and future work are finally discussed in Section 5

2 Dynamic Generation of Domain Lexicons

The Domain Detection step is inspired by the Domain Driven Disambiguation (DDD) methodology for WSD, originally proposed by [8]. DDD is an unsupervised approach to WSD consisting on selecting the word sense that maximizes the similarity with the domain of the context. In its original formulation the DDD methodology required (i) a knowledge base containing domain information for each sense of the word to be disambiguated and (ii) an domain relevance estimation algorithm to recognize the domain of the context in which the word occurs. To accomplish the first requirement authors proposed the exploitation of WordNet Domains [7], an extension of WordNet, where each synset has been manually annotated by domain labels selected from a predefined domain set. Unfortunately, this approach is very restrictive for the following reasons:

1. The manual development of lexical resources is very expensive³.
2. The domain set is fixed once for all in the resource, while the relevant domain distinctions are usually task and context dependent.
3. Domain information alone is not sufficient to resolve lexical ambiguity: syntagmatic and paradigmatic aspects of sense distinction are not taken into account

The Domain Detection step is an attempt to solve both the first and the second problems reported above, defining a dynamic approach to identify only those domain distinctions actually involved in the application domain without requiring any manual domain annotation. In fact, in the perspective proposed by the authors, the domain distinctions have been conceived as a "static" notion, reflecting the lexicographers' intuition of an a-priori organization of the world. On the other hand, we believe that such a notion is strongly dependent on the specificity of the particular discourse or inference we are dealing with, preventing us to define such a static domain model.

For these reasons we adopted the more flexible notion of topical-context to deal with the domain modeling problem. Topical context are collections of words, describing the domain in which the text is located. They can be determined in a totally unsupervised way by adopting term/text similarity techniques, and can be used to plug "external knowledge" from a large corpus into the disambiguation process.

Such a similarity metric can be provided by defining a Domain Space [5], where both terms and texts are represented by means of Domain Vectors (DVs). We exploit the duality property of the domain space to perform the Domain Detection step: word contexts are represented by text vectors in the domain space, then the more

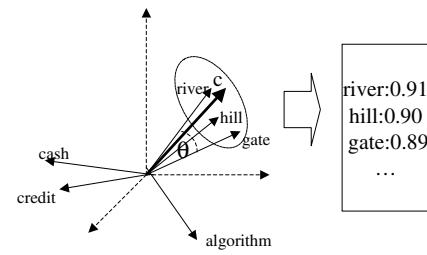

Figure 1. Output of the domain discovery step for the sentence $c = \text{"He took a walk along the bank of the river"}$

closely related terms are retrieved by exploiting the cosine similarity metric.

To show this, we illustrate the Domain Detection process by an example. Suppose that the word *bank* has to be disambiguated into the sentence "*He took a walk along the bank of the river*". The topical-context for this occurrence of *bank*, contains the terms *river*, *hill*, *snow* and *road*, among the others (see Figure 1).

The Domain Space can be defined once a Domain Model (DM) is available. A DM is represented by a $k \times k'$ rectangular matrix \mathbf{D} , containing the domain relevance for each term with respect to each domain, where k is the cardinality of the vocabulary, and k' is the size of the Domain Set. Once a DM has been defined by the matrix \mathbf{D} , the Domain Space is a k' dimensional space, in which both texts and terms are associated to Domain Vectors (DVs), i.e. vectors representing their domain relevances with respect to each domain. The DV \vec{w}_i for the term $w_i \in \mathcal{V}$ is the i^{th} row of \mathbf{D} , where \mathcal{V} is the vocabulary of the corpus. The similarity among DVs in the Domain Space is estimated by means of the cosine operation.

DMs can be acquired from texts in a totally unsupervised way by exploiting a lexical-coherence assumption [5]. To this aim, term clustering algorithms can be adopted: each cluster represents a Semantic Domain and the degree of association among terms and clusters, estimated by the learning algorithm, provides a domain relevance function. For our experiments we adopted a clustering strategy based on Latent Semantic Analysis (LSA), following the methodology described in [6]. This operation is done off-line, and can be efficiently performed on large corpora. To filter out noise, we included only those terms having a frequency higher than 5 in the corpus.

When a word w , located into the context $c = (w_{-h}, \dots, w_{-1}, w_0, w_{+1}, \dots, w_{+h})$, has to be disambiguated, first the DV \vec{c} of its context is estimated by

$$\vec{c} = \sum_{i=-h}^{+h} \vec{w}_i \quad (1)$$

\vec{c} defines a neighbourhood including the DVs \vec{w} of other corpus terms $w \in \mathcal{V}$, topically associated to the source text. A topical context for the \vec{c} can be thus formally defined by: $\{w \in \mathcal{V} \mid \| \vec{w} - \vec{c} \| < \theta\}$, where $\|\cdot\|$ is any valid norm in the LSA space derived from the cosine similarity and $\theta \in \mathbb{R}^+$. The topical-context includes all those terms whose distance (i.e. similarity) with the context c is below (above) a *domain specificity* threshold. In general, the lower the domain threshold θ , the higher the specificity of the returned topical-context and the smaller its size. Another restriction that can be imposed in the modeling of a proper topical-context is *polysemy*. In fact, ambiguous words inherently activate noisy generalizations during the similarity estimations due to their spurious sense(s). On the other hand, monosemous words should always refer to the unique correct sense, thus activating the "right" paradigmatic associations.

³ The development of WordNet Domains took about 2 man year.

In order to control such phenomenon, those words whose polysemy is over a predefined threshold ρ can be filter out. A formal definition for a topical-context in the disambiguation perspective is thus given by:

$$TC(c) = \{w \in \mathcal{V} \mid \| \vec{w} - \vec{c} \| < \theta \text{ and } pol(w) < \rho\} \quad (2)$$

where $pol(w)$ expresses the polysemy (i.e. number of senses) of w in WordNet.

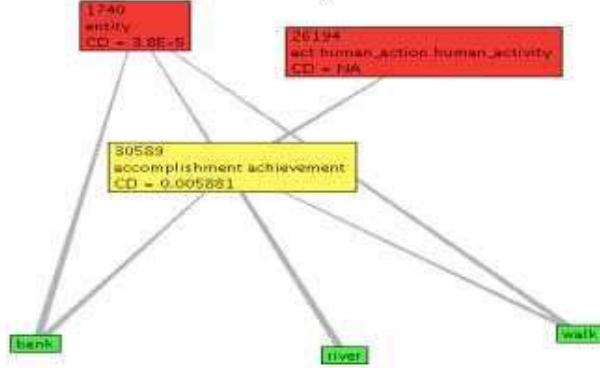

Figure 2. Conceptual Density for the words *bank*, *walk* and *river*

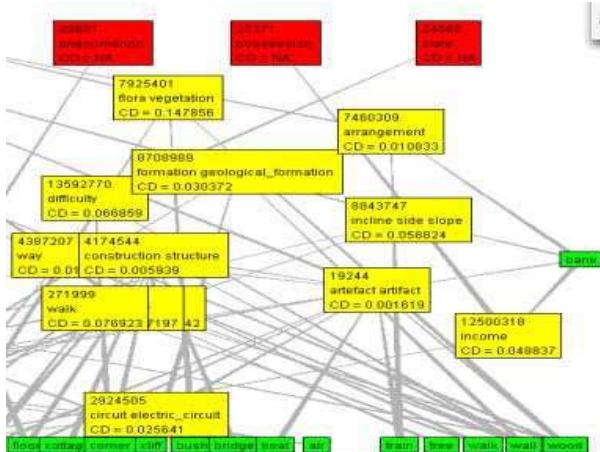

Figure 3. Conceptual Density for the word *bank* together with its topical-context

3 Semantic Disambiguation through Conceptual Density

In [2] an n -ary similarity measure aimed to support an unsupervised approach to semantic tagging has been presented. It represents a variant of the notion of *Conceptual Density* previously suggested as a tool for sense disambiguation [1]. In [3] it is applied for learning sense preferences in Wordnet from available syntagmatic patterns found in a corpus. Sets r of syntactically similar words are clustered and the best senses α as useful semantic explanations of the underlying syntactic phenomena are selected. In a Bayesian perspective, rules for disambiguation (i.e. estimates for $prob(\alpha|r, w)$) are derived from similar syntactic contexts r , i.e. the sets of different words w in the same grammatical contexts. In order to favour some senses an estimation of semantic similarity "local" to the contexts r is carried out via the *conceptual density* ($cd^r(\alpha)$) measure.

The same definition of conceptual density as in [3] is proposed here for the semantic disambiguation phase. However, a different notion of context r is applied. Instead of using syntactic equivalence

(i.e. occurrence in the same syntactic contexts), we define r as the *neighbourhood* $TC(c)$ determined by Eq. 2 for the source context c . The hypothesis is that some members in a topical context $TC(c)$ are expected to share paradigmatic properties with the target word tw : their sense in $TC(c)$ is thus semantically close to the suitable sense of the tw in the source context c . The closest sense α is thus selected by maximizing the conceptual density of the Wordnet hierarchy rooted at α .

As illustrated by Figure 3, the topical-context provide more evidence than the mere list of the words actually located in context of the word to be disambiguated (i.e. *walk* and *river*, see Figure 2) improving the final disambiguation. In fact, the (wrong) generalization for the word *bank* provided by the classical CD algorithm is *accomplishment achievement*, while if the topical-context is taken into account the CD algorithm select the (correct) sense of *incline slope land*.

3.1 A similarity measure for large scale semantic disambiguation

In Section 2 a topical context $TC(c)$, i.e. a domain specific lexicon, originating from a textual context c has been defined via Eq. 2. Words $w \in T(c)$ can be generalized through senses α of the Wordnet hierarchy. The likelihood of a sense α_{tw} for the target word tw is proportional to the number of other words $w \in TC(c)$ that have common generalizations with tw along the paths activated by their α in the hierarchy. A measure of the suitability of senses α for words $w \in TC(c)$ is thus the *information density* of the subtrees rooted at α . The higher is the number of nodes in the subhierarchy that generalize some nouns $w \in TC(c)$, the better is the related interpretation α . The conceptual density models the former notion and provides a measure for the latter.

DEF (Conceptual Density). Given a context c for a target word tw , its topical context $TC(c)$, a synset α in Wordnet used to generalize n different nouns $w \in TC(c)$, the conceptual density, $cd^{TC(c)}(\alpha)$, of α with respect to $TC(c)$ is defined as:

$$cd^{TC(c)}(\alpha) = \frac{\sum_{i=0}^h \mu^i}{area(\alpha)} \quad (3)$$

where :

- h is the estimation of the depth of a tree able to generalize the n nouns. Its actual value is estimated by:

$$h = \begin{cases} \lfloor \log_\mu n \rfloor & \text{if } \mu \neq 1 \\ n & \text{otherwise} \end{cases} \quad (4)$$

- μ is the average number of sons per node in the full Wordnet subhierarchy dominated by α . Its estimation is available statically from Wordnet and can be evaluated *a priori* without uncertainty. Notice that when nodes belong to unbalanced branches of the hierarchy, the value for μ can approach (and in fact is) 1, so that a specific treatment of them is needed in the definition.
- $area(\alpha)$ is the number of nodes in the α subhierarchy. This value is also estimated statically from Wordnet.

Equation 3 applies to *any* valid and common generalization of the nouns $w \in TC(c)$ as topically related to tw . The aim of this method however is to reduce as much as possible the number of such generalizations. In [3] two properties have been defined that determine the best generalization set $G(c)$ among all the valid generalization set S applicable to an originating context c , i.e.

$$S = \{\alpha | \alpha \text{ is an hyperonim of at least one sense } \sigma_w, w \in TC(c)\}.$$

a) (*Useful generalization*) S is a useful set of generalizations if S covers the entire set $TC(c)$ and $\forall \alpha \in S$, α is an hyperonym of at least two words $w_1 \neq w_2 \in TC(c)$

b) (*Maximally dense*) The factor $\sum_{\alpha \in S} cd^{TC(c)}(\alpha)$ must be maximal, among the different S in the family of useful sets of generalizations, i.e.

$$G(c) = \operatorname{argmax}_S \sum_{\alpha \in S} cd^{TC(c)}(\alpha)$$

where S satisfies a).

The $G(c)$ set characterized by a) and b) is the *best paradigmatic interpretation* of the topical context $TC(c)$ generated by c . In [3] a *greedy* algorithm able to efficiently compute the minimal set $G(c)$ that covers $TC(c)$ with a maximal density is defined⁴. The outcome is the minimal set $G(c)$ of synsets that are the *maximally dense generalizations of at least two words* in $TC(c)$. Words $w \in TC(c)$ for which no such generalization may exist and will not be represented in the resulting set $G(c)$. Scores $cd^{TC(c)}(\alpha)$ model the strength by which words $w \in TC(c)$ are related to senses α , as suitable *paradigmatic explanations* of the topical context $TC(c)$.

The semantic disambiguation of a target word tw in a context c depends on the subset of generalizations $\alpha \in G(c)$ concerning some of its senses σ_{tw} . Let $G_{tw}(c)$ be such a subset, i.e.

$$G_{tw}(c) = \{\alpha \in G(c) \mid \exists \sigma_{tw} \text{ such that } \sigma_{tw} \prec \alpha\} \quad (5)$$

where \prec denotes the transitive closure of the hyponymy relation in Wordnet.

DEF (Semantic disambiguation). Given a context c for a target word tw and the generalization set $G_{tw}(c)$ defined above, the set $\sigma(tw, c)$ of correct sense(s) for tw in c is given by:

$$\sigma(tw, c) = \{\sigma_{tw} \mid \sigma_{tw} \prec \bar{\alpha}\} \quad (6)$$

with $\bar{\alpha} = \operatorname{argmax}_{\alpha \in G_{tw}(c)} cd^{TC(c)}(\alpha)$. Notice that when $G_{tw}(c)$ is empty then also $\sigma(tw, c) = \emptyset$ so that no decision can then be taken for the underlying context c . Other disambiguation heuristics should be applied. Moreover, it is also possible that $|\sigma(tw, c)| > 1$ so that multiple senses may be assigned to a context c . Equation 6 thus defines an (unsupervised) semantic disambiguation model. It will be evaluated in the next section.

4 Evaluation

In order to show the benefits obtained from adding the topical-context words, we contrasted the DDST with a classical CD algorithm over a WSD benchmark. This evaluation helps in the objective assessment of the method, but it focuses on just one of the variety of tasks to which DDST applies.

In this section we first describe the details of the implementation of the DDST algorithm and the adopted WSD benchmark (Subsection 4.1). Then, we contrast the performances of the DDST algorithm with those of a classical CD approach to WSD (Subsection 4.2). Finally, Subsection 4.3 investigates the precision/recall trade-off.

4.1 Experimental Settings

For the experiments, we used a C++ implementation of the CD algorithm described in Subsection 3, developed at the University of Rome

⁴ A demo version of the algorithm and the conceptual density measure can be accessed at <http://ai-nlp.info.uniroma2.it/Estimator/cd.htm>

Tor Vergata. Independently from the target task, the input of the tool is a set of nouns and the output is a set of generalization synsets from WordNet 1.7.1 with the related CD values. For the WSD purposes, we concentrated just on the CD estimation of the target words. The tool also returns a probability estimation (based on the CD score) for each sense of the input words. In the experiments The sense of the target word with maximal probability is selected as a final output. The DM has been acquired from the British National Corpus [4], following the methodology described in [6].

Results reported in the following subsections have been evaluated on the Senseval-3 English All-Words task [10]. This task consists on tagging all the words contained in tree middle sized English texts (i.e about 1500 words each). As the CD algorithm depends on the topology of the lexical hierarchy, DDST applies best to nouns. Then, for our experiments, we concentrated on the subset of the target words made by the 876 nouns. The Senseval tasks also provides an automatic scoring procedure for *precision* and *recall*. As a baseline for the task, we implemented a random WSD algorithm, by assigning a randomly chosen sense to each target word, achieving $F1=0.39^5$. One peculiarity of the Senseval-3 task is that wide contexts are made available to the WSD algorithm. However, in many practical applications (e.g. the disambiguation of IR queries) this assumption is unrealistic, therefore in this paper we will try to minimize the context window to be taken into account for disambiguation as much as possible.

A preliminary investigation about the role of the underlying parameters has been carried. No significant variations are observed⁶. The following setting is thus adopted for the dimensionality, similarity and polysemy control, respectively: $k' = 100$, $\theta = 0.5$, $\rho = 2$.

4.2 Role of the Topical Context

To demonstrate the usefulness of the Domain Detection step, and the effectiveness of the proposed methodology, we compared the DDST results to those of a classical CD algorithm on the Senseval-3 task. Results are reported in Figure 4, where the two algorithms have been compared by varying the context size (i.e. $h = 5, 10, 20, 50$). DDST is largely above the random baseline for every test. DDST and CD converges asymptotically when the context size increase, while the former is always superior in our experiments. Improvements are impressive especially when small contexts are considered, increasing the accuracy from 29,45 to 52,05 when a window of ± 5 tokens is considered. Surprisingly, the performances of DDST slightly decrease when wider contexts are considered, in contrast to CD. However, data show that topical contexts generated from smaller text fragments have performance sensibly higher than larger text portions (52% vs. 48%).

In general, all the experiments confirm that the implicit domain of a text is a fundamental aspect to capture lexical semantics. This aspect is better addressed by adopting unsupervised learning techniques to expand small contexts with topical-contexts rather than considering larger fragments of the originating document. The role of the topical contexts is then crucial for all those application scenarios where just small texts are available, as in most of the typical IA settings (e.g. dialogue systems, natural language interfaces).

⁵ $F1$ is the harmonic mean between precision and recall, i.e. $F1 = \frac{2pr}{p+r}$

⁶ The difference between the $F1$ achieved by the best configuration and those achieved by the worst is about 0.03.

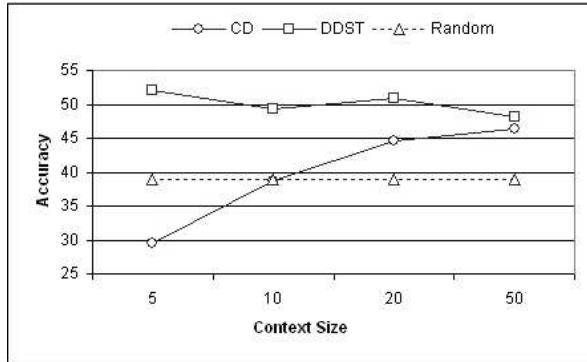

Figure 4. Accuracy varying the context size

4.3 Maximizing Precision

A relevant aspect to be taken into account when performing WSD is *precision*. In many cases, it would be preferable to tag only those words on which the algorithm is more confident, and reduce the tagging noise. For example, when WSD is used for query expansion, the wrong sense assignments would turn out in wrong expanding words, that result in misleading queries.

The DDST algorithm allows to define an effective selection criterion as its output can be considered as a probability distribution over the senses of the target word. This is done by normalizing the cumulative CD values of individual senses⁷ by the whole contribution. As this normalization gives rise to a probability estimate, then the entropy ($E(tw) = -\sum_{i=1}^n p_i(tw) \cdot \log(p_i(tw))$) with p_i as the probability of the i -th sense being correct for tw , and the perplexity, i.e. its exponential (i.e. $pp(tw) = 2^{E(tw)}$) can be measured. In particular the perplexity can be considered as an estimation of the confidence of the prediction provided by the DDST algorithm. The adopted selection criterion can thus be obtained by thresholding the perplexity of the output probability by a parameter τ .

Figure 5 reports Precision, Recall, F1 and Coverage of the system for different values of τ , showing that this parameter can be tuned meaningfully to control the trade-off between precision and recall. As shown in Fig. 5, τ allows to capture accurate predictions. Precision is above 80% along with reasonable recall values ($\tau \sim 0.1$), while a coverage of about the 60% of the cases can be still achieved with a 70% of precision ($\tau \sim 1.8$).

5 Conclusion and Future Work

In this paper we proposed a fully unsupervised methodology for semantic disambiguation useful in a large set of application scenarios, such as cross language information retrieval, question answering and ontology learning. The overall model combines in a natural and effective way distributional information observable in a corpus (mainly domain-specific topical associations among words) with the topological (i.e. paradigmatic) properties of a semantic network. A relevant side-effect of the disambiguation step is capturing paradigmatic properties, projecting out of the hierarchy a meaningful subportion as a suitable interpretation local to the source context. Such dynamic "view" can be seen as a domain-specific ontology that better characterizes the target text fragment. Results clearly shows that our ap-

proach works very well when small contexts of the target words are taken into account (e.g. queries and glosses), and can be tuned in order to boost precision to very high scores (over 80%). This is a very important feature in many IA settings, such us ontology population. Although experiments have been run over a classical WSD task, they demonstrate the technological perspectives opened by the proposed method over typical complex tasks in modern AI. This paper is just a first attempt to provide a dynamic notion to the concept of semantic domain and its relation to the paradigmatic structure in WordNet. For the future, we plan to further extend this methodology to address several lacks of this research. In particular we plan to improve the CD algorithm by providing a corpus score to each synset and to integrate syntagmatic constraints in the disambiguation process. In addition we plan to exploit the proposed technique to address the traditional AI problem tuning and large scale ontology to a specific domain.

⁷ Different generalizations in $G_{tw}(c)$ may cover the same sense $\sigma(tw, c)$ providing different evidence in favour of $\sigma(tw, c)$.

Disambiguating Personal Names on the Web using Automatically Extracted Key Phrases

Danushka Bollegala¹ and Yutaka Matsuo² and Mitsuru Ishizuka³

Abstract. When you search for information regarding a particular person on the web, a search engine returns many pages. Some of these pages may be for people with the same name. How can we disambiguate these different people with the same name? This paper presents an unsupervised algorithm which produces unique phrases to disambiguate different people with the same name (i.e. namesakes). Our algorithm takes in a personal name and outputs multiple sets of phrases which uniquely identify the different namesakes on the web. These phrases could then be added to the query to narrow down the search to a specific namesake. We evaluated the algorithm on a collection of documents retrieved from the Web. Experimental results show a significant improvement over the existing methods proposed for this task.

1 Introduction

The Internet has grown into a collection of billions of web pages. One of the most important interfaces to this vast information are web search engines. We send simple text queries to search engines and retrieve web pages. However, due to the ambiguities in the queries and the documents, search engines return lots of irrelevant pages. In the case of personal names, we may receive web pages to other people with the same name (*namesakes*). However, the different namesakes appear in quite different contexts. For example if we search for *Michael Jackson* in Google, among the top hundred hits we get a beer expert and a gun dealer along with the famous singer. Although namesakes share a common name, in most of the cases they appear in entirely different contexts. For example, in the case of Michael Jackson, terms such as *music*, *album*, *trial* associate with the famous singer, whereas we observe terms *beer*, *travel*, *hunter* for the *beer expert* namesake. This paper proposes an unsupervised algorithm which extracts such uniquely identifying key phrases from the Web to disambiguate people with the same name. These automatically extracted key phrases could then be used to modify the original query and narrow down the search.

Disambiguating namesakes on the Web is a challenging task. To begin with, the number of namesakes for a particular name is unknown. Moreover, not all namesakes are equally represented on the Web. In many cases there are two or three famous namesakes which have lots of pages about them and all other namesakes have just one or two pages on them. Another difficulty is identifying the scope of the context of a name. An entire web page/site may be written on a person (for example home pages and fan sites) or the name may ap-

pear on passing (for example book reviews on Amazon mentioning an author of a book, conference programs mentioning names of the authors of papers, etc). On the other hand there are cases where an individual has various web appearances. For example the renowned linguist Noam Chomsky appears as a linguist and also as a critic of American foreign policy. It would be interesting to see how a namesake disambiguation method responds to such complications.

Disambiguating namesakes is vital for social network extraction systems [14, 17]. Matsuo et al [14], proposes a social network extraction system in which they measure the connection between two persons *A* and *B* based on the number of hits for the query *A AND B* on a web search engine. However, this method cannot be used to create social networks for namesakes because of the ambiguity of the names. We can easily overcome this limitation by including a phrase in the query, that uniquely identifies the person under consideration from his or her namesakes.

2 Related Work

There is little previous work we know of that directly addresses the problem of extracting key phrases to disambiguate personal names on the web, but some related problems have been studied. Disambiguation of namesakes is similar to tuple matching in databases—the problem of deciding whether multiple relational tuples from heterogeneous sources refer to the same real-world entity [8, 1, 9].

From a natural language perspective, there has been a lot of work on the related problem of co-reference resolution [2, 15]. The goal in co-reference resolution is to link occurrences of noun phrases and pronouns, typically occurring in a close proximity, within a few sentences or a paragraph, based on their appearance and local context. Co-reference resolution is vital for many natural language tasks such as text summarization, question answering and entity extraction [5]. Various algorithms have been proposed for co-reference resolution. Fundamentally, these algorithms map the local information around a pronoun to a set of features and use a machine learning technique to determine whether a given pronoun corresponds to a given noun phrase.

A few works address the problem of personal name disambiguation across a collection of documents. Mann, et al [13] considers the problem of distinguishing occurrences of a personal name in different documents. They propose an unsupervised algorithm which extracts *people-specific* biographical information such as birth date, birth place, occupation etc using a set of regular expressions to cluster the documents to their namesakes. However, such person-specific information is not always available for all the namesakes on the web. Even in cases where such information is available, a set of fixed regular expressions as used by Mann et al [13] is not sufficient to ex-

¹ University of Tokyo, danushka@mi.ci.u-tokyo.ac.jp

² Japanese National Institute of Advanced Industrial Science and Technology, y.matsuo@aist.go.jp

³ University of Tokyo, ishizuka@i.u-tokyo.ac.jp

tract them. Bekkerman, et al [4] proposes a link structure model and an agglomerative-conglomerative double clustering (A/CDC) based algorithm to disambiguate a group of people on the web. The algorithm assumes our ability to obtain information regarding the social network (associates) of the person to be disambiguated. The method can be readily used when we have such information. However, in most of the situations we do not know well enough about the associates of the person which we want to disambiguate. Pedersen et. al. [18] proposes a method for discriminating names by clustering the instances of a given name into groups. They extract the context of each instance of the ambiguous name and generate second order context vectors using significant bigrams. The vectors are clustered such that instances that are similar to each other are placed into same clusters. Li, et al [12] suggests an algorithm which could be used to disambiguate not only personal names but other types of named entities such as organizations and locations. They propose a discriminative model based on agglomerative clustering and a generative model which uses a language model combined with EM algorithm. Their experimental results show that the generative model out performs the discriminative model. They do not discuss the topic of extracting key phrases to distinguish the different entities.

3 Method

3.1 Problem Settings and Modeling

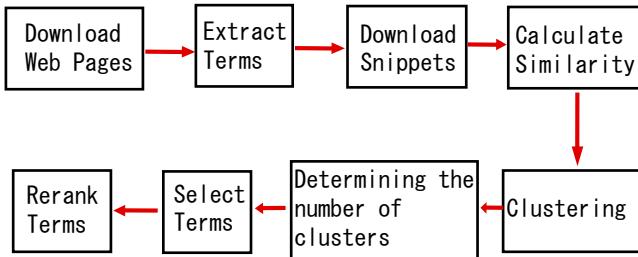

Figure 1. Outline of the method

The outline of our method is illustrated in figure 1. Our method takes the name to be disambiguated as the input and outputs a list of key phrases for each of the different namesakes. The first step is to collect a set of documents that covers all the namesakes for a given name. This step could be omitted in cases where a particular name is to be disambiguated in a given document collection. Collecting a set of documents from the Web that covers all namesakes of a given name is beyond the scope of this paper. In our system, to collect information regarding a particular name we use Google⁴ and download the top 100 web pages for the given name.

We assume each document in the collection to represent exactly one namesake. This assumption allows us to identify each document in the collection with a particular namesake. Thus, the problem of disambiguation becomes a one of document clustering. We cluster the set of documents such that each cluster represent a different namesake, and extract key phrases from each cluster to identify the namesake it represents.

⁴ <http://www.google.com/apis>

3.2 Term Model

Contextual Hypothesis for Senses [21] states that two occurrences of an ambiguous word belong to the same sense to the extent that their contextual representations are similar. According to this hypothesis, if the contexts of which two instances of a name appears are similar, then we could infer that both the instances of the name belong to the same person. In order to achieve this goal, we need a model that represents all the salient knowledge regarding a particular instance of a name. Traditionally, a document is modeled as a bag-of-words and represented by a word vector [19]. However, in our case the context of an instance of a name may vary from few lines to an entire web page. Considering all the words (excluding stop words) adds too much noise. Moreover, a document may not totally focus on the namesake, but also contain lots of other information. The knowledge representation model should be robust enough to capture the salient information for disambiguation.

In this paper, we propose *Term Models* as our knowledge representation model. A Term Model $T(A) = t_1, \dots, t_N$, of a personal name A (since we consider each document as representing exactly one namesake, we have exactly one term model for each document) is defined as the set of N terms t_i, \dots, t_N extracted from the context of a personal name. In our algorithm we consider the context of a name in a document to be the entire document and extract terms from the entire document. We use *C-value* [6, 7], an automatic term recognition algorithm, to extract multi-word terms.

The *C-value* approach combines linguistic and statistical information. The linguistic information consists of the part-of-speech tagging of the document being processed, the linguistic filter constraining the type of terms extracted and the stop lists. The statistical part combines statistical features of the candidate string. The linguistic filter contains a predefined set of patterns of nouns, adjectives and prepositions that are likely to be terms. The stop list is a list of words which are not expected to occur as term words in a given domain. The combinations of nouns, adjectives and prepositions that are allowed by the linguistic filter and the stop list are considered as the potential candidates as terms. The *termhood* (likeliness of a candidate to be a term) is evaluated using C-value. C-value is built using statistical characteristics of the candidate string, such as, the total frequency of occurrence of the candidate string in the document, the frequency of the candidate string as part of other longer candidate strings, the number of these longer candidate terms and the length of the candidate string (in number of words). C-value is defined as follows,

$$C\text{-}value(a) = \begin{cases} \log_2 |a| \cdot f(a) & \text{ais not nested,} \\ \log_2 |a|(f(a) - \frac{1}{P(T_a)} \sum_{b \in T_a} f(b)) & \text{otherwise} \end{cases} \quad (1)$$

where, a is the candidate string, $f(a)$ is its frequency of occurrence in the document, $|a|$ is the length of the candidate string, T_a is the set of extracted candidate terms that contain a , $P(T_a)$ is the number of candidate terms.

3.3 Similarity Calculation

In order to cluster the documents using the term model explained in previous section, we need to calculate the similarity between two documents. Exact matches of terms are rare. Therefore, we would require a similarity metric which is capable of comparing the terms at a semantic level. For example, the two terms *George Bush* and

“George Bush”	“The president of the United States”
(1) Official White House site presents issue positions, news, Cabinet, appointments, offices and major speeches. Includes biography, video tour and photo ...	(1) Whitehouse.gov is the official web site for the White House and President George W. Bush, the 43rd President of the United States.
(2) Official Internet home of the Republican National Committee. Updated daily with news and commentary from the RNC.	(2) Background information, election results, cabinet members, notable events, and some points of interest on each of the presidents.
(3) George Bush (41st President: 1988–1992).	(3) For a list of persons who served as the President of the United States following the ratification of the United States Constitution see the list of ...
(4) Zack Exley’s satirical site of George W. Bush campaign, now quite overt.	(4) A history of presidents, the presidency, politics and related subjects. Includes biographies for every president.
(5) Parody of official White House web site. Includes spoof news and gossip.	(5) ... Presidents of the Continental Congress as well as information about David Rice Atchison who some believe was the 12th President of the United States. ...

Figure 2. Top five snippets extracted for two terms

The *president of the United States* are closely related but do not have any words in common. Word Net⁵ based similarity metrics have been widely used as semantic similarity measures between words in sense disambiguation tasks [16, 3]. However, personal names are not covered in the Word Net. Sahami et al [20] proposes a method to calculate similarity between terms using snippets retrieved by a web search engine. A Snippet is a small piece of text, containing two or three sentences extracted from the document around the query term. Most web search engines provide snippets as short summaries of the search results.

For example, consider the first five snippets returned by Google for *George Bush* and *The president of the United States* in figure 2. Even among the first five snippets for these two terms, we find many common terms such as *President*, *White House*, *Official*, *and*, *site*, etc. For a given term we collect its snippets and construct the distribution of words in the snippet. The frequency of each word in the collection of snippets is divided by the total number of words. We compute Kullback-Liebler (KL) divergence, as a measure of dissimilarity of the two terms. For two probability distributions $p(x)$ and $q(x)$, which are defined over a random variable $x \in X$, their KL-divergence $D(p||q)$ is defined as follows,

$$D(p||q) = \sum_{x \in X} p(x) \log \frac{p(x)}{q(x)}. \quad (2)$$

Therein, X is the vocabulary. KL-divergence becomes undefined when there are words with zero probabilities. Skew divergence is used to overcome this problem [11]. Skew divergence $S_\alpha(p, q)$ is defined as follows,

$$S_\alpha(p, q) = D(q||\alpha p + (1 - \alpha)q). \quad (3)$$

Therein: $\alpha \in [0, 1]$ is the degree of skewness between the two distributions p and q . In order to transform the asymmetrical skew diver-

⁵ <http://wordnet.princeton.edu/perl/webwn>

gence to symmetric similarity measure $\text{sim}(p, q)$, we take the average divergence as follows,

$$\text{sim}(p, q) = \exp(-\frac{1}{2}(S_\alpha(p, q) + S_\alpha(q, p))). \quad (4)$$

In our implementation, we considered the top 100 snippets from Google and set $\alpha = 0.99$.

Let $T(A) = \{a_1, \dots, a_n\}$ be the term model of document A and $T(B) = \{b_1, \dots, b_m\}$ the term model of document B . Here, a_1, \dots, a_n are n terms extracted from document A and b_1, \dots, b_m are m terms extracted from document B . We define the similarity, $\text{DocSim}(A, B)$, between two documents A and B using their term models $T(A), T(B)$ as follows,

$$\text{DocSim}(A, B) = \frac{1}{mn} \sum_{a_i \in A; b_j \in B} \text{sim}(a_i, b_j). \quad (5)$$

Here, $\text{sim}(a_i, b_j)$ is calculated using equation 4 based on the probability distributions.

3.4 Clustering

We use group-average agglomerative clustering (GAAC) to cluster the documents to their namesakes. Initially, each document is assigned to a separate cluster. GAAC in each iteration executes the merger that gives rise to the cluster Γ with the largest average correlation $C(\Gamma)$ where,

$$C(\Gamma) = \begin{cases} \frac{1}{2} \frac{1}{|\Gamma|(|\Gamma|-1)} \sum_{u \in \Gamma} \sum_{v \in \Gamma} \text{DocSim}(u, v) & |\Gamma| = 1, \\ \text{otherwise.} & \end{cases} \quad (6)$$

Therein: $|\Gamma|$ denotes the number of documents in the merged cluster Γ ; u and v are two documents in Γ and $\text{DocSim}(u, v)$ is given by equation 5.

3.5 Cluster Quality

Ideally, clustering process should terminate when the number of formed clusters matches the number of different namesakes in the document collection. However, in real world problems the number of namesakes for a given name is not known. Clustering in general can be considered as an optimizing problem. In clustering we try to;

1. maximize the similarity of documents within a cluster,
2. minimize the similarity of documents between clusters.

We prefer our clusters to be well correlated internally and each of the clusters to be different among themselves. The quality (goodness) of the formed clusters can be evaluated based on how well the clusters satisfy these two conditions [10]. We define *internal correlation* as a measure of how well the first condition is satisfied (i.e. the degree of similarity of documents within clusters). Internal correlation, $\text{IntCor}(\Lambda)$, of a set Λ of n clusters c_1, c_2, \dots, c_n is defined as follows,

$$\text{IntCor}(\Lambda) = \frac{1}{n} \sum_{\Gamma \in \Lambda} C(\Gamma). \quad (7)$$

Where, $C(\Gamma)$ is the average correlation defined in equation 6. We define *external correlation* as a measure of how well the second condition is satisfied. Using the above notation, external correlation, $\text{ExtCor}(\Lambda)$, is defined as the dis-similarity between the two most similar clusters in Λ as follows,

$$\text{ExtCor}(\Lambda) = 1 - \frac{1}{|\Gamma_a||\Gamma_b|} \sum_{u \in \Gamma_a} \sum_{v \in \Gamma_b} \text{DocSim}(u, v). \quad (8)$$

Where,

$$(\Gamma_a, \Gamma_b) = \arg_{\Gamma_i, \Gamma_j \in \Lambda} \min C(\Gamma_i \oplus \Gamma_j) \quad (9)$$

and the operator \oplus denotes the merging operation between two clusters. Using equations 7 and 8 we define *Cluster Quality*, $Q(\Lambda)$, as follows,

$$Q(\Lambda) = \frac{1}{2} (\text{IntCor}(\Lambda) + \text{ExtCor}(\Lambda)). \quad (10)$$

To label the clusters we select all the terms that appear in a cluster for a certain namesake but do not appear in other clusters.

4 Results and Discussion

4.1 Test Data

We evaluated our algorithm on pseudo names as well as naturally ambiguous names. For automated pseudo name evaluation purposes, we collected 150 (50 per person) documents from the web for three different people for conflation. Our collection contains documents for *Maria Sharapova* the tennis player, *Bill Gates* chairman Microsoft and *Bill Clinton* former president of the United States. We then replace every occurrence of these names in the documents with *person-x*. We evaluate the algorithm on naturally ambiguous names such as *Jim Clark*, *William Cohen*, *Tom Mitchell* and *Michael Jackson*⁶. To evaluate our algorithm on people with different web appearances we tested for *Noam Chomsky*.

⁶ This collection contains 50 documents per ambiguous name

4.2 Disambiguation Accuracy

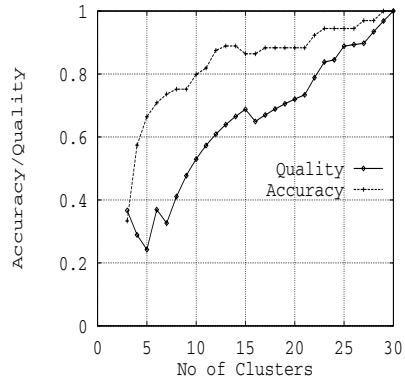

We assign each cluster to the namesake that appears most in that cluster (*holder* of the cluster). Precision, $P(C)$, of cluster C is calculated as follows,

$$P(C) = \frac{\text{No of docs in } C \text{ for its holder}}{\text{Total No of docs in } C}. \quad (11)$$

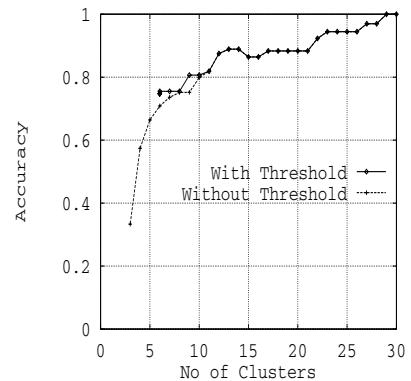

However, some namesakes have lots of documents on them, where as others are mentioned only in few documents. To reflect this fact in our evaluation metric we define *Disambiguation Accuracy*, as the weighted sum of each cluster's precision. Disambiguation accuracy (Accuracy) is defined as follows,

$$\text{Accuracy} = \sum_{C \in \Lambda} P(C) \frac{\text{No of docs in the collection for the holder of } C}{\text{Total No of docs in the collection}}. \quad (12)$$

Where, Λ is the set of clusters and $P(C)$ is given by equation 11.

(a) Accuracy/Quality Vs No of Clusters without Quality Threshold

(b) Accuracy Vs No of Clusters, with and without Quality Threshold

Figure 3. Effect of the quality threshold

Figure 3(a) depicts the accuracy/quality vs the number of clusters in the experiment with pseudo names. It shows that accuracy approximately correlates with cluster quality. This relationship enables us to

guide the clustering process based on unsupervisedly calculated cluster quality. Moreover, figure 3(a) shows that accuracy drops steadily as the number of clusters decreases. This is due to the outliers that get attached to the otherwise pure (representing the dominant namesakes) clusters. To avoid this, we terminate clustering when cluster quality drops below a fixed threshold and classify the remaining documents to the clusters. As seen from figure 3(b), this procedure prevents ill-formed clusters and yields high accuracy values. We experimentally set the cluster quality threshold to 0.6.

Table 1. Accuracy for ambiguous names

Name	Number of namesakes	Proposed	TF IDF
Jim Clark	8	71.95	59.20
Michael Jackson	3	94.96	88.76
William Cohen	10	72.71	57.96
person-X	3	81.10	39.88
Noam Chomsky	2	94.19	82.79

Table 1 shows results of our experiments. We implemented a TF-IDF based clustering algorithm as the baseline for comparison. In the baseline method, each document in the collection is represented by a word vector. We consider all the words (except a fixed list of stop words) in the document and calculate their term frequencies (TF: Term Frequency) in the document. For each word we find the number of documents containing it (DF: document frequency). Using TF,DF values we represent each document as a vector of words, with TF-IDF weights. Similarity between two documents is calculated as the cosine similarity of their word vectors. We then use GAAC to cluster the documents. Base line method utilizes the same cluster quality threshold as the proposed method. However, note that the TF-IDF based method does not produce any key phrases. Table 1 reports higher accuracy values for the proposed method over the baseline. There is a clear advantage to the proposed method over the baseline for person-X collection. Considering the fact that person-X collection contains three very different personalities, their term models are sufficiently discriminative to clearly separate the three personalities. However, for highly ambiguous names table 1 reports comparatively low accuracy values. One reason for this behavior is that, the distribution of documents among namesakes is not being even. Some of the namesakes are not sufficiently represented on the web to build a descriptive term model.

Our algorithm finds key phrases such as *racing driver Jim Clark, Formula One World Championships and motor racing* for the racing car driver-Jim Clark and *Silicon Valley, netscape* for the founder of netscape -Jim Clark. In the case of Michael Jackson, the top ranking terms for the singer are *Fan Club, World network, news, Micheal Jackson case and pop star*. The proposed method had the lowest accuracy for william cohen as it found only three out of the ten namesakes in the collection. In the person-X experiments, we find key phrases such as *first set, US open, Wimbledon, Venus Williams and Grand Slam title* for Maria Sharapova, *wealthiest person, Microsoft* for Bill Gates and *White house, former president* for Bill Clinton. Although, Noam Chomsky is not an ambiguous name, we tested on it to evaluate the algorithm on individuals with different web appearances. Interestingly, the algorithm produces key phrases such as *preventive war, government complicity, George Bush, Tony Blair* in the Chomskey the critic cluster and *universal grammar, linguistic theory* in the Chomskey the linguist cluster.

5 Conclusion

We proposed and evaluated an algorithm to extract key phrases from the web, to disambiguate personal names. The algorithm is unsupervised and uses a cluster quality metric to determine the number of namesakes. Our experiments show encouraging results. In future, we intend to explore the possibilities to extend the proposed method to disambiguate other types of named entities.

History-Based Inside-Outside Algorithm

Heshaam Feili and Gholamreza Ghassem-Sani¹

Abstract. Grammar induction is one of the most important research areas of the natural language processing. The lack of a large Treebank, which is required in *supervised* grammar induction, in some natural languages such as Persian encouraged us to focus on *unsupervised* methods. We have found the Inside-Outside algorithm, introduced by Lari and Young, as a suitable platform to work on, and augmented IO with a history notion. The result is an improved unsupervised grammar induction method called History-based IO (HIO). Applying HIO to two very divergent natural languages (i.e., English and Persian) indicates that inducing more conditioned grammars improves the quality of the resultant grammar. Besides, our experiments on ATIS and WSJ show that HIO outperforms most current unsupervised grammar induction methods.

1 INTRODUCTION

With the recent increasing interest in statistical approaches to natural language processing, *corpus* based linguistics has become a hot topic. This is due to the fact that computer based texts are available more than ever before, and easier to use for various data tasks. The success of part-of-speech tagging by using the Hidden Markov Model (HMM) [1, 2] also attracted the attention of computational linguists to the lexical analysis, language modeling, and machine translation by using various statistical methods [3, 4].

Manual design and refinement of a natural language grammar is a difficult and time-consuming task, and requires a large amount of skilled efforts. A hand-crafted grammar is not usually completely satisfactory, and frequently fails to cover many unseen sentences. Automatic acquisition of grammars is a solution to this problem. With the increasing availability of large, machine-readable, parsed corpora such as Penn Treebank [5], there have been numerous attempts to automatically derive a context free grammar by using such corpora [6].

Based on the level of supervision, which is used by different algorithms, grammar induction methods are divided in three main categories: *supervised*, *semi-supervised*, and *unsupervised*. Here, we present a novel unsupervised algorithm named **History-Based Inside-Outside** (HIO) as an extension of the well-known unsupervised **Inside-Outside** algorithm [7]. The experimental results of applying HIO to both English and Persian languages are also demonstrated and compared with that of several other unsupervised approaches.

2 PREVIOUS WORKS

In unsupervised grammar induction methods only tagged sentences without any bracketing information or other supervised information are used. Based on the Expectation Maximization (EM) algorithm, Lari and Young, proposed what they called the *Inside-outside* (IO) algorithm, that constructs a grammar from an unbracketed corpus [7]. The algorithm will converge to a local optimum when used to iteratively re-estimate probabilities on a training corpus in a manner, which maximizes the likelihood of the training corpus, given the grammar. This method is so far one of the basic algorithms for unsupervised automatic learning of grammars [8]. Also, Stolcke and Omohundro induced a small and artificial context free grammar with chunk-merge systems [9]. The results of these approaches for completely unsupervised acquisition showed that they are generally ineffective.

There are also other works to improve the quality of the unsupervised induction methods by considering some limitation or additional information. Magerman and Weir use a distituent grammar to eliminate undesirable rules [10]. Carroll and Charniak, restrict the set of non-terminals that may appear on the right hand side of rules with a given left hand side [11].

One of the most promising classes of unsupervised induction algorithms is based on particular distribution of words in sentences, and uses some distributional evidences to identify constituent structure [12]. Here, the main idea is that sequences of words (or tags) generated by the same non-terminal normally appear in similar contexts [13, 14]. Klein and Manning have introduced a new distributional method for inducing a bracketed tree structure of the sentence, with a dependency model to induces a word-to-word dependency structure [12, 14]. By combining these two models, they have achieved the best result in unsupervised grammar induction so far. Other dependency models with weaker results were presented by [11, 15, 16].

Alignment Based Learning (ABL) is a learning paradigm that can be regarded as a distribution based method. It is based on the principle of substitutability, whereby two constituents are of the same type, and then they could be substituted [17, 18]. Also, Adriaans presents EMILE, which initially used some aspects of supervision, but in later work is modified to be completely unsupervised [19]. Both the ABL and EMILE techniques look for *minimal pairs*; a specific form of distributional learning, where the contexts are the rest of the sentence.

Although supervised methods outperform current unsupervised induction algorithms with a relatively large gap, there are still compelling motivations for working on unsupervised methods [20]. Building supervised training data requires considerable resources, including time and linguistic expertise. This problem is more complicated when we deal with languages other than English,

¹ Department of Computer Engineering, Sharif University of Technology, Tehran, Iran, emails: {hfaili@mehr.sharif.edu, sani@sharif.edu}

which usually lack the necessary resources. Furthermore, the resulting hand-crafted treebank may be too susceptible to restriction to a particular domain, application, or genre [21].

On the other hand, applying probabilistic model to natural languages has been investigated in several works where the independence of the input sentence and its context is assumed in parsing [1, 22]. In fact, most works have used even stronger independence assumptions. For instance, the PCFG model assumes the independence of the probability of each constituent and its neighboring constituents [1]. On the other hand, there are some richer models of context that incorporate some additional information with the probability of each constituent and present a way of calculating the probability model more accurately [22, 23].

There have been some promising works adopted the history based grammar induction methods. For instance, *Pearl* is a probabilistic parser that is more sensitive to the model of context [24]. Using supervised learning methods; *Pearl* acquired 88% of bracketing accuracy.

Another important work, which increases the dependencies on the context, is the *history-based parser* that was originally developed by the researchers at IBM [23, 25]. In these models, the parse-tree representation was enriched in a couple of ways: non-terminal labels were augmented by some extra information such as lexical items and head word. An improvement from 59.8% to 74.6% in parsing accuracy was reported by using this model [23].

The idea of adding the parent of each non-terminal as the conditioning information to the grammar rules was also mentioned in [22, 26, 27]. Replacing $P(\alpha \rightarrow \beta | \alpha)$ by $P(\alpha \rightarrow \beta | \alpha, \text{Parent}(\alpha))$, where $\text{Parent}(\alpha)$ is the non-terminal dominating α , leads to an improvement from 69.6% / 73.5% to 79.3% / 80.1% of the precision/recall metrics. In this paper, we introduce an extension of the IO algorithm augmented by the history notion, and apply it to two very different languages (i.e., English and Persian).

3 HIO ALGORITHM

In this section, we explain HIO, a new estimation model to induce an extended form of a PCFG by using the traditional IO algorithm. Here, the output of IO algorithm and other partial information such as inner and outer probabilities are used as the input data. This information is necessary to calculate the history-based model. The main idea of HIO is to decompose the output probabilities of rules extracted from IO, over their parent non-terminal. This decomposition can guide the parser toward better decisions in analyzing its input sentences.

In order to incorporate the parent non-terminal into the Chomsky normal form, we use the following notation to state the probability of using rule $i \rightarrow jk^2$:

$$A[i, j, k] = P(i \rightarrow jk | i \text{ used in derivation}, C = \text{Parent}(i), C \text{ used in derivation}) \quad (1)$$

Considering the conditional probability:

$$\begin{aligned} p(i \rightarrow jk | i \text{-used}, &= \text{parent}(i), -\text{used}) = \\ p(i \rightarrow jk, C = \text{Parent}(i) | i \text{-used}, C \text{-used}) \\ p(C = \text{parent}(i)) \end{aligned} \quad (2)$$

and $C = \text{Parent}(i)$, we can infer:

$$\forall U (C \rightarrow U i \text{ or } C \rightarrow i U) \quad (3)$$

² For the sake of simplicity, we ignore the assumption of using grammar G in all probabilities. Also, in the remainder of the paper, we use “i-used” to show that non-terminal i has been used in the derivation process.

$$\begin{aligned} p(C = \text{Parent}(i)) &= P(\forall U, C \rightarrow U i) + P(\forall U, C \rightarrow i U) - \\ P(C \rightarrow i) \end{aligned} \quad (4)$$

In the original IO algorithm [7], matrix “ a ” is defined as follows:

$$a[i, j, k] = p(i \rightarrow jk | i \text{-used}) \quad (5)$$

From (3) and (4), we can derive:

$$\begin{aligned} \forall C, \forall i, & p(C = \text{parent}(i)) = \\ \sum_u a[c, u, i] + \sum_u a[c, i, u] - a[c, i, i] \end{aligned} \quad (6)$$

By the assumption of having observation O , we obtain:

$$p(C \Rightarrow^* O(s) \dots O(t) | S \Rightarrow^* O, G) = e(s, t, C) \cdot f(s, t, C) / P \quad (7)$$

where $P = p(S \Rightarrow^* O | G)$, and $e(s, t, C)$ and $f(s, t, C)$ are the inner and outer probabilities, respectively.

But:

$$e(s, t, i) = \sum_{j, k} [\sum_{r=s}^{t-1} a[i, j, k] \cdot e[s, r, j] \cdot e(r+1, t, k)] \quad (8)$$

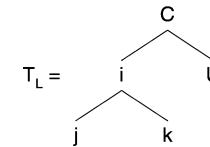

Thus, if at the first step of derivation starting from non-terminal C , rule “ $C \rightarrow i U$ ” is used, and by considering definitions of the inner probability (i.e., eq. 8) and matrix a (i.e., eq. 5), we can derive:

$$\begin{aligned} p(C \rightarrow iU \Rightarrow O(s) \dots O(t) | S \Rightarrow O, G) &= \\ \frac{1}{P} \sum_{r=s}^{t-1} \sum_{v=r}^{t-1} a[C, i, U] \cdot e(s, r, i) \cdot e(r+1, t, U) \cdot f(s, t, C) \quad \forall i, U, t > s \end{aligned} \quad (9)$$

Supposing that in the next step of the derivation, rule “ $i \rightarrow jk$ ” is used, the following equation holds:

$$\begin{aligned} p(C \rightarrow iU \rightarrow (jk)U \Rightarrow O(s) \dots O(t) | S \Rightarrow O, G) &= \\ \frac{1}{P} \sum_{r=s}^{t-1} \sum_{v=r}^{t-1} \sum_{w=v+1}^{t-1} a[C, i, U] \cdot e(s, r, i) \cdot e(r+1, t, U) \cdot f(s, t, C) \quad \forall i, j, U, t > s \end{aligned} \quad (10)$$

By naming the next left branching tree as T_L , we can rewrite equation (10) as follows:

$$p(T_L, i\text{-used}, C\text{-used}) = \text{equation (10)} \quad (11)$$

Therefore:

$$p(T_L | i\text{-used}, C\text{-used}) = \text{equation (10)} / P(i\text{-used}, C\text{-used}) \quad (12)$$

By assuming the independence of using non-terminals i and C , we have:

$$p(i\text{-used}, C\text{-used}) = p(i\text{-used}) \cdot p(C\text{-used}) \quad (13)$$

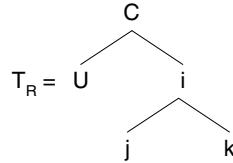

And from (12) and (13), we get the following equation:

$$p(T_L | i\text{-used}, C\text{-used}) = \text{equation(10)} / (p(i\text{-used}) \cdot p(C\text{-used})) \quad (14)$$

Equation (15) can be derived in a way similar to that of (10):

$$\begin{aligned} p(C \rightarrow U_i \rightarrow U(jk) \Rightarrow O(s) \dots O(t) | S \Rightarrow O, G) &= \\ \frac{1}{P} \sum_{r=s}^{t-1} a[C, U, i] \cdot \sum_{v=r+1}^{t-1} a[i, j, k] \cdot e(r, v, j) \cdot e(v+1, t, k) \cdot e(s, r, U) \cdot f(s, t, C) \quad \forall i, j, U, t > s \end{aligned} \quad (15)$$

And by defining T_R , as follows:

$$p(T_R \mid i\text{-used}, C\text{-used}) = \text{equation(15)} / (P(i\text{-used}) \cdot P(C\text{-used})) \quad (16)$$

Now, we can evaluate the main equation:

$$\begin{aligned} p(i \rightarrow jk, C = \text{Parent}(i) \mid i\text{-used}, C\text{-used}) &= \\ \Sigma_U p(i \rightarrow jk, (C \rightarrow U_i \text{ or } C \rightarrow iU) \mid i\text{-used}, C\text{-used}) &= \\ \Sigma_U p(i \rightarrow jk, C \rightarrow U_i \mid i\text{-used}, C\text{-used}) + \\ P(i \rightarrow jk, C \rightarrow iU \mid i\text{-used}, C\text{-used}) - \\ p(i \rightarrow jk, C \rightarrow ii \mid i\text{-used}, C\text{-used}) \end{aligned} \quad (17)$$

T_L and T_R are equal to:

$$T_L = \{ C \rightarrow i \text{ } U, i \rightarrow jk \}, T_R = \{ C \rightarrow U \text{ } i, i \rightarrow jk \} \quad (18)$$

By replacing T_L and T_R in (17), one gets:

$$\begin{aligned} p(i \rightarrow jk, C = \text{Parent}(i) \mid i\text{-used}, C\text{-used}) &= \\ \text{eq.(14)} + \text{eq.(16)} - \\ p(C \rightarrow i \text{ } i \rightarrow (jk) \text{ } i \rightarrow (jk)(jk) \mid i\text{-used}, C\text{-used}) \end{aligned} \quad (19)$$

The last term of (19), can be computed by using (10), where U is initialized to i and later expanded by $i \rightarrow jk$. Thus:

$$\begin{aligned} p(C \rightarrow i \text{ } i \rightarrow (jk) \text{ } i \rightarrow (jk)(jk) \Rightarrow O(s) \dots O(t) \mid S \Rightarrow O, G) &= \\ \frac{1}{P} \sum_{r=s}^{t-1} a[C, i, i].f(s, t, C). & \\ \sum_{v=s}^{r-1} a[i, j, k].e(s, v, j).e(v+1, r, k). & \\ \sum_{w=r+1}^{t-1} a[i, j, k].e(r+1, w, j).e(w+1, t, k) \quad \forall i, j, t > s & \end{aligned} \quad (20)$$

The third line of equation (20) is equal to $e(s, r, j)$ and the fourth line is $e(r+1, t, i)$ (see [7]).

The probability of using any non-terminal i in a derivation, is computed as in [7]:

$$p(i\text{-used}) = \sum_{s=1}^T \sum_{t=1}^T \frac{1}{P} e(s, t, i).f(s, t, i) \quad (21)$$

Considering equations (2), (5), (9), (20) and (21), we can compute the probability mentioned in (1), which is the main parameter of the history-based model:

$$\begin{aligned} p(i \rightarrow jk \mid i\text{-used}, C = \text{Parent}(i), C\text{-used}) &= \\ (\text{eq.(14)} + \text{eq.(16)} - \text{eq.(20)}) / \text{eq.(21)} & \end{aligned} \quad (22)$$

The last equation, denoted by $A/C, i, j, k$, is the main estimation formula used by HIO for supporting the history-based model.

In a similar manner, the second form of Chomsky rules ($i \rightarrow m$), can be extended to support probability of using such rules, considering parent non-terminals as well.

After evaluation of parameter matrices a and b in the traditional IO algorithm, we evaluate matrices A and B . The main iteration of inside-outside algorithm will be terminated when changes in the overall probability of observations is less than a pre-defined threshold.

The HIO model induced by the mentioned approach assumes parent non-terminals in the parsing. Therefore, the algorithm which is used during the parsing time, should consider the parent non-

terminal too. An extension of PCYK algorithm described in [27] is used for this purpose.

4 EXPERIMENTAL RESULTS

Two kinds of experiments are presented in this section. At first the results of evaluating HIO on a number of English data sets are demonstrated. Then the results of applying HIO to Persian, which is essentially very different from English, are also discussed. HIO was tested on both ATIS [28] and Wall Street Journal [6]. In order to be able to compare with others' work, we selected these data sets for testing the induced grammar. We used only POS tag sequences as the lexical information of the training and testing data sets.

We executed two different experiments on English sentences. At first, as in other works, ATIS was divided into two distinct sets: the *training* set with approximately 90% of data and the *test* set (i.e., remaining 10%). Note that although our approach is unsupervised and does not need a bracketing data set, we need the tree style of syntactic information of the test data set for the evaluation purpose. The results were computed using the so-called ten fold cross validation method. In the second experiment, 7400 sentences shorter than 11 words of the Wall Street Journal (WSJ-10) were selected. This data set was the main corpus used in training of HIO, and the induced grammar was tested on both ATIS and WSJ, too.

The initial grammar of IO is a full grammar, which contains all possible CNF rules, with random probabilities assigned to each rule. To alleviate the algorithm from any possible bias, the process was repeated one hundred times with different initial probabilities.

The outputs of all experiments were evaluated on a test corpus by using the extended PCYK parsing algorithm. This algorithm gets the extended model of PCFG and a test sentence, generates all possible parses of the input sentence in a dynamic programming manner, and selects the most probable parse. Then the parsed sentences were evaluated by comparison against the corresponding treebank of the same corpus.

In the first experiment, we selected spoken-language transcription of the Texas Instruments subset of the Air Travel Information System (ATIS) corpus [28]. This corpus, which has been automatically labeled, analyzed and manually checked, is included in Penn Treebank II [5]. There are two different pieces of labeling information in the Treebank: a part of speech tag and a syntactic labeling. We used 577 sentences of the corpus with 4609 words. We ran the experiments with both 5 and 15 non-terminals³, and every experiment was also repeated one hundred times. The means of the results from both IO and HIO, and the standard deviations of the latter are shown in table 1.

Table 1. the results of IO and HIO on ATIS data set

No. of non-terminals = 5			
	UP	UR	F1
IO	30.03	25.27	27.45
HIO	42.54(3.15)	38.95(5.8)	40.67(6.8)
No. of non-terminals = 15			
	UP	UR	F1
IO	42.19	35.51	38.56
HIO	46.85(3.2)	40.9(5.9)	43.67(3.9)

As it is shown, HIO significantly outperforms IO on the mentioned corpus. Moreover, the ratio of improvement of IO is

³ By considering the NULL non-terminal, the numbers of used non-terminal in these experiments are 6 and 16 respectively.

very sensitive to the number of non-terminals. In other words, the number of non-terminals used in the IO algorithm has a remarkable impact on the accuracy of the induced grammar; while HIO's accuracy improvement is much less dependent on this factor. This is due to the structure of the richer model used by HIO⁴.

To compare HIO with other unsupervised methods, we collected the results of testing several different approaches on ATIS data set in table 2: EMILE [19], ABL [17], CDC with 40 iterations [13], and CCM [14]. LEFT and RIGHT are left- and right-branching baselines applied to ATIS. The results of LEFT and RIGHT baselines have been taken from [14].

HIO was trained on two different data sets. It was trained on WSJ-10, and tested on ATIS data set. Then it was also trained on 90% of ATIS, and tested on the remaining 10%. The second experiment was evaluated by the ten fold cross validation method. HIO-WSJ and HIO-ATIS respectively correspond to these two experiments.

Table 2. the results of different approaches on ATIS data set

Method	UP	UR	F1
EMILE	51.59 (2.70)	16.81 (0.69)	25.35 (1.00)
ABL	43.64 (0.02)	35.56 (0.02)	39.19 (0.02)
CDC-40	53.4	34.6	42.0
CCM	55.4	47.6	51.2
LEFT	19.89	16.74	18.18
RIGHT	39.9	46.4	42.9
IO	42.19	35.51	38.56
HIO-WSJ	45.2 (2.6)	41.6 (1.5)	43.32 (1.9)
HIO-ATIS	46.85 (3.2)	40.9 (5.9)	43.67 (4.15)

As it's shown, HIO's output is superior to that of all other mentioned works except CCM, which seems to be the current state of the art in unsupervised grammar induction. Also, results of HIO-ATIS are better than that of HIO-WSJ because the test and training data set have been selected from the same corpus.

We also tested HIO on WSJ in order to compare it with other published works, especially with CCM [14]. The mean value of F1 score for HIO and other different methods on WSJ-10 are shown in Figure 1⁵. RANDOM selects a tree uniformly at random from the set of binary trees. DEP-PCFG is the result of duplicating the experiments of [11], using EM to train a dependency structured PCFG. SUP-PCFG is a supervised PCFG parser trained on a 90-10 split of WSJ-10 data set, using the treebank grammar with the Viterbi parse right-binarianized. UBOUND is the upper bound of how well a binary system can cope with the treebank sentences that are generally flatter rather than being binary, limiting the maximum achievable precision. As it is shown, although HIO outperforms the right-branching baseline, CCM still has the best rank among unsupervised methods.

We have also tested HIO on Persian, which is linguistically very divergent from English [3]. In order to test HIO on Persian, we manually produced a treebank adopting different notions of the Penn Treebank. We chose a data set called *Peykareh* as the initial corpus for our experiments [29]. This corpus has more than 7000 sentences collected from formal newsletters in Persian. The tag set that was used in the corpus is the same as one used by [30, 31]; however some of the tags were merged in order to be used in the

⁴ Note that HIO uses an extended PCFG model in which each rule is associated with the parent of its left-hand side.

⁵ The higher results on WSJ, compared with that of ATIS, are due to the tendency of ATIS to have shorter constituents, especially with one word. HIO and IO do not bracket single words, and that is why the F1 measure (especially recall) decreases.

syntactical analysis⁶, remaining only 18 POS tags. We selected 2200 sentences shorter than 11 words from *Peykareh* for both HIO and IO. Table 3, shows the results of these experiments.

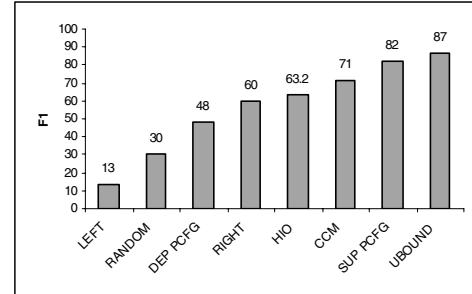

Figure 1. F1 score for various models on WSJ-10

Table 3. the results of IO and HIO on Persian corpus with sentences shorter than 11 words

No. of non-terminals = 5		
	UP	UR
IO	33.25(0.64)	31.93(0.87)
HIO	41.26(1.16)	38.59(2.3)
No. of non-terminals = 15		
	UP	UR
IO	44.35(0.5)	40.1(0.68)
HIO	52.5(1.29)	50.28(1.7)

As it is shown, in Persian too, HIO outperforms IO by more than 20% with respect to the F1 measure. Figure 2 compares the effect of the grammar size (i.e., the number of its non-terminals) on the quality of the induced grammar (again based on F1) in Persian with that of English. This comparison implies that the grammar size affects Persian more than English. In other words, a larger grammar is required to model Persian. That is mainly because Persian is a free-word-order language, and thus harder to model. Therefore, HIO can achieve even better results on free-word order languages by using larger grammars.

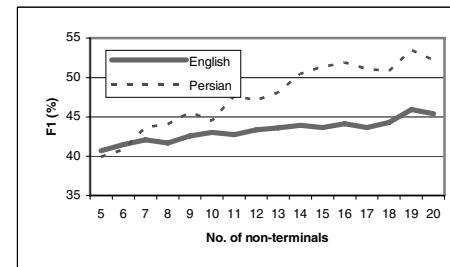

Figure 2. The effect of the grammar size on F1 measure in English and Persian

5 CONCLUSION

We showed that adding the parent non-terminal label to the rule assumptions increases the quality of output grammar. In other words, by relaxing the flawed independence assumption, we can construct a richer model of unsupervised grammar induction method. It might be the case that augmenting the model with some

⁶ The tag set presented by [29, 31] was used only for morphological analysis tasks; the set needed to be re-arranged and merged in a syntactical analysis view.

other conditions further improves the accuracy of the results. However, adding extra conditions to the model may also cause an exponential increase in the size of the output grammar, which hampers the parsing process.

We introduced HIO, a new approach based on the well-known IO algorithm for inferring stochastic context-free grammars. We relaxed the independence assumptions often used with the PCFG rules in the parsing process by adding some extra information about the context to the derivation process. Here, the parent non-terminal, which dominates the PCFG rule, was chosen as the contextual information.

The new method was applied to both English and Persian languages. The results showed a significant superiority over almost all other unsupervised methods. The results on Persian was even more prominent though it is a free-word-order language and harder to model. CCM, a distributional algorithm based on the idea that similar words occur in similar contexts [14], is the only unsupervised method that outperforms HIO on English. However, as it was also pointed out by Clark [11], we think that distributional methods might not be applicable to free-word-order languages, and intend to verify that.

Shallow Semantic Parsing Based on FrameNet, VerbNet and PropBank

Ana-Maria Giuglea¹ and Alessandro Moschitti²

Abstract. This article describes a semantic parser based on FrameNet semantic roles that uses a broad knowledge base created by interconnecting three major resources: FrameNet, VerbNet and PropBank. We link the above resources through a mapping between Intersective Levin classes, which are part of PropBank's annotation, and the FrameNet frames. By using Levin classes, we successfully detect FrameNet semantic roles without relying on the frame information. At the same time, the combined usage of the above resources increases the verb coverage and confers more robustness to our parser. The experiments with Support Vector Machines on automatic Levin class detection suggest that (a) tree kernels are well suited for the task and (b) Intersective Levin classes can be used to improve the accuracy of semantic parsing based on FrameNet roles.

1 INTRODUCTION

Knowing the semantic roles played by the entities that appear in a sentence is of major importance for understanding its underlying meaning. The inherent word ambiguity can lead to very different readings of the same sentence. One important step towards deciding the correct reading is to find the sense of the verb in the sentence.

The previous point was highlighted by the results, obtained with and without the frame information during the Senseval-3 competition on FrameNet [10] role labeling task [17]. When such information was not used by the systems, the performance drop was more than 10 percent points. This is quite intuitive as the semantics of many roles strongly depend on the focused frame. Thus, we cannot expect a good performance when this information is not available.

A solution to this problem is the automatic frame detection. Unfortunately, our preliminary experiments showed that given a FrameNet (FN) predicate-argument structure, the task of identifying the associated frame can be performed with very good results when the verb predicates have enough training examples, but becomes very challenging otherwise. The predicates not yet included in FN, e.g. belonging to new application domains, are especially problematic since there is no training data available. In such cases the frame classifier reaches very low accuracy (under 50%).

We have thus studied new means of capturing the semantic context, other than the frame, which can be easily annotated on FrameNet and are available on a larger scale (i.e. have a better coverage). A very good candidate seems to be the Intersective Levin class information [2] that can be found as well in other predicate resources like PropBank and VerbNet.

In this paper:

² University of Rome "Tor Vergata": moschitti@info.uniroma2.it

1. we employ SVM Tree Kernels and structural features [19] for automatic token-based verb classification³ of the Intersective Levin classes (ILCs);
2. we use the classifiers trained in step 1 to automatically annotate FrameNet with Levin class information which is needed for the semantic role labeling (SRL) task; and
3. we test the effectiveness of the ILC information in the FrameNet SRL task.

On FrameNet, we obtain the gold Levin class annotation through a mapping between Intersective Levin classes and FrameNet frames [7]. This mapping employs also the PropBank corpus [11] and the VerbNet lexicon [12].

In the remainder of this paper Section 2 and 3 introduce the resources used by our study, namely VerbNet, PropBank and FrameNet, Section 4 summarizes previous work on Levin verb sense disambiguation, Section 5 focuses on Tree Kernels and the features used while Section 6 contains a description of the performed experiments. Finally, Section 7 presents our results and conclusions.

2 LEVIN AND PROPBANK

Levin clusters [15] are formed according to diathesis alternation criteria which are variations in the way verbal-arguments are grammatically expressed when a specific semantic phenomenon arises. For example, two different types of diathesis alternations are the following:

- (a) Middle Alternation

[Subject, Agent The butcher] cuts [Direct Object, Patient **the meat**].
[Subject, Patient **The meat**] cuts easily.
- (b) Causative/inchoative Alternation

[Subject, Agent Janet] broke [Direct Object, Patient **the cup**].
[Subject, Patient **The cup**] broke.

In both cases, what is alternating is the grammatical function that the Patient role takes when changing from the transitive use of the verb to the intransitive one. The semantic phenomenon accompanying these types of alternations is the change of focus from the entity performing the action to the theme of the event.

Levin documented 79 alternations which constitute the building blocks for the verb classes. Although alternations are chosen as the primary means for identifying the classes, additional properties related to subcategorization, morphology and extended meanings of

³ The best semantic class is determined for the verb token given the local context of the phrase rather than using the set of verb occurrences across a corpus or a document (i.e. type-based classification).

verbs are taken into account as well. Thus, from a syntactic point of view, the verbs in one Levin class have a regular behavior, different from the verbs pertaining to other classes. Also, the classes are semantically coherent and all verbs belonging to one class share the same participant roles.

This constraint of having the same semantic roles is further ensured inside the VerbNet lexicon which is constructed based on a more refined version of the Levin classification called Intersective Levin classes [2]. The lexicon provides a regular association between the syntactic and semantic properties of each of the described classes. It also provides information about the syntactic frames (alternations) in which the verbs participate together with the set of possible semantic roles.

One corpus associated with the VerbNet lexicon is PropBank. The annotation scheme of PropBank ensures that the verbs belonging to the same Levin class and exhibiting the same diathesis alternations share similarly-labeled arguments. Inside one Levin class to one argument corresponds one semantic role numbered sequentially from Arg0 to Arg5. Higher numbered argument labels are less consistent and assigned per verb basis.

Besides semantic roles, PropBank is annotated also with Intersective Levin class information and contains gold parse trees. These features made PropBank very suitable for testing the effectiveness of our Tree Kernel approach for ILC detection. We were able to measure the accuracy of our machine learning algorithm in the presence of gold predicate-argument structures, which gave us a performance upper bound.

During the second step (i.e. annotating FrameNet with ILC), in order to train ILC classifiers also on FrameNet we need gold Intersective Levin class annotations. To achieve that we employed a semi-automatic algorithm that mapped FrameNet frames to Levin classes, thus assigning gold ILC to FrameNet. More details about FrameNet and the mapping algorithm are presented in the next section.

3 LEVIN AND FRAMENET

One of the goals of the FrameNet project is to design a hierarchical linguistic ontology that can be used for automatic processing of semantic information. This hierarchy contains an extensive semantic analysis of verbs, nouns, adjectives and situations in which they are used, called frames. The basic assumption on which the frames are built is that each word evokes a particular situation with specific participants [5]. The situations depict the entities involved and the roles they play. The word that evokes a particular *frame* is called *target word* or predicate and can be an adjective, noun or verb. The participant entities are defined using semantic roles and they are called *frame elements*.

Predicates belonging to the same FrameNet frame were proven [6] to have a coherent syntactic behavior that is also different from predicates pertaining to other frames. This finding is consistent with the assumption on which Levin's verb classification is build. This insight determined us to study the relation between FrameNet frames and Levin classes.

The Levin classes were constructed based on regularities exhibited at grammatical level and the resulting clusters were shown to be semantically coherent. As opposed, the FrameNet frames were build on semantic bases, by putting together verbs, nouns and adjectives that evoke the same situations. Although different in conception, the FrameNet verb clusters and VerbNet verb clusters have common properties:

1. Different syntactic properties between distinct verb clusters (as proven by the experiments in [6])
2. Shared sets of possible semantic roles for all verbs pertaining to the same cluster.

Having these insights, we have assigned a correspondent VerbNet class not to each verb predicate but rather to each frame. In doing this we have applied the simplifying assumption that a frame has a unique corresponding Levin class. Thus, we have created a one-to-many mapping between the Levin classes and the frames.

The mapping algorithm consists of three steps: (a) we link the frames and Intersective Levin verb classes that have the largest number of verbs in common and we create a set of pairs $\langle FN \text{ frame}, VN \text{ class} \rangle$ (see Table 1); (b) we refine the pairs obtained in the previous step based on diathesis alternation criteria, i.e. the verbs pertaining to the FN frame have to undergo the same diathesis alternation that characterize the corresponding VN class and (c) we manually check the resulting mapping.

INPUT
$VN = \{C C \text{ is a VerbNet class}\}$
$VN \text{ Class } C = \{v v \text{ is a verb of } C\}$
$FN = \{F F \text{ is a FrameNet frame}\}$
$FN \text{ frame } F = \{v v \text{ is a verb of } F\}$
OUTPUT
$Pairs = \{(F, C) F \in FN, C \in VN : F \text{ maps to } C\}$
COMPUTE PAIRS:
<i>Let Pairs = \emptyset</i>
<i>for each $F \in FN$</i>
<i>(I) compute $C^* = \arg \max_{C \in VN} F \cap C$</i>
<i>(II) if $F \cap C^* \geq 3$ then $Pairs = Pairs \cup \langle F, C^* \rangle$</i>

Table 1. Linking FrameNet frames and VerbNet classes.

During the second step of the mapping we make use of the property (2) of the Levin classes and FN frames presented in this section. According to this property, all verbs pertaining to one frame or Levin class have the same participant roles. Thus, a first test of compatibility between a frame and a Levin class is that they share the same participant roles. As FN is annotated with frame-specific semantic roles, we manually mapped these roles into the VN set of thematic roles. Given a frame, we assigned thematic roles to all frame elements that are associated with verbal predicates. For example the *Speaker*, *Addressee*, *Message* and *Topic* roles from the *Telling* frame were respectively mapped into the *Agent*, *Recipient*, *Theme* and *Topic* theta roles.

After the role matching, the mapping algorithm checks both the syntactic and semantic consistency by comparing the role frequency distributions on different syntactic positions for the two candidates. More details are given in [7]. We mention that the algorithm identifies correctly the cases for which our simplifying assumption does not hold, having an overall accuracy of 89.6%.

Having gold ILC annotation on FrameNet allows us to train Intersective Levin class classifiers also on this corpus. In this way, we can extend the verb coverage to encompass both PropBank and FrameNet.

In the next sections we describe our approach on ILC automatic detection and also some of the literature work on this subject.

4 PREVIOUS WORK ON LEVIN CLASS DETECTION

Levin's verb classification is based on straightforward syntactic criteria which makes it especially appealing for automation. As a consequence, it was used in many different studies ranging from machine translation [3] and information retrieval [16] to automatic acquisition of lexical semantic information and creation of dictionaries [4].

Regarding automatic verb classification, most of the previous studies focused on type-based classification. We mention Merlo and Stevenson [18, 21] who use grammatical features to classify verbs into three classes: unergative, unaccusative and object-drop. These classes comprise several Levin classes and were chosen because they participate in similar alternations (i.e. transitive alternations) but they assign different thematic roles to their arguments.

In their study, Merlo and Stevenson investigate to what extent features extracted from the predicate argument structures are useful for disambiguating among unergative, unaccusative and object-drop. Some of the most successful features used were Causativity and Transitivity. Causativity feature is a marker for verbs participating in causative alternations (e.g. the sentences of the example (b) of Section 2) and measures how many times the same noun occurs as subject and as object of the verb (i.e. the degree of overlap). Transitivity is a binary feature that marks whether the verb is used in a transitive or intransitive form. We will show in the next section that structural features capture both the causative and transitive markers.

Other studies use subcategorization information and selectional restrictions to cluster verbs into Levin compatible classes [8]. The resulting clusters are measured against Levin's classification having a 61% match. Although it is counterintuitive, the selectional preferences for the arguments in the subcategorization frames seem to have a negative impact on performance.

The subcategorization feature is used also in Lapata and Brew's studies [14, 13] which focus on dative and benefactive alternations. They view the choice for a class as being estimated by the joint probability $P(\text{verb}, \text{syntactic frame}, \text{class})$ and they design a distributional model that uses the BNC corpus. The results obtained are very promising considering that only subcategorization information is used (74.6% accuracy for genuinely ambiguous verbs). Also, Lapata and Brew incorporate their distributional model as prior knowledge in a naive Bayes classifier for performing token-level disambiguation. Unfortunately, their results are reported per syntactic frame which makes them hard to compare with ours.

Overall, the previous studies are restricted in scope by focusing only on specific aspects or alternations involved in the Levin's verb classification. One novelty of our approach is the fact that we use corpora that are annotated with Levin class information. Thus, we are able to appreciate better to what extent our method is applicable for Levin class disambiguation in general. Our analysis is conducted on a number of 179 classes that had training examples in the corpora.

In the following section we will present the algorithm and the features used by our model. We will show that structural features include some of the best features developed in the literature like causativity, transitivity and also, the very important subcategorization information.

5 Tree Kernels and Feature Space

The main idea of tree kernels is the modeling of a $K_T(T_1, T_2)$ function which computes the number of common substructures between two trees T_1 and T_2 . Thus, we can use, as features, structures drawn

directly from the syntactic parse tree of the sentence.

The kernel that we employed in our experiments was devised in [19]. We used a reduced version of the predicate-argument structure (Figure 1) which contains also the headwords of the arguments, useful for representing the selectional preferences. This feature is a variant of the SCF feature from [19], but in a reduced format (hereafter called SCF-reduced). In the following figure we present an example of the SCF-reduced feature constructed for the sentences of the example (b) of Section 2.

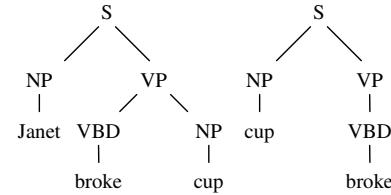

Figure 1. SCF-reduced of the sentences from the example (b) of Section 2

The trees in Figure 1 have respectively 17 and 10 substructures from which 3 are shared (Figure 2).

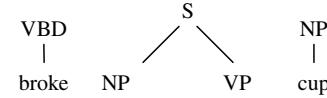

Figure 2. Common substructures of the sentences of Figure 1.

We note that the overlap between "cup" used on the subject position and "cup" used on the object position increases the similarity measure between the two sentences of the example (b). Thus, the Causativity feature from [18] is subsumed by the SCF-reduced feature. Other substructures contain the subcategorization frame with or without the verb marked (Figure 3). As in general the subcategorization frame embeds also the transitivity or intransitivity marker, we conclude that both the Transitivity feature [18] and Subcategorization feature [14, 8] are subsumed by SCF-reduced.

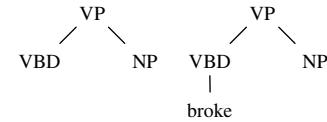

Figure 3. Substructures embedding the Subcategorization feature.

The next section shows that SCF-reduced detects ILCs with high accuracy and is very robust with respect to automatic parse trees and different corpora.

6 EXPERIMENTS

The aim of this research is to show that the ILC feature is very effective for the FrameNet semantic role labeling (SRL) task. For this purpose we carried out several tests.

During our first experiment set we trained (1) an ILC multiclassifier from FN, (2) an ILC multiclassifier from PB and (3) a frame multiclassifier from FN. We compared the results obtained when trying to classify ILCs with the results obtained when classifying frame. We show that ILCs are easier to detect than FN frames.

	run- 51.3.2	cooking -45.3	characterize- 29.2	other_cos- 45.4	say- 37.7	correspond- 36.1	Multiclassifier

LF	79.76	75.00	64.17	80.82	80.99

Table 3. Argument classifier F1s and the overall multiclassifier accuracy for FN semantic role labeling.

Our second set of experiments regards the automatic labeling of FN semantic roles on FN corpus when using as features: gold frame, gold ILC, automatically detected frame and automatically detected ILC. We show that in all situations in which the ILC feature is used, the accuracy loss, compared to the usage of the frame feature, is negligible. We thus show that the ILC can successfully replace the frame feature for the task of semantic role labeling.

Another set of experiments regards the generalization property of the ILC. We show the impact of this feature on SRL when very few training data is available and its evolution when adding more and more training examples. We again perform the experiments for: gold frame, gold ILC, automatically detected frame and automatically detected ILC.

Finally, we simulate the difficulty of free text by annotating PB with FN semantic roles. We used PB because it is different from FN from a domain point of view. This characteristic makes PB a complex test bed for semantic role models trained on FN. In the following section we present the results obtained for each of the experiments mentioned above.

6.1 Experimental setup

The corpora available for the experiments were PB and FN. PB contains about 54,900 sentences and gold parse trees. We used sections from 02 to 22 (52,172 sentences) to train the ILC classifiers and section 23 (2,742 sentences) for testing purposes.

For the experiments on FN corpus, we extracted 58,384 sentences from the 319 frames that contain at least one verb annotation. There are 128,339 argument instances of 454 semantic roles. Only verbs are selected to be predicates in our evaluations. Moreover, as there is no fixed split between training and testing, we randomly selected 20% of sentences for testing and 80% for training. The sentences were processed using Charniak's parser [1] to generate parse trees automatically.

The classification models were implemented by means of the SVM-light-TK software available at <http://ai-nlp.info.uniroma2.it/moschitti> which encodes tree kernels in the SVM-light software [9]. We used the

default parameters. The classification performance was evaluated using the F_1 measure for the single-argument classifiers and the accuracy for the multiclassifiers.

6.2 Automatic VerbNet class vs. automatic FrameNet frame detection

In these experiments, we classify the ILCs on PB and FN and the frames on FN. For the training stage we use SVMs with Tree Kernels.

For ILC detection the results are depicted in Table 2. The first six columns report the F_1 measure of some verb class classifiers whereas the last column shows the global multiclassifier accuracy. We note the ILC results on PB are similar to those obtained for the ILCs on FN. This suggests that the training corpus does not have a major influence. Also, the SCF-based tree kernel seems to be robust with respect to the quality of the parse trees. The performance decay is very small on FN that uses automatic parse trees with respect to PB that contains gold parse trees.

For frame detection on FN, we trained our classifier on 46,734 training instances and tested on 11,650 testing instances, obtaining an accuracy of 91.11%. Consequently, the ILC detection on both PB (92.96%) and FN (92.63%) is more accurate than the frame detection.

6.3 Automatic semantic role labeling on FrameNet

In the experiments involving semantic role labeling, we used SVMs with polynomial kernels. We adopted the standard features developed for semantic role detection by Gildea and Jurafsky : *Predicate*, *Headword*, *Phrase Type*, *Governing Category*, *Position*, *Voice* and *Path*. Also, we considered some of the features designed by [20]: *First and Last Word/POS in Constituent*, *Subcategorization*, *Head Word of Prepositional Phrases* and the *Syntactic Frame* feature from [22]. For the rest of the paper, we will refer to these features as being literature features (LF). The results obtained when using the literature features alone or in conjunction with the gold frame feature, gold ILC, automatically detected frame feature and automatically detected ILC are depicted in Table 3.

The first four columns report the F_1 measure of some role classifiers whereas the last column shows the global multiclassifier accuracy. The first row contains the number of training and testing instances and each of the other rows contains the performance obtained for different feature combinations. The results are reported for the labeling task as the argument-boundary detection task is not affected by the frame-like features [6].

We note that automatic frame produces an accuracy very close to the one obtained with automatic ILCs suggesting that these latter are very good candidate for replacing the frame feature. Also, both automatic features are very effective, decreasing the error rate of 20%.

To test the impact of the ILC feature on SRL with different amount of training data, we additionally draw the learning curves with respect to different features: LF, LF+ gold ILC , LF+automatic ILC trained on PB and LF+automatic ILC trained on FN. As can be noted, the automatic ILC information provided by the ILC classifiers (trained on FN or PB) performs almost as good as the gold ILC (Figure 4).

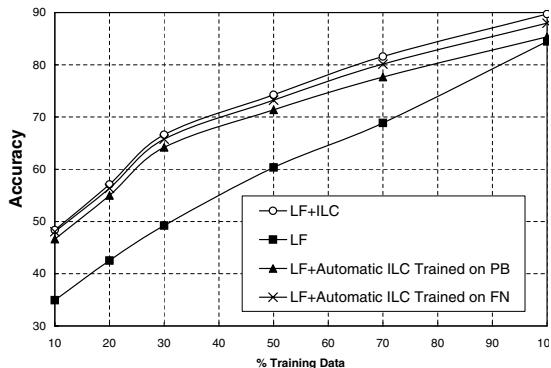

Figure 4. Semantic role learning curve.

6.4 Annotating PB with FN semantic roles

To show that our approach can be suitable for semantic role free-text annotation, we have automatically classified PB sentences with the FN semantic-role classifiers. In order to measure the quality of the annotation, we randomly selected 100 sentences and manually verified them. We measured the performance obtained with and without the automatic ILC feature. The sentences contained 189 arguments from which 35 were incorrect when ILC was used compared to 72 incorrect in the absence of this feature, i.e. an accuracy of 81% with ILC versus 62% without it. This demonstrates the importance of the ILC feature outside the scope of FrameNet where the frame feature is not available.

7 CONCLUSIONS

In this paper, we pursue Levin's thesis and we automatically classify verbs based on their predicate-argument structure and their selectional preferences on different argument slots. We show that Tree Kernels and structural features are more suitable for our goal compared with other methods that use for example linear features. Also, by comparing our structural features with previously developed and linguistically motivated features we found a reasonably degree of overlap. Additionally, we demonstrate that our approach is very robust and can be applied successfully on any type of parse trees (gold or automatic) or corpora.

Regarding the impact of ILC feature on SRL, we have shown that it can replace the frame feature without appreciable accuracy decay. This is very important as (1) several frames are not covered by enough training data and (2) thanks to our mapping algorithm we can reuse the data from PropBank to extend the verb coverage.

Semantic Tree Kernels to classify Predicate Argument Structures

Alessandro Moschitti¹ and Bonaventura Coppola² and Daniele Pighin³ and Roberto Basili⁴

Abstract. Recent work on Semantic Role Labeling (SRL) has shown that syntactic information is critical to detect and extract predicate argument structures. As syntax is expressed by means of structured data, i.e. parse trees, its encoding in learning algorithms is rather complex.

In this paper, we apply tree kernels to encode the whole predicate argument structure in Support Vector Machines (SVMs). We extract from the sentence syntactic parse the subtrees that span potential argument structures of the target predicate and classify them in incorrect or correct structures by means of tree kernel based SVMs. Experiments on the PropBank collection show that the classification accuracy of correct/incorrect structures is remarkably high and helps to improve the accuracy of the SRL task. This is a piece of evidence that tree kernels provide a powerful mechanism to learn the complex relation between syntax and semantics.

1 INTRODUCTION

The design of features for natural language processing tasks is, in general, a critical problem. The inherent complexity of linguistic phenomena, often characterized by structured data, makes difficult to find effective attribute-value representations for the target learning models.

In many cases, the traditional feature selection techniques [8] are not very useful since the critical problem relates to feature generation rather than selection. For example, the design of features for a natural language syntactic parse-tree re-ranking problem [2] cannot be carried out without a deep knowledge about automatic syntactic parsing. The modeling of syntax/semantics-based features should take into account linguistic aspects to detect the interesting context, e.g. ancestor nodes or semantic dependencies [15].

A viable alternative has been proposed in [3], where convolution kernels were used to implicitly define a tree substructure space. The selection of the relevant structural features was left to the voted perceptron learning algorithm. Such successful experimentation shows that tree kernels are very promising for automatic feature engineering, especially when the available knowledge about the phenomenon is limited.

In a similar way, automatic learning tasks that rely on syntactic information may take advantage of a tree kernel approach. One of such tasks is the Semantic Role Labeling (SRL), as defined e.g. in [1] over the PropBank corpus [7]. Most literature work models SRL as the classification of tree nodes of the sentence parse containing the target predicate. Indeed, a node can uniquely determine the set of words that compose an argument (boundaries) and provide, along

with the local tree structure, information useful to the classification of the role. Accordingly, most SRL systems split the labeling process into two different steps: Boundary Detection (i.e. determine the text boundaries of predicate arguments) and Role Classification (i.e. labeling such arguments with a semantic role, e.g. Arg0 or Arg1).

Both the above steps require the design and extraction of features from the parse tree. Capturing the interconnected relationships among a predicate and its arguments is a hard task. To decrease such complexity we can design features considering a predicate with only one argument at a time, but this limits our ability to capture the semantics of the whole predicate structure. An alternative approach to engineer syntactic features is the use of tree kernels as the substructures that they generate potentially correspond to relevant syntactic clues.

In this paper we use tree kernels to model classifiers that decide if a predicate argument structure is correct or not. We apply a traditional boundary classifier (*TBC*) [11] to label all parse tree nodes that are potential arguments, then we classify the syntactic subtrees which span the predicate-argument dependencies, i.e. Predicate Argument Spanning Trees (*PASTs*). Since the design of effective features to encode such information is not simple, tree kernels are a very useful method. To validate our approach we experimented tree kernels with Support Vector Machines for the classification of *PASTs*. The results show that this classification problem can be learned with high accuracy (about 88% of F_1 -measure⁵) and the impact on the overall SRL labeling accuracy is also relevant.

The paper is organized as follows: Section 2 introduces the Semantic Role Labeling based on SVMs and the tree kernel spaces; Section 3 formally defines the *PASTs* and the algorithm to classify them; Section 4 shows the comparative results between our approach and the traditional one; Section 5 presents the related work; and finally, Section 6 summarizes the conclusions.

2 SEMANTIC ROLE LABELING

In the last years, several machine learning approaches have been developed for automatic role labeling, e.g. [5, 11]. Their common characteristic is the adoption of attribute-value representations for predicate-argument structures. Accordingly, our basic system is similar to the one proposed in [11] and is hereby described.

We use a boundary detection classifier (for any role type) to derive the words compounding an argument and a multiclassifier to assign the role (e.g. ARG0 or ARG1) described in PropBank [7]). To prepare the training data for both classifiers, we used the following algorithm:

- Given a sentence from the *training-set*, generate a full syntactic parse tree;

⁵ F_1 assigns equal importance to Precision P and Recall R , i.e. $F_1 = \frac{2P \times R}{P + R}$.

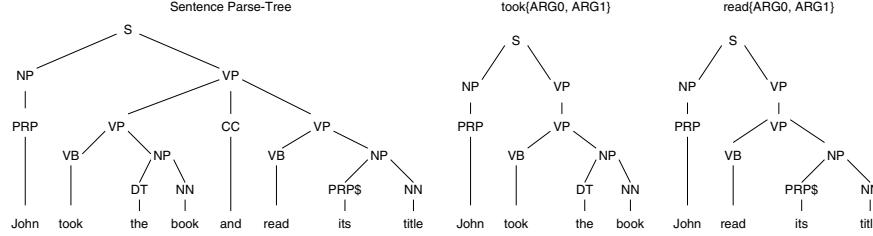

Figure 1. A sentence parse tree with two predicative subtree structures (*PASTs*)

2. Let P and A be respectively the set of predicates and the set of parse-tree nodes;

3. For each pair $\langle p, a \rangle \in P \times A$:

- extract the feature representation set, $F_{p,a}$;
- if the subtree rooted in a covers exactly the words of one argument of p , put $F_{p,a}$ in the T^+ set (positive examples), otherwise put it in the T^- set (negative examples).

The outputs of the above algorithm are the T^+ and T^- sets. For the subtask of Boundary Detection these can be directly used to train a boundary classifier (e.g. an SVM). Concerning the subtask of Role Classification, the generic binary role labeler for role r (e.g. an SVM) can be trained on the T_r^+ , i.e. its positive examples and T_r^- , i.e. its negative examples, where $T^+ = T_r^+ \cup T_r^-$, according to the ONE-vs-ALL scheme. The binary classifiers are then used to build a general role multiclassifier by simply selecting the argument associated with the maximum among the classification scores resulting from the individual binary SVM classifiers.

Regarding the design of features for predicate-argument pairs, we can use the attribute-values defined in [5] or tree structures [10]. Although we focus on the latter approach, a short description of the former is still relevant as they are used by *TBC*. They include the *Phrase Type*, *Predicate Word*, *Head Word*, *Governing Category*, *Position* and *Voice* features. For example, the *Phrase Type* indicates the syntactic type of the phrase labeled as a predicate argument and the *Parse Tree Path* contains the path in the parse tree between the predicate and the argument phrase, expressed as a sequence of nonterminal labels linked by direction (up or down) symbols, e.g. $V \uparrow VP \downarrow NP$.

A viable alternative to manual design of syntactic features is the use of tree-kernel functions. These implicitly define a feature space based on all possible tree substructures. Given two trees T_1 and T_2 , instead of representing them with the whole fragment space, we can apply the kernel function to evaluate the number of common fragments.

Formally, given a tree fragment space $\mathcal{F} = \{f_1, f_2, \dots, f_{|\mathcal{F}|}\}$, the indicator function $I_i(n)$ is defined, which is equal to 1 if the target f_i is rooted at node n and equal to 0 otherwise. A tree-kernel function over T_1 and T_2 is $K(T_1, T_2) = \sum_{n_1 \in N_{T_1}} \sum_{n_2 \in N_{T_2}} \Delta(n_1, n_2)$, where N_{T_1} and N_{T_2} are the sets of the T_1 's and T_2 's nodes, respectively. In turn $\Delta(n_1, n_2) = \sum_{i=1}^{|\mathcal{F}|} \lambda^{l(f_i)} I_i(n_1) I_i(n_2)$, where $0 \leq \lambda \leq 1$ and $l(f_i)$ is the number of levels of the subtree f_i . Thus $\lambda^{l(f_i)}$ assigns a lower weight to larger fragments. When $\lambda = 1$, Δ is equal to the number of common fragments rooted at nodes n_1 and n_2 . As described in [3], Δ can be computed in $O(|N_{T_1}| \times |N_{T_2}|)$.

3 AUTOMATIC CLASSIFICATION OF PREDICATE ARGUMENT STRUCTURES

Most semantic role labeling models rely only on the features extracted from the current candidate argument node. To consider a complete predicate argument structure, the classifier should formulate a

hypothesis on the potential parse-tree node subsets which include the argument nodes of the target predicate. Without the boundary information, we should consider all possible tree node subsets, i.e. an exponential number.

To solve such problems we apply a traditional boundary classifier (*TBC*) to select the set of potential arguments \mathcal{PA} . Such a subset can be associated with a subtree which in turn can be classified by means of a tree kernel function. Intuitively, such a function measures to what extent a given candidate subtree is *compatible* with the subtree of a correct predicate argument structure.

3.1 The Predicate Argument Spanning Trees (*PASTs*)

We consider the predicate argument structures annotated in PropBank along with the corresponding TreeBank data as our object space. Given the target predicate p in a sentence parse tree T and a subset $s = \{n_1, \dots, n_k\}$ of its nodes, N_T , we define as the spanning tree root r the lowest common ancestor of n_1, \dots, n_k . The node set spanning tree p_s is the subtree rooted in r from which the nodes that are neither ancestors nor descendants of any n_i are removed.

Since predicate arguments are associated with tree nodes (i.e. they exactly fit into syntactic constituents), we can define the *Predicate Argument Spanning Tree (PAST)* of a predicate argument set, $\{a_1, \dots, a_n\}$, as the node set spanning tree (*NST*) over such nodes, i.e. $p_{\{a_1, \dots, a_n\}}$. A *PAST* corresponds to the *minimal* subparse tree whose leaves are all and only the words compounding the arguments. For example, Figure 1 shows the parse tree of the sentence "John took the book and read its title". $took_{\{ARG_0, ARG_1\}}$ and $read_{\{ARG_0, ARG_1\}}$ are two *PAST* structures associated with the two predicates *took* and *read*, respectively. All the other possible *NSTs* are not valid *PASTs* for these predicates. Note that labeling $p_s, \forall s \subseteq N_T$ with a *PAST* Classifier is equivalent to solve the boundary detection problem.

The critical points for the application of *PASTs* are: (1) how to design suitable features for the characterization of *PASTs*. This new structure requires a careful linguistic investigation about its significant properties. (2) How to deal with the exponential number of *NSTs*.

For the first problem, the use of tree kernels over the *PASTs* can be an alternative to the manual feature design as the learning machine, (e.g. SVMs) can select the most relevant features from a high dimensional feature space. In other words, we can use a tree kernel function to estimate the similarity between two *PASTs* (see Section 2), hence avoiding to define explicit features.

For the second problem there are two main approaches: (1) We can consider the classification confidence provided by *TBC* [11] and evaluate the m most probable argument node sequences $\{n_1, \dots, n_k\}$. On the m *NSTs* derived from such sequences, we can apply a re-ranking approach based on SVMs with tree kernel. (2) We can use only the set of nodes \mathcal{PA} decided by *TBC* (i.e. those classified as

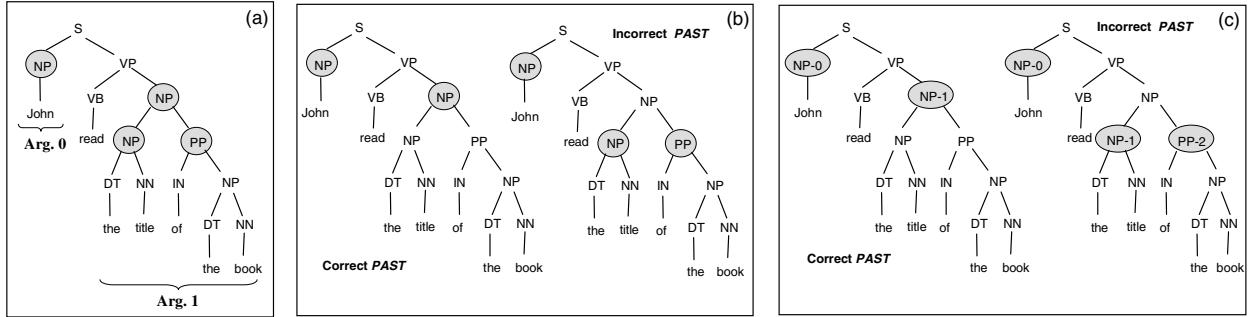

Figure 2. Two-step boundary classification. a) Sentence tree; b) Two candidate *PAST*s; c) Extended *PAST*-*Ord* labeling

arguments). Thus we need to classify only the set \mathcal{P} of *NSTs* associated with any subset of \mathcal{PA} , i.e. $\mathcal{P} = \{p_s : s \subseteq \mathcal{PA}\}$.

As a re-ranking task would not give an explicit and clear indication of the classifier ability to distinguish between correct and incorrect predicate argument structures, we preferred to apply the second approach. However, also the classification of \mathcal{P} may be computationally problematic, since theoretically there are $|\mathcal{P}| = 2^{|\mathcal{PA}|}$ members.

In order to develop a very efficient procedure, we applied the *PAST* Classifier only to structures that we know that are incorrect. A simple way to detect them is to look for node pairs $\langle n_1, n_2 \rangle \in \mathcal{PA} \times \mathcal{PA}$ that overlap, i.e. either n_1 is ancestor of n_2 or vice versa. Note that structures that contain overlapping nodes often also contain correct substructures, i.e. subsets of \mathcal{PA} can be associated with correct *PAST*. Assuming the above hypothesis, we create two node sets $\mathcal{PA}_1 = \mathcal{PA} - \{n_1\}$ and $\mathcal{PA}_2 = \mathcal{PA} - \{n_2\}$ and classify them with the *PAST* Classifier to select the correct set of argument boundaries. This procedure can be generalized to a set of overlapping nodes greater than 2 by selecting a maximal set of non-overlapping nodes. Additionally, as the Precision of *TBC* is generally high, the number of overlapping nodes is very small. Thus we can explore the whole space.

Figure 2 shows a working example of the multi-stage classifier. In Frame (a), *TBC* labels as potential arguments (gray color) three overlapping nodes related to ARG1. This leads to two possible solutions (Frame (b)) of which only the first is correct. In fact, according to the second one, the propositional phrase *of the book* would be incorrectly attached to the verbal predicate, i.e. in contrast with the parse tree. The *PAST* Classifier, applied to the two *NSTs*, is expected to detect this inconsistency and provide the correct output.

3.2 Designing Features with Tree Fragments

The Frame (b) of Figure 2 shows two perfectly identical *NSTs*. Therefore, it is not possible to discern between them using only their fragments. To solve the problem we can enrich the *NSTs* by marking their argument nodes with a progressive number, starting from the leftmost argument. For example, in the first *NST* of Frame (c), we mark as NP-0 and NP-1 the first and second argument nodes whereas in the second *NST* we transform the three argument node labels in NP-0, NP-1 and PP-2. We will refer to the resulting structure as a *PAST*-*Ord* (ordinal number). This simple modification allows the tree kernel to generate different argument structures for the above *NSTs*. For example, from the first *NST* in Figure 2.c, the fragments [NP-1 [NP] [PP]], [NP [DT] [NN]] and [PP [IN] [NP]] are generated. They do not match anymore with the [NP-0 [NP] [PP]], [NP-1 [DT] [NN]] and [PP-2 [IN] [NP]] fragments generated from the second *NST* in Figure

2.c.

We also explored another relevant direction in enriching the feature space. It should be noted that the semantic information provided by the role type can remarkably help the detection of correct or incorrect predicate argument structures. Thus, we enrich the argument node label with the role type, e.g. the NP-0 and NP-1 of the correct *PAST* of Figure 2.c becomes NP-Arg0 and NP-Arg1 (not shown). We refer to this structure as *PAST*-*Arg*. Of course, to apply the *PAST*-*Arg* Classifier, we need a traditional role multiclassifier (*TRM*) which labels the arguments detected by *TBC*.

4 THE EXPERIMENTS

The experiments were carried out within the setting defined in the CoNLL-2005 Shared Task [1]. We used the PropBank corpus available at www.cis.upenn.edu/~ace, along with the Penn TreeBank 2 for the gold trees (www.cis.upenn.edu/~treebank) [9], which includes about 53,700 sentences.

Since the experiments over gold parse trees inherently overestimate the accuracy in the semantic role labeling task, e.g. 93% vs. 79% [11], we also adopted Charniak parse trees from the CoNLL 2005 Shared Task data (available at www.lsi.upc.edu/~srlconll/) along with the official performance evaluator.

All the experiments were performed with the SVM-light software [6] available at svmlight.joachims.org. For *TBC* and *TRM*, we used the linear kernel with a regularization parameter (option *-c*) equal to 1. A cost factor (option *-j*) of 10 was adopted for *TBC* to have a higher Recall, whereas for *TRM*, the cost factor was parameterized according to the maximal accuracy of each argument class on the validation set. For the *PAST* Classifier, we implemented the tree kernel defined [3] inside SVM-light with a λ equal to 0.4 (see [10]).

4.1 Gold Standard Tree Evaluations

In these experiments, we used the sections from 02 to 08 of the TreeBank/PropBank (54,443 argument nodes and 1,343,046 non-argument nodes) to train the traditional boundary classifier (*TBC*). Then, we applied it to classify the sections from 09 to 21 (125,443 argument nodes vs. 3,010,673 non-argument nodes). We obtained 2,988 *NSTs* containing at least one overlapping node pair out of the total 65,212 predicate structures (according to the *TBC* decisions). From the 2,988 overlapping structures, we derived 3,624 positive and 4,461 negative *NSTs*, that we used to train the *PAST*-*Ord* Classifier.

The performance was evaluated through the F_1 measure over Section 23, which includes 10,406 argument nodes out of 249,879 parse

									73.4	73.8	73.9	72.9

Table 2. Semantic Role Labeling performance on automatic trees using *PAST* classifiers.

tree nodes. After applying the *TBC* classifier, we detected 235 overlapping *NSTs*, from which we extracted 204 correct *PASTs* and 385 incorrect ones. On such gold standard trees, we measured only the performance of the *PAST*-Arg Classifier which was very high, i.e. 87.1% in Precision and 89.2% in Recall (88.1% of F_1).

Using the *PAST*-Ord Classifier we removed from the *TBC* outcome the nodes that caused overlaps. To measure the impact on the boundary detection task, we compared it with three different boundary classification baselines:

1. *TBC*: overlaps are ignored and no decision is taken. This provides an upper bound for the recall as no potential argument is rejected for later labeling. Notice that, in presence of overlapping nodes, the sentence cannot be annotated correctly.

2. *RND*: one among the non-overlapping structures with maximal number of arguments is randomly selected.

3. *HEU* (heuristic): one of the *NSTs* which contains the nodes with the lowest overlapping score is chosen. This score counts the number of overlapping node pairs in the *NST*. For example, in Figure 2.a we have an NP that overlaps with two nodes NP and PP, thus it is assigned a score of 2.

The third row of Table 1 shows the results of *TBC*, *TBC+RND*, *TBC+HEU* and *TBC+PAST-Ord* in the columns 2,3,4 and 5, respectively. We note that: First, the *TBC* F_1 is slightly higher than the result obtained in [11], i.e. 95.4% vs. 93.8% under the same training/testing conditions (i.e. same PropBank version, same training and testing split and same machine learning algorithm). This is explained by the fact that we did not include continuations and co-referring arguments that are more difficult to detect. Second, both *RND* and *HEU* do not improve the *TBC* result. This can be explained by observing that in the 50% of the cases a correct node is removed. Third, when the *PAST*-Ord Classifier is used to select the correct node, the F_1 increases of 1.49%, i.e. (96.86 vs. 95.37). This is a relevant result as it is difficult to increase the very high baseline given by *TBC*. Finally, we tested the above classifiers on the overlapping structures only, i.e. we measured the *PAST*-Ord Classifier improvement on all and only the structures that required its application. Such reduced test set contains 642 argument nodes and 15,408 non-argument nodes. The fourth row of Table 1 reports the classifier performance on such task. We note that the *PAST*-Ord Classifier improves the other heuristics of about 20%.

4.2 Automatic Tree Evaluations

In these experiments we used the automatic trees generated by Charniak's parser and the predicate argument annotations defined in the

CoNLL 2005 shared task. Again, we trained *TBC* on sections 02-08 whereas, to achieve a very accurate role classifier, we trained *TRM* on all sections 02-21. Then, we trained the *PAST*, *PAST*-Ord, and *PAST*-Arg Classifiers on the output of *TBC* and *TRM* over sections 09-20 for a total of 183,642 arguments, 30,220 *PASTs* and 28,143 incorrect *PASTs*.

—	69.8	77.9	73.7	62.2	77.1	68.9
Ord	73.7	81.2	77.3	63.7	80.6	71.2
Arg	73.6	84.7	78.7	64.2	82.3	72.1

Table 3. *PAST*, *PAST*-Ord, and *PAST*-Arg performances on sections 21 and 23.

First, to test the *TBC*, *TRM* and the *PAST* classifiers, we used Section 23 (17,429 arguments, 2,159 *PASTs* and 3,461 incorrect *PASTs*) and Section 21 (12,495 arguments, 1,975 *PASTs* and 2,220 incorrect *PASTs*). The performance derived on Section 21 corresponds to an upper bound of our classifiers, i.e. the results using an ideal syntactic parser (Charniak's parser was trained also on Section 21) and an ideal role classifier. They provide the *PAST* family classifiers with accurate syntactic and semantic information. Table 3 shows Precision, Recall and F_1 measures of the *PAST* classifiers over the *NSTs* of sections 21 and 23. Rows 2, 3 and 4 report the performance of *PAST*, *PAST*-Ord, and *PAST*-Arg Classifiers, respectively. Several points should be remarked: (a) the general performance is lower than the one achieved on gold trees with *PAST*-Ord, i.e. 88.1% (see Section 4.1). The impact of parsing accuracy is also confirmed by the gap of about 6% points between sections 21 and 23. (b) The ordinal numbering of arguments (*Ord*) and the role type information (*Arg*) provide the tree kernel with more meaningful fragments since they improve the basic model of about 4%. (c) The deeper semantic information generated by the *Arg* labels provides useful clues to select correct predicate argument structures, since it improves the *Ord* model on both sections.

Second, we measured the impact of the *PAST* classifiers on both phases of semantic role labeling. Table 2 reports the results on the sections 21 and 23. For each of them, the Precision, Recall and F_1 of different approaches to the boundary identification (bnd) and to the complete task, i.e. boundary and role classification (bnd+class), is shown. Such approaches are based on different strategies to remove the overlaps, i.e. *PAST*, *PAST*-Ord, *PAST*-Arg and the baseline (*RND*) which uses a random selection of non-overlapping struc-

tures. We needed to remove the overlaps from the baseline in order to apply the CoNLL evaluator.

We note that: (a) for any model, the boundary detection F_1 on Section 21 is about 10 points higher than the F_1 on Section 23 (e.g. 87.0% vs. 77.9% for *RND*). As expected, the parse tree quality is very important to detect argument boundaries. (b) On the real test (Section 23) the classification introduces labeling errors which decrease the accuracy of about 5% (77.9 vs 72.9 for *RND*). (c) The *Ord* and *Arg* approaches constantly improve the baseline F_1 of about 1%. Such a result does not surprise as it is similar to the one obtained on Gold Trees: the overlapping structures are a small percentage of the test set thus the overall impact cannot be very high.

Third, the comparison with the CoNLL 2005 results [1] can only be carried out with respect to the whole SRL task (bnd+class in table 2) since boundary detection versus role classification is generally not provided in CoNLL 2005. Moreover, our best global result, i.e. 73.9%, was obtained under two severe experimental factors: a) the use of just 1/3 of the available training data, and b) the usage of the linear SVM model for the TBC classifier, which is much faster than the polynomial SVMs but also less accurate. However, we note the promising results of the *PAST* meta-classifier, which can be used with any of the best figure CoNLL systems.

Finally, kernel outcome suggests that: (a) it is robust to parse tree errors since it preserves the same improvement across trees derived with different accuracy, i.e. the gold trees of Penn TreeBank and the automatic trees of Section 21 and Section 23. (b) It shows a high accuracy for the classification of correct and incorrect predicate argument structures. This last property is quite interesting considering the important findings of a recent paper [13]. The winning strategy to improve semantic role labeling relates to the exploiting of different labeling hypotheses, i.e. several \mathcal{PA}_i sets derived from different parsing alternatives. A joint inference procedure was used to select the most likely set $s \subseteq \cup_i \mathcal{PA}_i$. In our opinion, the *PAST* Classifiers seem very well suited to select such set.

5 RELATED WORK

Recently, many kernels for natural language applications have been designed. In what follows, we highlight their difference and properties.

The tree kernel used in this article was proposed in [3] for syntactic parsing reranking. It was experimented with the Voted Perceptron and was shown to improve the syntactic parsing. In [4], a feature description language was used to extract structural features from the syntactic shallow parse trees associated with named entities. The experiments on the named entity categorization showed that when the description language selects an adequate set of tree fragments the Voted Perceptron algorithm increases its classification accuracy. The explanation was that the complete tree fragment set contains many irrelevant features and may cause overfitting. In [13], a set of different syntactic parse trees, e.g. Charniak n best parse trees, were used to improve the SRL accuracy. These different sources of syntactic information were used to generate a set of different SRL outputs. A joint inference stage was applied to resolve the inconsistency of the different outputs. This approach may be applied to our tree kernel strategies to design a joint tree kernel model. In [14], it was observed that there are strong dependencies among the labels of the semantic argument nodes of a verb. Thus, to approach the problem as the classification of an overall role sequences, a re-ranking method is applied to the assignments generated by a *TRM*. This approach is in line with our *PAST* Classifier that can be used to refine such re-ranking strategy. In [12], some experiments were conducted on SRL

systems trained using different syntactic views. Again, our approach may be used in conjunction with this model to provide a further syntactic view related to the whole predicate argument structure.

6 CONCLUSIONS

The feature design for new natural language learning tasks is difficult. We can take advantage of the kernel methods to model our intuitive knowledge about the target linguistic phenomenon. In this paper we have shown that we can exploit the properties of tree kernels to engineer syntactic features for the semantic role labeling task.

The experiments on gold standard trees as well as on automatic trees suggest that (1) the information related to the whole predicate argument structure is important and (2) tree kernels can be used to generate syntactic/semantic features. The remarkable result is that such structures are robust with respect to parse tree errors.

In the future, we would like to use an approach similar to the *PAST* classifier to select the best predicate argument annotation from those carried out on several parse trees provided by one or more parsing models.

7. Planning and Scheduling

This page intentionally left blank

A Multivalued logic model of planning

M. Baioletti and A. Milani and V. Poggioni and S. Suriani¹

Abstract. In this work a model for planning with multivalued fluents and graded actions, based on the infinite valued Łukasiewicz logic, is introduced. In multivalued planning, fluents can assume truth values in the interval [0, 1] and actions can be executed at different application degrees also varying in [0, 1]. The notions of planning problem and solution plan also reflect a multivalued approach. Multivalued fluents and graded actions allow to model many real situations where some features of the world cannot be modeled with boolean values and where actions can be executed with varying strength which produces graded effects as well. Even if most existing planning models fail to address this kind of domains, our model is comparable with models allowing flexible actions and soft constraints. A correct/complete algorithm which solves bounded multivalued planning problems based on MIP compilation is also described and a prototype implementation is presented.

1 Introduction

Many-valued logics have recently been considered in Software Engineering research because they provide a support for an explicit modelling of uncertainty, disagreement and fuzziness. In many areas of artificial intelligence research, related to AI planning, several extensions of classical models with multivalued approaches have been proposed. In model checking, the classical approach has been extended to a multi-valued framework [4]. In [2] a new framework for soft constraint satisfaction problems (CSP), in which fuzzy CSP and weighted CSP are particular cases, has been proposed. In [10] a many-valued SAT solver based on clauses with multivalued literals has been presented.

In AI planning there exist many real application domains in which the relevant properties cannot be expressed by a crisp boolean value, the actions can be applied with a graded level and the effects can depend on that level. Consider for instance a simple scenario where the action *open_door* is available in the domain and modifies the truth value of the fluent *door_is_open*.

A typical probabilistic planning model would treat both the fluent *door_is_open* and the successful execution of the action *open_door* as uncertain, assigning to them a belief degree in [0, 1]. Such degrees are different from the truth value that the real world will assign to the fluent and to the action, which will be definitely 1 or 0, i.e. true/false or successful/unsuccessful. In other words, the planner is uncertain about boolean, but unknown, properties like *door_is_open*. A planner with resources would treat the fluent *door_is_open* as a real function whose initial value has to be measured, for instance by the openness angle. Since the action *open_door* cannot have as a numerical parameter the angle by which *door_is_open* is changed, it is not possible to model the strength of the action. From a multivalued point

of view, instead, the truth value of the fluent *door_is_open* denotes a real world property which can vary from 0 (the door is completely closed) to 1 (the door is completely opened). In other words the door can “really” be opened at an intermediate degree, between “completely closed” and “completely opened”. Moreover the multivalued action *open_door* can be applied with a “strength” ranging from 0 (not applied at all) to 1 (completely applied). The resulting effect on the fluent *door_is_open* will depend on the application level of action *open_door* and on the previous truth value of the fluent itself, i.e. the effects can also be additive.

Choosing a suitable execution degree of an action *a*, it is possible to obtain a sufficient level for some fluents, for instance goals or subgoals, while keeping low the side effects of the execution of *a*.

The use of graded actions is also useful in domains where the execution degree is related to the cost/execution time of the action. Therefore it is possible to define a metric function based on execution degrees by which optimal plans in terms of overall cost/time are generated.

It is worth noticing that many fuzzy concepts cannot be represented by numerical resources, because the fuzzy values could not be obtainable by a measurement process or they could be affected by subjective factors.

In the multivalued/fuzzy logics scenario we preferred to use a logic based on T-norms because of its well-founded mathematical aspects. Among this class of logics we have chosen the Łukasiewicz logic because the semantics of its operators is more suitable for our framework. For these reasons we have excluded other well-known logics as Product Logic, in which for instance the negation operator is not involutive.

In this paper a new framework for a general theory of multivalued planning based on the infinite-valued Łukasiewicz logic [5, 9] is introduced and an algorithm for a multivalued planner is described. The proposed model can be seen as a generalization of the classical planning, since boolean and multivalued actions and fluents can be used in the same domain.

The paper is organized as follows. Some basic concepts on Łukasiewicz logic are recalled in Section 2, the model of multivalued planning is presented in Section 3 and an algorithm solving problems in such a model is proposed in Section 4. Finally an example, related works and conclusions are pointed out in Sections 5 and 6.

2 A brief introduction to Łukasiewicz logic

Łukasiewicz logic is a multivalued extension of classical logic, well known from the theoretical point of view [9, 5]. In this section we will report only some useful definitions. The conjunction operator, $x \odot y = \max(0, x + y - 1)$, has the properties of a generic *T*-norm: it is commutative, associative, monotonic with respect to all the variables; it has 0 as absorbing element and 1 as unit element.

¹ Università degli Studi di Perugia, Italy, email: {baioletti,milani,poggioni,suriani}@dipmat.unipg.it

The implication is defined as the residual of the conjunction operator and is expressed by $x \rightarrow y = \min(1, 1 - x + y)$.

The negation, which can be defined as $\neg x = x \rightarrow 0$, is expressed as $\neg x = 1 - x$ and is involutive. Using the last property and De Morgan's law it is possible to define a disjunction operator, expressed as $x \oplus y = \min(1, x + y)$. This operation is a co-norm: it is commutative, associative, monotonic monotonic with respect to all the variables; it has 1 as absorbing element and 0 as unit element.

Implication and disjunction are related by the condition $x \rightarrow y = \neg x \oplus y$.

It is possible to define an operation similar to subtraction, as $x \ominus y = x \odot \neg y = \max(0, x - y)$. Under some condition on x and y , it is the inverse of additive disjunction. Moreover $(x \ominus y) \odot z = x \ominus (y \oplus z)$ holds.

Lastly we introduce the lattices operators *min*-conjunction $x \wedge y = x \odot (x \rightarrow y)$ and *max*-disjunction $x \vee y = (x \rightarrow y) \rightarrow y$. They coincide, respectively, with the minimum and the maximum between x and y .

3 The Model

In this section a model of multivalued fluents and graded actions is presented. This model allows to use boolean fluents and classical actions jointly with these new kinds of fluents and actions.

3.1 States

Let \mathcal{F} be the finite set of fluents. A state is described by a function S which assigns to each fluent f a truth value belonging to $[0, 1]$ and denoted by $S(f)$.

It can be seen as a natural extension of the classical state definition in which the range of the state function is $[0, 1]$ instead of $\{0, 1\}$.

The value of a negated fluent is denoted by $S(\neg f)$ and it is computed as $S(\neg f) = \neg S(f)$. In general, given a generic logic formula ϕ , $S(\phi)$ denotes the truth value of ϕ in the state S .

A boolean fluent is a fluent whose possible values are restricted in $\{0, 1\}$.

3.2 Actions

Following the classical action definition introduced in STRIPS, an action a is described by a list of preconditions $pre(a)$ and a list of effects $eff(a)$.

Differently from the classical models, an application degree $\alpha(a) \in [0, 1]$ is assigned to each action a . The application degree of a boolean action is only 0 or 1, while for a multivalued action, $\alpha(a)$ can assume any intermediate value.

The degrees 0 and 1 have the same meaning as in the classical model (respectively, the action is not executed and the action is fully executed), while an intermediate value means that the action is executed with a lesser strength.

Informally we can say that each precondition is provided with a threshold. The action is fully executable only when the truth values of each precondition exceed the corresponding thresholds, while in the other cases the action can be executed with a smaller degree.

The execution of an action a can modify the truth value of fluents by means of additive changes: p is a positive effect of a if, after its execution, the value of p is increased, while p is a negative effect if the value is decreased. The amount of increment is proportional to the application degree of the action and can be tuned by a parameter which models the strength of the effect.

3.2.1 Action Preconditions and Action Executability

Definition 1 Action Preconditions

The preconditions of an action a are defined by a list of pairs (β_i, p_i) , where p_i is a literal (i.e. a fluent or its negation) and β_i is a real number in $[0, 1]$, called the threshold of p_i .

The threshold can be read as a coefficient of importance of p_i for a or a sort of a hardness degree of the precondition. $\beta_i = 0$ means that the precondition is *totally soft*, i.e. the truth value of the fluent does not affect the executability of a . While $\beta_i = 1$ means that the precondition is *totally hard*, i.e. that the truth value of p_i is required to be 1 for a to be fully executed.

If p_i is a boolean fluent, then β_i must be 0 or 1.

Definition 2 Action Executability

An action a is executable in a state S with application degree $\alpha \in [0, 1]$ if $\alpha \leq \alpha_{max}(a, S)$, where

$$\alpha_{max}(a, S) = \bigwedge_{(\beta, p) \in pre(a)} (\beta \rightarrow S(p)). \quad (1)$$

It is reasonable to compute a maximum application degree because the minimum application degree must be always 0, i.e. the planner can choose whether to apply a and, in this case, it can apply a with any actual application degree smaller or equal to $\alpha_{max}(a, S)$.

The *min*-conjunction \wedge is used in (1), instead of the usual Łukasiewicz conjunction \odot , because the latter, differently from the former, is not idempotent and if x and y are smaller than 1, $x \odot y$ is smaller than x and y . This property would cause some problems when there are some preconditions which are strictly related, modelling, for instance, the same feature of the world. In that case it is reasonable to expect that the presence of both the preconditions would not alter the executability of the action with respect to the case in which only one precondition is present.

The expression $\beta_i \rightarrow S(p_i)$ can be seen as a fuzzy extension of the crisp relation $S(p_i) \geq \beta_i$. In fact, if $S(p_i) \geq \beta_i$, then the implication assumes truth value 1, while if $S(p_i) < \beta_i$ then the implication assumes a value lesser than 1. The higher the difference between $S(p_i)$ and β_i is, the lesser the value of the implication is. The use of \rightarrow therefore allows to execute a (with $\alpha(a) < 1$) even if $S(p_i) \leq \beta_i$. Moreover, as desirable, this expression is increasing with respect to $S(p_i)$ and decreasing with respect to β_i .

Finally, it is important to note that a negative precondition has a particular semantics, i.e. it requires that the truth value of the fluent is small. In fact $\beta \rightarrow S(\neg p) = 1$ if and only if $S(\neg p) \geq \beta$, i.e. $S(p) \leq 1 - \beta$.

3.2.2 Action Effects and Action Execution

Definition 3 Action Effects.

The effects of an action a are defined by a list of pair (γ_i, e_i) , where e_i is a literal and γ_i is a real number in $[0, +\infty)$, called weight of a over e_i .

It is not allowed to have an action having both a positive and a negative effect over the same fluent.

Definition 4 Action Execution.

In the state S' , resulting from the execution of an action a with application degree α in a state S , for each effect (γ, e) of a

$$S'(e) = S(e) \oplus \Pi_\gamma(\alpha) \quad (2)$$

where $\Pi_\gamma(\alpha) = \min(\gamma \cdot \alpha, 1)$.

Since the aim of our model is to deal with actions which modify the world state according to their application degrees, additive effects are more suitable. For instance, if an action is executed with a low application degree, the change on the world has to be small. An action which assigns truth values to fluents depending only on α does not verify this important property.

The unary operator Π_γ allows to reduce or to amplify the effect of the action execution with respect to the application degree and, in particular, reflects the idea of effects proportionally related to the application degree.

It is easy to see that the application of (2) to a negated fluent $\neg f$ yields to $S'(\neg f) = S(\neg f) \oplus \Pi_\gamma(\alpha)$ and, since $S'(\neg f) = 1 - S'(f)$, to

$$S'(f) = S(f) \ominus \Pi_\gamma(\alpha).$$

Therefore, as expected, the action execution decrements the truth value of fluents in its negative effects, while increments the fluents in its positive effects.

If e_i is a boolean literal, then the corresponding γ_i is represented by ∞ because by this value it is possible to simulate assignments to 1 (or to 0).

3.2.3 Multivalued Planning Problems

A *multivalued planning problem* is defined by a quadruple $(I, \mathcal{O}, G, \sigma)$ where I is a truth assignment over the fluents $I : \mathcal{F} \rightarrow [0, 1]$ and denotes the initial state; \mathcal{O} is a set of boolean and multivalued actions; G is defined by a list of pairs (θ_i, g_i) having the same structure of action preconditions, and σ is a real number in $[0, 1]$ called *global threshold*.

A valid plan is an ordered sequence of pairs $\langle a_1 : \alpha_1, a_2 : \alpha_2, \dots, a_n : \alpha_n \rangle$, where each α_i represents the application degree of action $a_i \in \mathcal{O}$. Moreover, let $S_0 = I$ and S_{i+1} the state resulting from the execution of the action a_i is S_i , each action a_i must be executable in S_i with application degree α_i .

It is clear that non interfering actions could be simultaneously executed. While a boolean concept of interference among actions is natural, it is not straightforward to define a multivalued version of this concept and this point needs further investigations. Therefore in this first model we restrict our attention only to linear plans.

Definition 5 Solution Plan

A solution plan is a valid plan where in the final state S_n

$$\bigwedge_{(\theta, g) \in G} (\theta \rightarrow S_n(g)) \geq \sigma \quad (3)$$

Note that a solution plan is a plan which achieves all the goals in a multivalued fashion. First, the θ s represent the importance or hardness of each goal, similarly to what the β s represent for the action preconditions. Then, σ specifies a global parameter which represents a minimal satisfaction degree desired for the solution plan.

Since we are solving a planning problem by means of a MIP solver, it is straightforward to allow the definition of a metric function in terms of a linear function of the application degrees of some actions. Then a solution plan must also minimize the metric function.

4 An Algorithm for Multivalued Planning

The idea of the algorithm is to solve bounded multivalued planning problems described in the model presented in Section 3 in three steps.

At first, a planning graph [3] is constructed until either the upper bound U for time-steps is exceeded or a state verifying the necessary condition for the solution existence is reached. Then the graph representation is translated into a MIP problem (Mixed Integer Programming), and finally a MIP problem solver is called. If the MIP problem has a solution, then also the planning problem has a solution which is directly derived from the MIP problem solution. If the MIP problem has no solution, the main loop continues by adding a new level until a solution is found or the bound U is exceeded. It is easy to prove that this algorithm is correct and complete in the class of the U -bounded multivalued planning problems.

4.1 Planning Graph Construction

The planning graph built in our system is similar to the planning graph used in Graphplan and other planning systems. The planning graph is a $2T + 1$ -leveled graph $G = (V, E)$ whose vertex set is $V = F_0 \cup A_0 \cup F_1 \cup A_1 \cup \dots \cup F_T$, where F_t is the set of *multivalued fluents* at time $t = 0, \dots, T$ and A_t is the set of *graded actions* at time $t = 0, \dots, T - 1$. Each edge in E links either a fluent $f \in F_t$ to an action $a \in A_t$, such that $(\beta, f) \in \text{pre}(a)$, or an action $a \in A_t$ to a fluent $f \in F_{t+1}$, such that $(\gamma, f) \in \text{eff}(a)$.

Note that there are no edges denoting mutual exclusion relationship, since such a concept is not used in our framework.

In the following, $S_t(f)$ means the truth value of the fluent $f \in F_t$ at the time-step t and $\alpha_t^*(a)$ denotes the upper bound for the application degree α of the action $a \in A_t$.

The values of $S_0(f)$ and $\alpha_0^*(a)$ can be computed in an exact way, because the initial state is completely known and $\alpha_0^*(a)$, for each $a \in A_0$, can be computed directly using the formula 1.

When $t > 0$, since it is not known which action will be executed in each time-step, the truth value $S_t(f)$ for each fluent $f \in F_t$ is unknown and, for the same reason, it is not possible to compute a realistic value of $\alpha_t^*(a)$ for each action $a \in A_t$.

Anyway, it is possible to compute a lower bound $\underline{S}_t(f)$ and an upper bound $\overline{S}_t(f)$ for the value $S_t(f)$ by taking into account the maximum change (in the positive and in the negative cases) caused by any possible action executed at time $t - 1$.

In order to compute a tighter upper bound for $\alpha_t(a)$ which takes into account the fact that in each time-step only one action is executed, we must compute lower and upper bounds for $S_t(f)$ conditioned to the execution at time $t - 1$ of a given action.

Therefore for each fluent $f \in F_t$ and each action a , we define the interval $[\underline{S}_t^a(f), \overline{S}_t^a(f)]$ which provides a bound for $S_t(f)$ after the application of the action a at time $t - 1$. Clearly,

$$[\underline{S}_t(f), \overline{S}_t(f)] = [\min_{a \in A_{t-1}} \underline{S}_t^a(f), \max_{a \in A_{t-1}} \overline{S}_t^a(f)] \quad (4)$$

holds, where

$$\underline{S}_t^a(f) = \begin{cases} \underline{S}_{t-1}(f) & \text{if } (\gamma, \neg f) \notin \text{eff}(a) \\ \underline{S}_{t-1}(f) \ominus \Pi_\gamma(\alpha_{t-1}^*(a)) & \text{if } (\gamma, \neg f) \in \text{eff}(a) \end{cases}$$

$$\overline{S}_t^a(f) = \begin{cases} \overline{S}_{t-1}(f) & \text{if } (\gamma, f) \notin \text{eff}(a) \\ \overline{S}_{t-1}(f) \oplus \Pi_\gamma(\alpha_{t-1}^*(a)) & \text{if } (\gamma, f) \in \text{eff}(a) \end{cases}$$

Then, we define $\alpha_{bt}^*(a)$ as the maximum execution degree of the action a , computed considering $[\underline{S}_t^b(p), \overline{S}_t^b(p)]$ as the interval bounding the truth values at time t for each fluent p involved in the preconditions of the action a . In other words, $\alpha_{bt}^*(a)$ is the maximum

execution degree of the action a at the time t taking into account that the action b was executed at time $t - 1$.

$$\alpha_{bt}^*(a) = \bigwedge_{(\beta, p) \in pre(a)} (\beta \rightarrow \bar{S}_t^b(p)) \wedge \bigwedge_{(\beta, \neg p) \in pre(a)} (\beta \rightarrow \neg \underline{S}_t^b(p)).$$

Finally, we compute

$$\alpha_t^*(a) = \max_{b \in A_{t-1}} \alpha_{bt}^*(a). \quad (5)$$

It is easy to prove that the computation of $\alpha_t^*(a)$ directly from $\underline{S}_t(f)$ and $\bar{S}_t(f)$, would produce a higher estimate of the maximum application degree.

Note nevertheless that a complete implementation of the previous method is not feasible. In fact the computation of $\alpha_t^*(a)$ at a time t would require the computation of $\underline{S}_t^{a_0, \dots, a_{t-1}}(f)$ and $\bar{S}_t^{a_0, \dots, a_{t-1}}(f)$ for every possible sequence of actions a_0, \dots, a_{t-1} .

The first time-step where a solution can exist is the first one which verifies the goal condition

$$\bigwedge_{(\theta, f) \in G} (\theta \rightarrow \bar{S}_t(f)) \wedge \bigwedge_{(\theta, \neg f) \in G} (\theta \rightarrow \neg \underline{S}_t(f)) \geq \sigma. \quad (6)$$

4.2 Constraints Extraction

Since it has been shown, for instance in [8], that constraints expressed by operators of Łukasiewicz logic can be transformed in linear constraints on integer and real variables, the constraints contained in the planning graph built as explained in Section 4.1 can be compiled into a Mixed Integer Programming (MIP) problem.

The truth value of each fluent f and the application degree of each action a at time t are respectively denoted by the real variables x_{ft} and x_{at} which take values in $[0, 1]$. For boolean fluent and actions the range is restricted to $\{0, 1\}$.

Different kinds of constraint must be satisfied in order to have a solution plan according to the model presented in Section 3. They can be grouped in *action executability rules*, *action execution rules* and *goal satisfiability rules*. Moreover, according to the definition of a valid plan, we have to express a linearity condition for each plan called *plan linearity constraint*.

The number of constraints in the MIP problem will be a polynomial of the number of fluents and actions in the planning graph as shown in the following sections.

4.2.1 Action Executability Rules

At each time-step t , the actual application degree of an action a must be less or equal than the upper bound $\alpha_t^*(a)$. Therefore,

$$x_{at} \leq \min\left(\min_{(\beta, f) \in pre(a)} \{\beta \rightarrow x_{ft}\}, \min_{(\beta, \neg f) \in pre(a)} \{\beta \rightarrow \neg x_{ft}\}\right).$$

Therefore for each $a \in A_t$ and for every $t = 0, \dots, T - 1$

$$\begin{cases} x_{at} \leq (1 - \beta) + x_{ft} & \text{for all } (\beta, f) \in pre(a) \\ x_{at} \leq (1 - \beta) + (1 - x_{ft}) & \text{for all } (\beta, \neg f) \in pre(a) \end{cases}$$

The number of constraints added to MIP problem for each time-step is equal to the total number of preconditions of every action.

4.2.2 Action Execution Rules

The value of of a fluent f at a time-step $t + 1$, $x_{f,t+1}$, can be computed by the following equation which depends on the value of f at the previous time-step and on the execution of some action.

$$x_{f,t+1} = x_{ft} \oplus \left(\bigoplus_{(\gamma, f) \in eff(a)} \Pi_\gamma(x_{at}) \right) \ominus \left(\bigoplus_{(\gamma, \neg f) \in eff(a)} \Pi_\gamma(x_{at}) \right). \quad (7)$$

Note that since only one action is executed at each time-step, in (7) at most one term among $\Pi_\gamma(x_{at})$ is greater than zero and affects the value of x_{ft} .

The translation of (7) in MIP constraints is performed by means of the techniques shown in [8] and in [1]. The overall number of constraints added to the MIP problem for each time-step is proportional to the number of fluents.

4.2.3 Goal Satisfiability Rule

This rule derives directly from the goal condition defined in (6) and requires that each subgoal (θ, f) must be fulfilled with a truth value greater or equal to the global threshold. It is expressed by the formula

$$\bigwedge_{(\theta, f) \in G} (\theta \rightarrow x_{ft}) \geq \sigma. \quad (8)$$

As shown in subsection 4.2.1, this constraint can be encoded as

$$\begin{cases} (1 - \theta) + x_{ft} \geq \sigma & \text{for all } (\theta, f) \in G \\ (1 - \theta) + (1 - x_{ft}) \geq \sigma & \text{for all } (\theta, \neg f) \in G \end{cases}$$

The number of constraints added to the MIP problem is equal to the number of problem goals.

4.2.4 Linearity Plan Rule

With this constraint we express the condition that only one action can be executed in a given time-step, i.e. at each time t , $\exists! a \in A_t : x_{at} \neq 0$.

This constraint can be represented directly by the MIP system

$$\begin{cases} x_{at} \leq \lambda_{at} & \text{for all } a \in A_t \\ \sum_{a \in A_t} \lambda_{at} = 1 & \\ \lambda_{at} \in \{0, 1\} & \text{for all } a \in A_t \end{cases} \quad (9)$$

It is easy to see that this condition is true if and only if at each time-step t there exists at most an action a , such that $x_{at} \neq 0$.

The number of constraints added to the MIP problem for each time-step is equal to the number of actions plus one.

4.3 Implementation

A prototype implementation of the previously described algorithm has been made in C++, using as a MIP solver the open-source library *lpsolve*, which is not very efficient, although the preliminary results obtained on small examples are encouraging.

We expect that further code optimizations and the use of more efficient linear programming libraries, like CPLEX, will produce good results from the computational point of view.

Another different approach to solve multivalued planning problems without metric is a compilation into a Linear Arithmetic Logic problem, handled by some solvers like MathSAT [6].

5 An Example

In order to model domains and problems with multivalued fluents and graded actions some obvious extensions to PDDL3 were added.

In this small example we present a domain having generic objects that can be wet and must to be painted. There are also some grippers that can be wet and hold objects. These domain properties are represented by the following fluents: (*obj_wet o*), (*painted o*), (*gr_wet g*), (*holding o g*) where *o* is an object and *g* is a gripper.

This domain has four actions. *dry* is a graded action that can dry a free gripper. *paint* is a graded action that can paint an object held by a gripper. *pickup* and *putdown* are boolean actions that respectively pick an object up from the table and put an object down to the table. The property to be on the table is represented by (*on_table o*). A gripper can hold only one object, can pick an object up only if it is free and the object is on the table. It can put an object down only if it holds it. A gripper can be wet and can be safely used only if it is not too much wet.

This example cannot realistically be modeled by classical planning domains, because qualitative properties like “be wet” or “be painted” cannot suitably be represented by boolean propositions: a gripper could be “a little wet” or “just damp”. Soft preconditions allow, for instance, to execute the action *pickup(gr,obj)* even if the gripper is not totally dry. Moreover, the classical planning model is not adequate for an action like *dry(gr)* because it would be applied with the same strength, both when the gripper is *very wet* and when it is *a little wet*. These are the action descriptions:

```
(:action paint
  :type graded
  :parameters (?obj - object ?gr - gripper)
  :precondition (and (1 (holding ?obj ?gr)))
  :effect (0.8 (painted ?obj)) )
(:action dry
  :type graded
  :parameters (?gr - gripper)
  :precondition (0.8 (gr.wet ?gr))
  :effect (0.9 not(gr.wet ?gr)) )
(:action pickup
  :type boolean
  :parameters (?obj - object ?gr - gripper)
  :precondition (and (1 (free ?gr))
    (1 (on_table ?obj))
    (0.7 (not(gr.wet ?gr)))) )
  :effect (and (infinity not(free ?gr)) (infinity (not(on_table ?obj)))
    (infinity (holding ?obj ?gr))) )
(:action putdown
  :type boolean
  :parameters (?obj - object ?gr - gripper)
  :precondition (1 (holding ?obj ?gr))
  :effect (and (infinity (free ?gr)) (infinity (on_table ?obj)))
    (infinity (not(holding ?obj ?gr))) ) )
```

An example of a problem is presented. We suppose to have the goal to paint the objects minimizing the *dry* application degrees in all the plan.

```
(define (problem example)
  (:domain slippery_gripper)
  (:objects gr1-gripper gr2-gripper obj1-object obj2-object)
  (:init (= 1 (free gr1)) (= 1 (free gr2))
    (= 1 (on_table obj1)) (= 1 (on_table obj2))
    (= 0.2 (gr.wet gr1)) (= 0.5 (gr.wet gr2))
    (= 0.2 (obj.wet obj1)) (= 0.7 (obj.wet obj2))
    (= 0.3 (painted obj1)) (= 0.6 (painted obj2)) )
  (:goal (and (0.8 (painted obj1)) (0.7 (painted obj2))) )
  (:threshold 0.9)
  (:metric minimize (is-executed dry)) )
```

6 Related Works and Conclusions

One of the mainly related planning models is the non-Boolean approach introduced in [11]. In this model *propositions* denoting fuzzy relations and *flexible operators* are allowed. The main differences with our approach is that they use finite-valued fluents and the mapping between preconditions and effects is obtained by a set of dis-

joint conditional clauses, where each clause determines the satisfaction degree of the effects associated with it. Despite of the fuzziness of the approach, the activation of a conditional clause is crisp, i.e. in flexible planning slight differences in the satisfaction degree of pre-conditions can activate completely different set of effects. Finally the concept of graded action is not present in [11], where operators are applied only at fixed application degree, because only the satisfaction degree of preconditions determines the effects of the action. In our approach, instead, the planner decides which application degree to assign to an action among the available values.

It is easy to see that some types of resources can be encoded in our model by appropriate multivalued properties values and additive effects. For instance the quantitative resource *fuel* in a tank, varying between 0 and 100 litres, can be modeled by a multivalued fluent *tank_full* in [0,1] which represents, in some sense, a fuzzy normalization of the resource *fuel*. Operators which produce/consume *fuel* would increment/decrement the truth value of fluent *tank_full*.

Recently PDDL [7] has been extended in order to allow *soft* constraints and goals preferences; the planning problem consists then in finding an admissible solution which maximizes the preference function. It is worth noticing that, although preferences are not considered in our approach, they could be encoded by introducing explicit multivalued *preference fluents* into the operators, and by specifying in the goals the desired preference level.

An interesting direction for future work is to study the effects of building the planning model on a finite-valued logic.

Different and more efficient approaches to solve multivalued planning problems need to be considered, such as graph based algorithms or using mixed boolean-real solvers.

Finally, from an experimental point of view, it is necessary to develop a set of benchmark problems for significant domains involving graded actions in order to test the performance of the implementation.

Strong Cyclic Planning under Partial Observability

Piergiorgio Bertoli¹, Alessandro Cimatti¹, Marco Pistore²

Abstract. Strong Cycling Planning aims at generating iterative plans that implement trial-and-error strategies, where loops are allowed only so far as there is a chance to reach the goal. In this paper, we tackle the problem of Strong Cyclic Planning under Partial Observability, making three main contributions. First, we provide a formal definition of the problem. We point out that several degrees of solution are possible and equally interesting, depending on the admissible delay between achieving the goal and detecting that it has been achieved. Second, we present a family of planning algorithms that tackle the different versions of the problem. Third, we implement the algorithms using efficient symbolic representation techniques, and experimentally compare their performances.

1 Introduction

Planning for nondeterministic domains has lately received considerable attention, for its ability to relax some basic limitations of classical planning [9, 2, 11, 4, 8, 5].

Dealing with nondeterminism is very difficult for the key reason that, in general, in such a setting, a plan is associated with multiple runs. In *strong* planning, a solution must *guarantee* that the goal is achieved in a finite number of steps *for all runs* associated with a plan. Often, however, strong plans may not exist. It is therefore reasonable to address the problem of finding a *strong cyclic solution*, i.e. a conditional plan that implements a trial-and-error strategy, either achieving the goal in a finite number of steps, or going through a possibly infinite but *good* loop, where there is still the possibility of reaching the goal.

The problem of strong cyclic planning has been addressed so far under the hypothesis of full observability, see [10, 5, 8]. In this paper, we tackle the problem of strong cyclic planning under the more realistic hypothesis of *partial observability*. We make three main contributions. First, we provide a formal definition of the problem of strong cyclic planning under partial observability. This turns out not to be straightforward, since different interpretations are possible, and equally interesting. In particular, partial observability results in uncertainty at execution time, which may prevent or delay the detection of goal achievement. We distinguish different degrees of solutions where a plan guarantees to (i) achieve the goal and detect achievement at the same time, (ii) achieve the goal and detect achievement after some delay, and (iii) achieve the goal without ever detecting achievement. As a second contribution, we provide a family of correct and complete algorithms for tackling the different classes of problems. The algorithms are based on forward search over an and-or graph, where the “or” branching corresponds to the choice of ac-

tions and the “and” branching is the effect of observations. Search nodes contain information on *belief states*, i.e. sets of indistinguishable states compatible with the perceived observations. While sharing a conceptual structure similar to that for strong planning under partial observability presented in [2], and while close in spirit to some work on heuristic cyclic planning [6], our approach departs considerably from both of them, due to the need of handling both loops and delayed detection. As a final contribution, we implement the algorithms based on efficient symbolic data structures, and we compare their performance. To the best of our knowledge, this implementation is the first to be able to tackle strong cyclic planning problems, also considering relaxed goal detection requirements.

The paper is structured as follows. First, we provide a formal framework for planning in partially observable, nondeterministic domains, and we define the different interpretations of strong cyclic planning problems under partial observability. Then, we present the algorithms, we outline their implementation and discuss their performance. We wrap up by discussing related and future work.

2 Planning in Nondeterministic Domains

A planning domain is a generic transition system, defined in terms of its *states* (of which some are marked as *initial*), of the *actions* it accepts, and of the possible *observations* that it can exhibit. A *transition function* describes how executing an action leads from one state to possibly many different states. Finally, an *observation function* defines what observations are associated to each state of the domain.

Definition 1 (planning domain) A nondeterministic planning domain with partial observability is a tuple $\mathcal{D} = \langle \mathcal{S}, \mathcal{A}, \mathcal{O}, \mathcal{I}, \mathcal{T}, \mathcal{X} \rangle$, where:

- \mathcal{S} is the set of states.
- \mathcal{A} is the set of actions.
- \mathcal{O} is the set of observations.
- $\mathcal{I} \subseteq \mathcal{S}$ is the set of initial states; we require $\mathcal{I} \neq \emptyset$.
- $\mathcal{T} : \mathcal{S} \times \mathcal{A} \rightarrow 2^{\mathcal{S}}$ is the transition function; it associates to each current state $s \in \mathcal{S}$ and to each action $a \in \mathcal{A}$ the set $\mathcal{T}(s, a) \subseteq \mathcal{S}$ of next states.
- $\mathcal{X} : \mathcal{S} \rightarrow 2^{\mathcal{O}}$ is the observation function; it associates to each state s the set of possible observations $\mathcal{X}(s) \subseteq \mathcal{O}$.

An action a is executable in state s if $\mathcal{T}(s, a) \neq \emptyset$. We require that in each state $s \in \mathcal{S}$ there is some executable action, and that some observation is associated to each state $s \in \mathcal{S}$ (i.e., $\mathcal{X}(s) \neq \emptyset$).

If $Q \subseteq \mathcal{S}$, we write $\mathcal{X}(Q)$ for $\bigcup_{s \in Q} \mathcal{X}(s)$; also, we write $\mathcal{X}^{-1}(o)$ for $\{s \in \mathcal{S} \mid o \in \mathcal{X}(s)\}$.

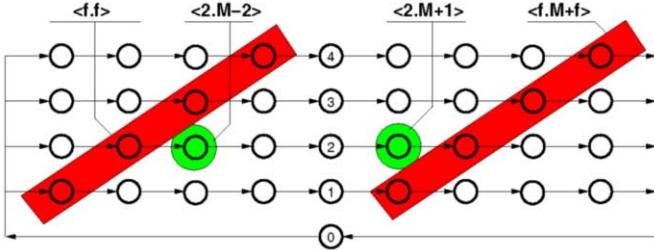

Figure 1. A simple explanatory robot domain

Example 2 Consider the domain composed of floors from 0 to M , and rooms from 0 to $R = 2 \times M$ (depicted in Fig. 1 for $M=4$). At the ground floor, composed of a single room, the robot can MoveUp with an elevator, which lands unpredictably at any floor. Then it can only MoveLeft, until it gets at room R , where it can MoveDown back to ground floor. All the rooms are indistinguishable, except for the middle room M of each floor, where a tag displays the current floor. The states of the domain are the pairs of the form $\langle f . r \rangle$, where $f \in 1 \dots M$ is the floor and $r \in 0 \dots R$ is the room of the robot, and $\langle 0 . M \rangle$ denotes the only location of the ground floor. The set of observations is $\{0, 1, \dots, M, \bullet\}$. The observation function is defined as follows: $\mathcal{X}(\langle f . r \rangle) = f$ iff $r = M$ (i.e., when in the room with the tag, the floor is perceived), and $\mathcal{X}(\langle f . r \rangle) = \bullet$ in the other locations (i.e. \bullet represents the absence of information).

We are interested in complex plans that may encode sequential, conditional and iterative behaviors. We model them as finite state machines, as follows.

Definition 3 (plan) A plan for planning domain $\mathcal{D} = \langle \mathcal{S}, \mathcal{A}, \mathcal{O}, \mathcal{I}, \mathcal{T}, \mathcal{X} \rangle$ is a tuple $\Pi = \langle \mathcal{C}, c_0, \alpha \rangle$, where:

- \mathcal{C} is the set of plan contexts.
- $c_0 \in \mathcal{C}$ is the initial context.
- $\alpha : \mathcal{C} \times \mathcal{O} \rightarrow 2^{\mathcal{A} \times \mathcal{C}}$ is the action relation; it associates to a plan context c and an observation o a set of pairs (a, c') , where a is an action to be executed and c' is a new plan context.

The *context* is the internal state of the plan. Actions to be executed depend on the context, and on the observation. Once an action is executed, the context is updated depending on the observation and on the action that has been carried out. Notice that our plans, in general, implement nondeterministic behaviors, i.e. different actions and new contexts may be taken (at different times during execution) when the plan is in the same context and receives the same observation. We call a plan deterministic when $\alpha(c, o)$ contains at most one pair (a, c') .

Example 4 With the plan $\Pi_{\text{ONE}}^{\langle f . M + f \rangle}$, the robot takes the elevator, moves to the middle room where it looks at the floor tag, and stops after f steps, where f is the number displayed on the tag. The plan has $R + 1$ contexts, of which S_{Init} is initial and T_0 is final; α is defined as follows:

c	o	a	c'	
S_{Init}	0	MoveUp	S_0	
S_i	\bullet	MoveLeft	S_{i+1}	$i = 0 \dots M - 1$
S_M	f	MoveLeft	T_{f-1}	
T_i	\bullet	MoveLeft	T_{i-1}	$i = 1..F$

The execution of a plan can be defined in terms of transitions between configurations that describe the state of the domain and of the plan, and it terminates when a context c is reached and an observation o is done for which $\alpha(c, o)$ is empty.

Definition 5 (configuration) A configuration for domain $\mathcal{D} = \langle \mathcal{S}, \mathcal{A}, \mathcal{O}, \mathcal{I}, \mathcal{T}, \mathcal{X} \rangle$ and plan $\Pi = \langle \mathcal{C}, c_0, \alpha \rangle$ is a tuple (s, o, c) such that $s \in \mathcal{S}$, $o \in \mathcal{X}(s)$, and $c \in \mathcal{C}$.

Configuration (s, o, c) may evolve into configuration (s', o', c') , written $(s, o, c) \rightarrow (s', o', c')$, if there is some action a such that:

- $(a, c') \in \alpha(c, o)$,
- $s' \in \mathcal{T}(s, a)$,
- $o' \in \mathcal{X}(s')$.

Configuration (s, o, c) is initial if $s \in \mathcal{I}$ and $c = c_0$. The reachable configurations for domain \mathcal{D} , plan Π , and goal \mathcal{G} , are defined as those in the transitive closure of \rightarrow from the initial configurations. Configuration (s, o, c) is terminal iff it is reachable and $\alpha(c, o) = \emptyset$.

Definition 6 (path) A finite [infinite] path P for a domain \mathcal{D} and a plan Π is a finite [infinite] sequence of configurations $\gamma_0, \gamma_1, \dots$ such that γ_0 is initial and $\gamma_i \rightarrow \gamma_{i+1}$ for all i . Path prefixes are defined in the usual way.

We denote with $\text{PATHS}(\mathcal{D}, \Pi)$ the set of the paths for \mathcal{D} and Π that either are infinite or end with a terminal configuration.

We are interested in plans that guarantee the executability of actions they produce on each reachable configuration.

Definition 7 (executable plan) Plan Π is executable on domain \mathcal{D} iff for each reachable configuration (s, o, c) , if $(a, c') \in \alpha(c, o)$, then $\mathcal{T}(s, a) \neq \emptyset$.

3 Defining Strong Cyclic Planning

We are interested in finding plans that achieve the goal despite initial state uncertainty and nondeterministic action effects. Strong planning [5] requires that this is achieved in a finite number of steps. Strong cyclic planning [5] relaxes this by admitting loops, so far as from each loop there still is a chance to reach the goal.

However, the definitions in [5] do not immediately lift to the case of partial observability. This is because while, in the fully observable case, after executing an action, we can always decide whether the goal has been reached, in the partially observable case, such “immediate” goal detection may be impossible.

In order to illustrate this point, we start by considering some problems in our example domain that can be solved by strong planning. If our goal is to reach and detect that the robot is at $\langle f . M + f \rangle$ (see Fig. 1, plan $\Pi_{\text{ONE}}^{\langle f . M + f \rangle}$) is a solution: the uncertainty about the position of the robot after the ride in the elevator disappears after looking at the sensors, so that at the end of every possible plan execution, we are sure that the desired condition is achieved. Consider now the goal of reaching one of the locations $\langle f . f \rangle$. With a plan $\Pi_{\text{ONE}}^{\langle f . M \rangle}$ that first takes the elevator and then takes M steps left, the robot will traverse the required state. However, the plan does not stop the robot in one of the required positions – in fact, this goal would be unsolvable. Thus, at the end of the plan execution, all we can guarantee is that “the goal has been achieved sometimes during the execution”. This example highlights the fundamental difference between a plan that only achieves a certain goal condition, and a plan that, in addition, guarantees that the executor will know when the goal is achieved (and will

stop accordingly). The first interpretation is the standard one used in strong planning under partial observability: a solution plan is associated with final belief states that are entirely contained in the goal. The second interpretation is new: a solution plan guarantees that, for each of the states in any final belief states, a goal state was previously visited. Accordingly, we distinguish between goal achievement *with immediate detection*, and goal achievement *with delayed detection*. Obviously, the requirement of immediate achievement detection is stronger than that of delayed achievement detection.

Let us now turn to the general case of strong cyclic planning. Consider the goal $\langle 2 \cdot M + 1 \rangle$. It is easy to see that it admits no strong solution in either interpretation. However, if we admit the possibility of infinite executions, the problem of goal achievement with immediate detection is solvable. A possible solution is given by a plan $\Pi_{\text{CYCLE}}^{(2 \cdot M + 1)}$ where the robot iterates taking the lift, traversing the rooms and descending, until it sees the floor 2 tag, and in that case it stops after moving left once. With such a plan, either the goal is reached (and immediately detected), or the system loops through states with a possibility of reaching the goal. Now consider the goal $\langle 2 \cdot M - 2 \rangle$. It is unsolvable under the immediate detection hypothesis. However there exists a strong cyclic solution with delayed achievement detection, e.g. a plan $\Pi_{\text{CYCLE}}^{(2 \cdot M)}$ where the robot iterates traversing taking the lift, traversing the rooms and descending, stopping as soon as it sees the floor 2 tag. Finally, consider a variation of the domain, where sensors are not precise and associate the same information to adjacent floors, and let our goal be $\langle 2 \cdot M + 1 \rangle$. Due to the robot being unable to localize its floor, it is not possible to achieve the goal and detect it (immediately or later). However a cyclic solution exists if goal detection is given up completely, by a plan Π_{CYCLE}^* that traverses the rooms without ever stopping.

We can formally characterize (strong and) strong cyclic solutions under partial observability, by first defining a notion of *observational equivalence* among paths which are indistinguishable under the point of view of an external observer:

Definition 8 (equivalent paths) Paths $P = (s_0, o_0, c_0), (s_1, o_1, c_1), \dots$ and $P' = (s'_0, o'_0, c'_0), (s'_1, o'_1, c'_1), \dots$ are said to be equivalent, denoted with $P \equiv P'$, iff for every i , $o_i = o'_i$.

Definition 9 (strong and strong cyclic solution) Let plan Π be executable in domain \mathcal{D} . Π is a strong solution to \mathcal{G} for

- achievement with immediate detection (SID) iff $\text{PATHS}(\mathcal{D}, \Pi)$ contains only finite paths, and $s \in \mathcal{G}$ holds for each terminal configuration (s, o, c) ;
- achievement with delayed detection (SDD) iff $\text{PATHS}(\mathcal{D}, \Pi)$ contains only finite paths, and each (finite) path in $\text{PATHS}(\mathcal{D}, \Pi)$ traverses some state $s \in \mathcal{G}$.

Π is a strong cyclic solution to \mathcal{G} for

- achievement with immediate detection (SCID) iff $s \in \mathcal{G}$ holds for each terminal configuration (s, o, c) , and each prefix of an infinite path in $\text{PATHS}(\mathcal{D}, \Pi)$ is observationally equivalent to some prefix of a finite path in $\text{PATHS}(\mathcal{D}, \Pi)$.
- achievement with delayed detection (SCDD) iff each finite path in $\text{PATHS}(\mathcal{D}, \Pi)$ traverses some state $s \in \mathcal{G}$, and each prefix of an infinite path in $\text{PATHS}(\mathcal{D}, \Pi)$ is observationally equivalent to some prefix of a finite path in $\text{PATHS}(\mathcal{D}, \Pi)$.
- achievement without detection (SCND) iff each (finite and infinite) path in $\text{PATHS}(\mathcal{D}, \Pi)$ traverses some state $s \in \mathcal{G}$.

8   until fixpoint for label(n)
9 end
```

Figure 3. Labeling Routine for SID

We remark that, even within a strong cyclic solution for SCND, there may exist paths for which (immediate/delayed) detection takes place. That is, there may be cases where an SCND solution terminates, just as well as for SCID and SCDD solutions; but as soon as detection cannot be always guaranteed, only SCND solutions may exist for the problem at hand.

4 Strong (Cyclic) Planning Algorithms

The algorithms for strong and strong cyclic planning share the same top-level structure, presented in Fig. 2. The TopLevelPlanner routine takes in input a problem class (SID, SDD, SCID, SCDD, SCND); \mathcal{D} and G are assumed to be globally available to the subroutines. The search iterates by extracting and expanding one node from the search graph and computing whether a solution exists; it returns when either all the nodes have been expanded (and the search frontier is empty), or when a solution has been found. Gph contains the search space explored so far. Intuitively, the search space is an and-or graph, where each edge represents a possible observation o (produced by the do-

main), and a subsequent action a (which can be executed given that observation). All through the search, each search node n is associated with two pieces of information: the belief state $n.bs \subseteq \mathcal{S}$ contains all the states that are compatible with the history of previous observations/actions, and the set of open states $n.os \subseteq n.bs$ stores the states of $n.bs$ that have not reached the goal in their past history.

The algorithms differ only in the labeling routine. In the strong cases, labeling is carried out by computing a least fix point (see Fig. 3 for the case of SID). The nodes are initially labeled depending on local information (line 3); then, for each node, the label is recomputed, based on the labels of connected nodes, until a stable condition is reached (lines 6-8). In the case of SID, a node is initially successful if its belief state is contained in \mathcal{G} (see $ID.gotG$), and a node labeled false becomes labeled true if, for every possible observation, either the belief state resulting after the observation is contained in \mathcal{G} (see $ID.gotO$), or there exists a successor node that is labeled true. In the case of SDD, it is initially successful if it has no open states, and it becomes successful if, for every possible observation, either the belief state resulting after the observation has no open states, or there exists a successor node that is labeled true. That is, the labeling routine for SDD can be obtained from the one for SID by substituting $ID.gotG$ and $ID.gotO$ with $DD.gotG$ and $DD.gotO$ respectively.

The main difficulty with the strong cyclic cases is in handling loops: it is not possible to consider a single fixed-point computation for labeling nodes as success. Admitting loops means that “weakly successful” nodes, from which termination is not guaranteed, must also be considered as taking part to possible solutions. Such nodes may be computed by a least fix point computation, starting from locally successful ones, and establishing that a node is “weakly successful” if it has at least one weakly successful successor. Once weakly successful nodes are computed, we have to discard loops where there is no chance to reach the goal. This can be performed by a subsequent greatest fix point computation, that sets as false the labels of nodes for which some observation does not lead to success (or to a successful successor). These two computations influence each other, and are interleaved until the situation stabilizes, i.e. a (higher-level) fix point is reached.

In the case of SCID (Fig. 4), the labeling function contains a high-level fix point computation at lines 4-20; within this, we first label nodes as weak solutions with the least fix point at lines 7-11; then, at lines 12-17, we relabel as not successful all those nodes for which success is not supported for every possible observation (either by a an action leading to a successful node, or by direct containment in the goal). The case of SCDD is analogous, and can be obtained by replacing the $ID.gotG$ and $ID.gotO$ success checks with $DD.gotG$ and $DD.gotO$ respectively.

The labeling routine for the case of SCND shares the same nested fix-point structure as the previous cases. However, it is more complicated, since it is no longer possible to detect whether a node can be labeled as success simply based on its belief state (as in SCID) or on its set of open states (as in SCDD). Thus, a node is no longer labeled with a truth value, but with a set of states (in particular, a subset of the open states). A state is in the label when it has been checked to satisfy the goal, i.e. all its possible future executions either reach \mathcal{G} or loop through states from which \mathcal{G} can be reached. A node is then successful iff its label is equal to its set of open states. The external fix point at lines 4-21 iterates by inserting into the label every weakly successful state (lines 7-12), and then (lines 13-18) by removing those states whose presence is not justified by the existence, for each observation, of an action that guarantees either reaching \mathcal{G} or a state (temporarily) labeled as success.

```

1 function SCID.propagateLabels()
2   forall  $n \in Gph.nodes$ 
3      $label(n) := true$ 
4   repeat
5     forall  $n \in Gph.nodes$

21   until fixpoint for  $label(n)$ 
22 end
```

Figure 5. Labeling Routine for SCND

All the reported algorithms are correct and complete; we omit the proofs due to lack of space. Notice that the algorithms, in general, produce nondeterministic plans. These can either be directly executed via a scheduler that must choose “fairly” amongst different possible actions, or transformed offline into deterministic plans. Producing nondeterministic plans is crucial to the effectiveness of the

algorithms, since the deterministic counterpart Π_D of a nondeterministic plan Π_{ND} may be exponentially larger than Π_{ND} , since the states of Π_D must encode the history of the traversed states of Π_{ND} .

5 Experimental Evaluation

We implemented all of the presented algorithms, leveraging on efficient BDD-based image primitives to progress sets of states (e.g. beliefs and open sets) by observations and actions, to intersect and check the entailment amongst sets of states, and to perform quantification operations on sets of states. To provide a common basis for comparing the algorithms, we did not introduce problem-specific optimizations, and we adopted a simple breadth-first heuristic to insure that plans are optimal and that the heuristic does not favor a given algorithm, cluttering our comparison.

In our tests, we considered the domain of the example, scaling up its size up to 100 floors (and 201 rooms), and a set of 6 different problems of increasing difficulty, so to test every combination of requirements on the strength of the plan and on the guarantee of detecting its success. In particular, we report here the results for the problem of reaching room $\langle \lceil M/2 \rceil . [3 \times M/2] \rangle$. For such problem, no strong solution exists; a strong cyclic solution with immediate detection exists, given by a plan along the lines of $\Pi_{CYCLE}^{\langle 2 \cdot M + 1 \rangle}$. The results are

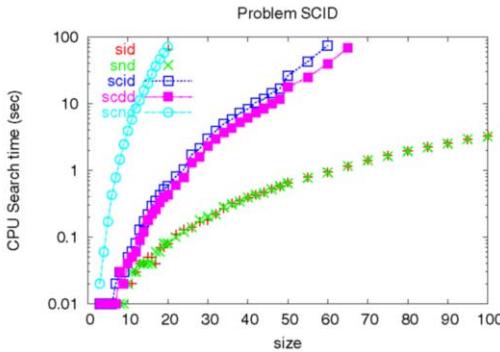

Figure 6. Results for the tests.

shown in Fig.6. A line-point style is used to indicate that the algorithm found a solution for the problem; only points are reported to indicate it signaled the absence of such a solution.

These results show clearly that strong algorithms perform much faster than strong cyclic ones. Moreover, amongst the strong cyclic algorithms, the one with no detection is far slower than those with immediate/delayed goal detection. This is mainly due to the different label propagation schema used by the algorithms: while the strong algorithms basically simply propagate boolean labels bottom-up on the graph, the strong cyclic algorithms with immediate/delayed detection compute such labels by interleaving an optimistic and a pessimistic fixed point computation, which may imply more computations of the label for a single node. For the SCND algorithm this becomes even far more complicated because the label is actually a set of states, and the number of interleaved fix-point computations may equal, in the worse case, the number of states in the beliefs. The remaining tests, which we do not report for reasons of space, consistently confirm the above intuitions.

6 Related works and Conclusions

In this paper we tackle the open problem of strong cyclic planning under partial observability. We provide a thorough, formal definition of the problem, and we present a family of algorithms which solve it under different requirements on the detection of goal achievement.

Amongst the many works in planning in nondeterministic domains [9, 2, 11, 4, 8], only few deal with strong cyclic planning ([5, 10, 8]), and, with the exception of [7], only for the much simpler case of full observability. The work in [7], on the other side, only provides an informal statement of the problem, and completely overlooks the issue of goal detection, constraining to the immediate detection case, and adopting a logical representation that sacrifices expressiveness to allow for a more effective implementation.

Our algorithms for strong cyclic planning share a nested least-greatest fix-point structure with LAO* [6], an algorithm for optimal search in and-or graphs. However, the extensions required to implement the termination checks cannot be easily encoded within the LAO* setting by means of probabilities, costs, and rewards. To solve strong cyclic planning under partial observability, LAO* would have to be changed by replacing its dynamic programming cost update procedure with a sub-procedure that tests whether the explicit and-or graph includes a valid cyclic plan. This is indeed what we devise, realizing our idea in a symbolic setting that allows for scalable algorithms by avoiding explicit state enumeration.

Strong cyclic planning could be thought of as a special case of the framework for planning under partial observability with extended goals presented in [1, 3]. This is not the case, since KCTL goals are not expressive enough to directly codify strong cyclic planning with delayed detection. Our algorithms, on the other hand, are amenable to the use of the efficient mechanisms for planning with nondeterministic domains (e.g. symbolic data structures, heuristics), and pave the way to an efficient implementation for planning for more general forms of temporally extended goals under partial observability.

Approximation Properties of Planning Benchmarks

Malte Helmert and Robert Mattmüller and Gabi Röger¹

Abstract. For many classical planning domains, the computational complexity of non-optimal and optimal planning is known. However, little is known about the area in between the two extremes of finding *some* plan and finding *optimal* plans. In this contribution, we provide a complete classification of the propositional domains from the first four International Planning Competitions with respect to the approximation classes **PO**, **PTAS**, **APX**, **poly-APX**, and **NPO**.

1 INTRODUCTION

Considering the important role that benchmark domains such as **LOGISTICS** and **SATELLITE** play in evaluating the performance of classical planning algorithms, comparatively little is known about their computational properties. With the notable exception of the **BLOCKSWORLD** domain [4, 12, 13], the published results on the computational complexity of planning benchmarks are rather coarse-grained. In most cases, they are limited to the analysis of two decision problems (relative to a certain planning domain):

- *Plan existence*: Is a given planning task solvable?
- *Bounded plan existence*: Is a given planning task solvable using no more than a certain number of actions?

For many planning domains, it turns out that the former problem is solvable in polynomial time, while the latter is **NP**-complete [5, 6]. In practice, this means that finding *some* plan for such a planning task is easy, while finding an *optimal* plan is difficult. In such a situation, it is natural to ask just how close to optimality we can get without sacrificing polynomial run-time.

This question has been raised and (partially) answered for many classical optimization problems such as the traveling salesperson problem, set covering problems, satisfiability-type problems, and countless others; it is the topic of the area of *approximation algorithms* [1]. In this contribution, we investigate the propositional planning domains introduced in the first four International Planning Competitions [2, 7, 9, 10] from this perspective, providing a complete classification with respect to the standard approximation classes.

We start our investigation by providing some background on the theory of approximation algorithms and how it applies to classical planning domains. We then present our main results in two parts, first discussing planning domains for which good, but not arbitrarily good, approximation algorithms exist, then planning domains for which good approximation algorithms do not exist. Finally, we summarize and conclude.

2 APPROXIMATION ALGORITHMS

Due to limited space, we keep our discussion of the theory of approximation algorithms short, pointing to the literature for formal

detail [1]. An *optimization problem* is either a *maximization problem* or a *minimization problem*; we focus on the latter exclusively. A minimization problem is given by a set of *instances*, a set of *feasible solutions* for each instance (possibly empty), and a *measure function* associating a number with each feasible solution of each instance. A solution is called *optimal* for a given instance if it minimizes the measure function among all feasible solution for that instance. An *approximation algorithm* for a minimization problem is a polynomial-time algorithm that, given an instance of the problem, generates a feasible solution for that instance or detects that none exists. An approximation algorithm that only generates solutions with measure at most c times the optimal measure (for some $c \in \mathbb{R}$) is called *c-approximating*. If such an algorithm exists, the problem is called *c-approximable*.

For the purposes of this paper, *planning domains* are minimization problems; their instances are called *planning tasks*. Solutions to planning tasks are sequences of *actions* called *plans*. The only measure function we consider is *sequential plan length*, which associates each plan with the number of actions it contains. Other common measure functions include parallel plan length, or weighted sequential plan length where some actions are more costly than others.

Optimization problems are grouped into different *approximation classes* in the same way that decision problems are classified into decision complexity classes like **P** and **NP**. Translating the usual definitions to the terminology of planning domains and tasks, the most important approximation classes are the following ones:

- Domains where optimal plans can be generated in polynomial time (**PO**).
- Domains which are *c*-approximable for *all* $c > 1$ (**PTAS**).
- Domains which are *c*-approximable for *some* $c > 1$ (**APX**).
- Domains where plans of length polynomially bounded by the optimal plan length can be generated in polynomial time (**poly-APX**).
- Domains where optimal plans can be generated in polynomial time by a non-deterministic Turing Machine (**NPO**).

It is easy to see that **PO** ⊆ **PTAS** ⊆ **APX** ⊆ **poly-APX** ⊆ **NPO** and that all these classes are identical if **P** = **NP**. More interestingly, all these inclusions are strict if **P** ≠ **NP** [1].

Membership of a minimization problem (planning domain) in one of these approximation classes can be shown constructively by providing a suitable approximation algorithm. Non-membership can be shown by *approximation-preserving reductions* (AP-reductions) from problems that are known to be hard, similar to the way many-one reductions are employed in classical complexity theory. Due to space restrictions, we do not present reductions in full formal details, so that we do not need to formally introduce AP-reductions.²

3 APPROXIMATION AND PLANNING

There is little work in the literature on the approximation properties of planning domains, the main exception being Selman's paper which links approximability to *reactive planning* and shows that the BLOCKSWORLD domains is 2-approximable and thus in **APX**, but not in **PTAS** unless $P = NP$ [12]. However, the literature does contain classifications of these planning domains from a classical complexity theory point of view [5, 6], addressing the *plan existence* and *bounded plan existence* decision problems. We can benefit from this body of work in the following ways:

- A domain belongs to **NPO** if shortest plan lengths are polynomially bounded by task size. Otherwise, it is not in **NPO**, as it is not always possible to *write down* a plan in polynomial time.
- Domains with polynomial-time planning algorithms belong to **poly-APX**, and to **PO** if the algorithms generate optimal plans.
- Domains with **NP-hard** *plan existence* problems do not belong to **poly-APX** unless $P = NP$.
- Domains with **NP-hard** *bounded plan existence* problems do not belong to **PO** unless $P = NP$.

Applying these rules to the complexity results for the benchmark domains of the four International Planning Competitions [5, 6], there are ten planning domains for which the classification into the approximation classes introduced in the previous section is not implied by the decision complexity results, namely BLOCKSWORLD, DEPOT, DRIVERLOG, GRID, LOGISTICS, MICONIC-SIMPLEADL, MICONIC-STRIPS, ROVERS, SATELLITE, and ZENOTRAVEL. In all these domains, polynomial non-optimal planning algorithms exist, but bounded plan existence is an **NP**-complete problem. Therefore, all these domains belong to **poly-APX**, but none belongs to **PO** unless $P = NP$. The open question, then, is whether these domains belong to **PTAS**, to **APX \ PTAS**, or to **poly-APX \ APX**.

As noted above, the approximation properties of BLOCKSWORLD have already been studied: it belongs to **APX**, but not to **PTAS** unless $P = NP$. In the following two sections, we present similar classification results for the remaining nine domains. We begin our investigation with domains which, like BLOCKSWORLD, are c -approximable but cannot be approximated arbitrarily well unless $P = NP$.

4 c -APPROXIMABLE DOMAINS

For most domains admitting polynomial planning algorithms, plans can be generated by simple greedy algorithms which satisfy the individual subgoals one after the other. If the number of steps required for each such individual goal can be bounded by a constant and an optimal plan requires at least one separate action per subgoal, then such an approach is c -approximating for some $c \in \mathbb{R}$. We first investigate a family of related domains sharing this property.³

Planning domain 1 SIMPLETRANSPORT

OBJECTS: Locations V , packages P , and vehicles T .

STATES: Each package has an associated location or is inside a vehicle. Each vehicle has an associated location. Initially, no package is inside a vehicle.

ACTIONS: Moving a vehicle between any two locations; picking up a package with a vehicle at the same location; unloading a package from a vehicle.

GOALS: Each package has an associated goal location.

The SIMPLETRANSPORT domain is not itself a planning competition benchmark, but it is closely related to some of them:

- **LOGISTICS** is a generalization of SIMPLETRANSPORT where vehicles are partitioned into *trucks* and *airplanes* and locations are partitioned into a set of *cities*, each with a distinguished *airport* location. Trucks may only move between locations in the same city, and airplanes may only move between (and be initially located at) airports.
- **MICONIC-STRIPS** is the SIMPLETRANSPORT domain restricted to a single vehicle. In the MICONIC domains, the vehicle is usually called an *elevator*, the locations *floors*, and the packages *passengers*. Instead of saying that a passenger is picked up or unloaded, we say that he *boards* or *leaves* the elevator.
- **MICONIC-SIMPLEADL** is identical to MICONIC-STRIPS except that pickup and unload actions are replaced by a single *stop* action. When this action is applied at location l , all passengers at l which are not at their goal location board the elevator, and all passengers inside the elevator with goal location l leave.
- **ZENOTRAVEL** is identical to SIMPLETRANSPORT except that each vehicle has an associated *fuel level* (a natural number). Vehicles can only move if their fuel level is non-zero, and movement reduces their fuel level by one.⁴ Refueling actions, increasing the fuel level of a vehicle by one, are applicable at any time.

It is quite easy to come up with c -approximation algorithms for these four domains. Indeed, for three of them, the greedy goal-at-a-time approach suffices. Therefore, all these domains belong to **APX**. We now show that it is hard to generate arbitrarily good plans.

Theorem 2 SIMPLETRANSPORT \notin **PTAS**, unless $P = NP$. This is true even in the special case with only one vehicle.

Proof sketch: Proof by AP-reduction from the MINIMUM VERTEX COVER problem for graphs where all vertices have degree 2 or 3, which is not in **PTAS** unless $P = NP$ [11]. A given graph $G = (V, E)$ is mapped to a SIMPLETRANSPORT task with one location for each vertex in V , plus one start location for the single vehicle. For each edge $\{u, v\} \in E$, one package must be moved from u to v and another one from v to u . The key observation is that the set of locations visited at least twice in a plan must form a vertex cover of G (i.e., includes at least one vertex from each edge in E). The degree restriction on the graphs guarantees that the size of a minimum vertex cover is $\Omega(|V|)$, which is important for proving that the reduction is approximation-preserving. ■

While the theorem shows that there must be *some* value $c > 1$ for which there is no c -approximating algorithm for SIMPLETRANSPORT with a single vehicle if $P \neq NP$, it does not provide us with an actual lower bound for approximability. In fact, the hardness result used for the reduction does not provide a lower bound either, but it is known that the MINIMUM VERTEX COVER problem for graphs with a vertex degree bound of 5 is not approximable within 1.0029 unless $P = NP$ [1]. By adjusting our reduction accordingly, we can exploit this result to show that MICONIC-STRIPS is not approximable within 1.000112 unless $P = NP$.

Corollary 3 LOGISTICS \in **APX \ PTAS**, unless $P = NP$.

MICONIC-STRIPS \in **APX \ PTAS**, unless $P = NP$.

MICONIC-SIMPLEADL \in **APX \ PTAS**, unless $P = NP$.

ZENOTRAVEL \in **APX \ PTAS**, unless $P = NP$.

³ To keep discussion short, we introduce planning domains informally and refer to the literature for exact PDDL definitions [2, 7, 9, 10].

⁴ There are also movement actions reducing fuel level by two, but there is no point in applying them.

Proof sketch: Greedy algorithms delivering one package (or passenger) at a time 2-approximate LOGISTICS and MICONIC-STRIPS and 3-approximate ZENOTRAVEL. (More sophisticated algorithms yield a $\frac{4}{3}$ -approximation for LOGISTICS and a $\frac{7}{6}$ -approximation for MICONIC-STRIPS.) These three domains are generalizations of SIMPLETRANSPORT with one vehicle, so they do not belong to PTAS unless $P = NP$.

MICONIC-SIMPLEADL is 2-approximable by an algorithm that moves to and stops at all initial floors of all passengers, then moves to and stops at all goal floors of all passengers. For proving non-membership in PTAS, essentially the same reduction as in the previous theorem can be used. ■

There are two more c -approximable benchmark domains. One of them is DEPOT, a combination of SIMPLETRANSPORT (packages are transported between locations by trucks) and BLOCKSWORLD (packages at each location are stacked into towers). The BLOCKSWORLD subproblem uses named and limited table positions; however, trucks provide unlimited auxiliary storage, so limitation of table positions is not problematic.⁵ Hardness for DEPOT follows from the BLOCKSWORLD and SIMPLETRANSPORT results immediately, and membership in APX is again fairly straightforward, so we do not define the domain formally but simply state our results briefly.

Theorem 4 $DEPOT \in APX \setminus PTAS$, unless $P = NP$.

Proof sketch: A straight-forward adaptation of the well-known 2-approximation for BLOCKSWORLD leads to a 3-approximation of DEPOT. The PTAS result follows because the domain generalizes both SIMPLETRANSPORT and BLOCKSWORLD. ■

Finally, we turn our attention to the SATELLITE domain, which is defined as follows.

Planning domain 5 SATELLITE

OBJECTS: Satellites S , instruments I , modes M , and directions D . Each instrument is located on one satellite, supports a set of modes, and has one direction as its calibration target.

STATES: Each satellite points at a certain direction. Each instrument may be powered on or off. Each instrument may or may not be calibrated. For each direction and mode, an image of this direction in this mode may or may not be available. Initially, no instrument is powered on or calibrated, and no images are available.

ACTIONS: Pointing a satellite at another direction; powering on an instrument (requires that no other instrument on this satellite is powered on; the instrument is not calibrated afterwards); powering off an instrument; calibrating an instrument (requires that its satellite points at its calibration target); taking an image of the pointing direction of a satellite in some mode (requires a powered-on, calibrated instrument supporting this mode on this satellite).

GOALS: Satellites may have associated target directions; images may need to be available for certain combinations of directions and modes.

SATELLITE falls into the same approximation category as the other domains in this section.

Theorem 6 $SATELLITE \in APX \setminus PTAS$, unless $P = NP$.

⁵ We require that there is at least one truck in each DEPOT task. DEPOT tasks without trucks would partition into sets of unrelated BLOCKSWORLD tasks with limited table positions. This BLOCKSWORLD variant is polynomially solvable [4], but we do not claim that it is in APX.

Proof sketch: A greedy algorithm solving one goal at a time (taking images first, then pointing satellites to their final directions, if any) is 6-approximating, showing membership in APX.

Limits of approximability can again be shown by an AP-reduction from MINIMUM VERTEX COVER for graphs with degree 2 or 3. A graph $G = (V, E)$ is mapped to a SATELLITE task with one satellite for each vertex $v \in V$ and one mode for each edge $e \in E$. The satellite corresponding to v has a single instrument supporting exactly the modes corresponding to edges incident to v . There is only one pointing direction d , which also serves as a calibration target for all satellites. An image of d must be taken in each mode. Given a plan for the task, the set of satellites used for taking images during the plan defines a vertex cover on G . The reduction is easily shown to be approximation-preserving. ■

Instead of using many satellites with a single instrument each, we could also prove hardness for the case of a single satellite with many instruments. Similarly, instead of requiring many images of one direction, we could also require one image each of many directions.

5 NON-APPROXIMABLE DOMAINS

In this section, we discuss the remaining three planning domains: ROVERS, DRIVERLOG, and GRID. The results we present are mostly negative: While it is easy to see that all these domains are in poly-APX, none of them admit constant-factor approximations unless $P = NP$. Like some of the domains we have seen previously, all three domains have a transportation or path-planning flavor. Differently to the domains we have seen previously, however, they do not exhibit a *fixed roadmap*. In the ROVERS domain, different vehicles use different roads. In DRIVERLOG, some edges can only be traversed by car, others only on foot. In GRID, locations can be initially inaccessible and need to be opened by using keys. We will see that these aspects of the problems are responsible for hardness of approximation, starting with the ROVERS domain.

Planning domain 7 SIMPLEROVERS

OBJECTS: Rovers R , waypoints W , and soil sample waypoints $S \subseteq W$. Each rover has an associated roadmap graph, which is a tree on a subset of waypoints. Each waypoint must be included in some roadmap graph. There is a waypoint common to all roadmap graphs called the lander location.

STATES: Each rover has an associated location, a waypoint on its roadmap graph. Rovers may carry a soil sample for a given waypoint or be empty. Soil data for a given waypoint may or may not have been transmitted. Initially, all rovers are empty and no soil data has been transmitted.

ACTIONS: Moving a rover between two waypoints connected on its roadmap; sampling soil on a soil sample waypoint with some rover (loads a soil sample into the rover, which must be empty; can only be done once for each waypoint); transmitting data for a soil sample with some rover (the soil sample must be inside the rover); emptying a rover.

GOALS: For each soil sample waypoint, a soil sample must be transmitted.

The domain is called SIMPLEROVERS because it excludes features of the full ROVERS domain such as other science targets besides soil samples (namely, rock samples and images), restricted visibility for transmitting science data, and rovers equipped for only a subset of science tasks [9]. Including these would require many more details without providing much further insight. Our results equally apply to the unrestricted domain.

Theorem 8 ROVERS $\in \text{poly-APX} \setminus \text{APX}$, unless $\mathbf{P} = \mathbf{NP}$. This is true even in the restricted SIMPLEROVERS domain.

Proof sketch: Any solvable ROVERS task can easily be solved one goal at a time, which shows membership in **poly-APX**. For the non-approximability result, we reduce from the MINIMUM SET COVER problem: Given a collection of subsets \mathcal{C} of a set S , find a sub-collection $\mathcal{C}' \subseteq \mathcal{C}$ with $\bigcup_{C' \in \mathcal{C}'} C' = S$, using the cardinality of the chosen sub-collection as the measure of the solution. The problem is not c -approximable for any $c \in \mathbb{R}$ unless $\mathbf{P} = \mathbf{NP}$ [1].

For a given instance (\mathcal{C}, S) , the corresponding SIMPLEROVERS task has one rover for each subset in \mathcal{C} , and one soil sample waypoint for each element of S . The roadmaps for the rovers are designed in such a way that the rover for $C \in \mathcal{C}$ can reach exactly those soil sample waypoints corresponding to elements of C . All soil sample waypoints reachable by a rover are very near to each other and a very long distance from the original rover location, so that plan lengths are dominated by the number of rovers used for solving the goals. Any such set of rovers defines a solution to the set covering instance; the reduction is approximation-preserving. ■

We presented this proof first because the other two are similar in spirit, but somewhat more involved technically. In both cases, the key idea is again that selecting a certain subset for the set cover allows achieving a set of goals corresponding to the elements of that subset, and the total length of the plan is dominated by the number of chosen subsets. This is enforced by requiring that a very large distance needs to be crossed in the planning task at least once for each chosen subset. We continue our exposition with the DRIVERLOG domain.

Planning domain 9 DRIVERLOG

OBJECTS: Trucks T , drivers D , major locations L , minor locations L_M (disjoint from L), and packages P . There is a connected road graph, whose vertices are the major locations, and a connected footpath graph, whose vertices are the major and minor locations. In the footpath graph, the degree of all minor locations is 2, and both adjacent vertices of a minor location are major locations.

STATES: A truck is located at some major location, a package at some major location or inside a truck, a driver at some major or minor location or inside a truck. Initially, all are located at major locations.

ACTIONS: Having a driver walk from one location to another (must be connected in the footpath graph); driving a truck from one location to another (must be connected in the road graph, must have a driver inside the truck); boarding a truck with a driver at the same location (must not have another driver inside the truck); debarking from a truck with a driver; loading a package into a truck at the same location; unloading a package from a truck.

GOALS: Packages, drivers, and trucks may have associated goal locations (which are always major locations).

The somewhat peculiar restriction on footpath graphs merely ensures that walking from one major location to another requires two actions rather than just one, to reflect the fact that walking usually takes longer than driving. There is never a good reason to walk from a major location to a minor location except to continue to the other adjacent major location, so instead of modeling minor locations explicitly, our following proof assumes that there is only one kind of location and assigns a cost of 2 to walk actions.

Theorem 10 DRIVERLOG $\in \text{poly-APX} \setminus \text{APX}$, unless $\mathbf{P} = \mathbf{NP}$. This is true even when there is only a single driver, and goals are only defined for packages.

Proof sketch: Again, a simple greedy algorithm solving one goal at a time suffices for showing membership in **poly-APX**. For hardness, we again provide an approximation-preserving reduction from MINIMUM SET COVER, mapping instance (\mathcal{C}, S) to the following DRIVERLOG task:

- There is a central location l_* , where the only driver starts. This is connected to *subset locations* l_C for each $C \in \mathcal{C}$ by very long disjoint footpaths. There is a truck at each subset location.
- For each element $s \in S$, there is an *element start location* l_s^- and an *element goal location* l_s^+ , and a road connecting the two. There is a truck and a package at each element start location. The package must be moved to the corresponding element goal location.
- For each subset $C \in \mathcal{C}$ and element $s \in C$, there is a location $l_{C,s}$ connected to l_C by a road and to l_s^- by a footpath.

It is easy to see that the subsets corresponding to the subset locations visited in a plan correspond to a set cover. By making the distances between central location and subset locations long enough, we can ensure that plan length is dominated by the cardinality of this set cover, so that the reduction is approximation-preserving. (The DRIVERLOG task does not have connected road and footpath graphs, but this can be repaired by introducing connecting paths that are too long to be useful for generating short plans.) ■

The last missing domain is GRID, another variation of the transportation theme.

Planning domain 11 GRID

OBJECTS: A single robot, locations L arranged into a rectangular grid, key shapes S , and keys K . Each key has a shape from S . A location may be initially locked by a lock with a certain shape from S . **STATES:** The robot has an associated location. Keys have an associated location or are carried. Locations can be open or locked. Initially, no key is carried.

ACTIONS: Moving the robot to an adjacent open location; picking up a key at the current robot location if no key is currently being carried; dropping a key being carried; switching the currently carried key with a key at the current robot location; opening a locked location adjacent to the robot with a key of the same shape as the lock. **GOALS:** Keys may have associated goal locations.

From our earlier analysis of the GRID domain, we know that GRID $\in \text{poly-APX}$ [5]. This reference also contains two proofs of hardness for the bounded plan existence problem in this domain, one based on satisfiability and one based on a traveling-salesperson type problem. However, neither of these reductions can be used to prove hardness of approximation. Indeed, the GRID tasks generated by the satisfiability reduction can easily be 2-approximated, and the restricted version of the GRID domain considered in the traveling salesperson reduction even belongs to **PTAS**. We thus require a new reduction.

Theorem 12 GRID $\in \text{poly-APX} \setminus \text{APX}$, unless $\mathbf{P} = \mathbf{NP}$.

Proof sketch: Membership in **poly-APX** is known [5]. Again, we map MINIMUM SET COVER instances (\mathcal{C}, S) to planning tasks via an approximation-preserving reduction. The GRID task has three kinds of keys: for each subset $C \in \mathcal{C}$, there is a *subset key* k_C with key shape S_C ; for each subset $C \in \mathcal{C}$ and element $s \in C$, there is an *element key* $k_{C,s}$ with key shape S_s ; for each element $s \in S$, there is a *goal key* k_s with a key shape that cannot be used for opening any location. Goals are only defined for the goal keys.

The grid of the planning tasks consists of two areas which are very distant from each other. The first area contains the initial locations of the element and goal keys and the robot as well as the goal locations of the goal keys. The second area contains the initial locations of the subset keys. The initial location of element key $k_{C,s}$ is locked with a lock of shape S_C , and the initial location of goal key k_s is locked with a lock of shape S_s . These are the only locations which are initially locked.

To solve the task, the robot must unlock the initial locations of all goal keys, which requires obtaining keys of shape S_s for all $s \in S$. This in turn requires obtaining subset keys for a collection of subsets that covers S , so the set of subset keys picked up in a plan defines a set cover. By putting a large enough distance between the first and second area, we can ensure that the cardinality of this set cover dominates total plan length. (Note that the robot can only carry one key at a time.) Thus, the reduction is approximation-preserving. ■

We point out that the hardness of approximately solving GRID tasks is largely due to the necessity of opening locations. If we restrict ourselves to tasks where opening is impossible (i.e., the shapes of locks are disjoint from the shapes of keys), we can provide a $(2 + \varepsilon)$ -approximating planning algorithm for all $\varepsilon > 0$. However, we will not prove this result here, but instead turn to discussion.

6 SUMMARY AND CONCLUSION

The approximation properties of the benchmark domains are summarized in Fig. 1. There are some interesting observations to be made. First, there are no domains in the benchmark set that fall into the class **PTAS** \ **PO**. There is no fundamental reason why this should be the case, except maybe for the fact that **PTAS** problems are rare in general.⁶ However, as we pointed out when discussing the GRID domain, there are **NP**-hard special cases of the competition domains that do admit polynomial-time approximation schemes.

Looking into the hardness proofs, we observe that we could easily get away with only using two different optimization problems for our reductions, both of which are set covering problems. We believe that this is no coincidence: Set covering problems arise naturally in planning tasks through positive interactions of subgoals. We believe that finding a good way of integrating heuristics for set covering problems into admissible heuristics for domain-independent planning could lead to a significant advance for optimal planning algorithms. However, we consider this a very challenging avenue of research.

What to do with these results? After our earlier results [5, 6] on the decision complexity of planning in the benchmark domains, we see our work as a second step on the road towards a better understanding of the benchmark suite, which we believe to be critical to provide “the level of understanding required for its effective use as a benchmark” [13, Slaney and Thiébaux on BLOCKSWORLD]. In comparison to Slaney and Thiébaux’s effort, at least two more steps are required until we can consider these standard benchmarks “understood”: one is the identification of phase transition regions to know where the hard instances are, and the other is the provision of (domain-dependent) optimal solvers as a reference point for evaluation of solution quality.

In addition to such deeper domain-specific studies, we believe that some important insights into domain-*independent* planning can be

⁶ To readers familiar with other approximation classes, we point out that there is a good reason why there is no domain in the class **FPTAS** \ **PO**; this follows quite easily from Theorem 3.15 in the book by Ausiello et al. [1]. Similarly, we cannot have planning domains in the class **exp-APX** \ **poly-APX**.

Approximate linear-programming algorithms for graph-based Markov decision processes

Nicklas Forsell^{1,2} and Régis Sabbadin²

Abstract. In this article, we consider a form of compact representation of MDP based on graphs, and we propose an approximate solution algorithm derived from this representation. The approach we propose belongs to the family of *Approximate Linear Programming* methods, but the graph-structure we assume allows it to become particularly efficient. The proposed method complexity is linear in the number of variables in the graph and only exponential in the width of a dependency graph among variables.

1 INTRODUCTION

Markov Decision Processes (MDP) have become a standard model for decision-theoretic planning. However, classical dynamic programming algorithms [7] do not scale to the size of problems that can be compactly represented by the factored representations traditionally used in AI. Therefore several methods of aggregation/decomposition of large problems have been proposed in the AI community. Aggregation methods ([1, 4]) use a compact representation of the probability and reward functions involved in the MDP, and the proposed algorithms are designed to explicitly work with these factored descriptions.

In this article, we consider a form of compact representation of MDP based on graphs, and propose an approximate solution algorithm derived from this representation. The algorithm belongs to the family of *Approximate Linear Programming* methods and the graph-structure of the representation allows the algorithm to become particularly efficient. While previously proposed algorithms typically have a complexity exponential in the number of variables in the graph, our algorithm's is linear in the number of variables and only exponential in the width of a dependency graph among the variables.

First, we will describe the *Approximate Linear Programming* (ALP) method for solving large MDP [3]. We will then present the Graph-based multidimensional MDP framework (GMDP). The state and action variables of these MDP are multidimensional and attached to the nodes of a graph G allowing the representation of local dynamics. In this class of problems, it is assumed that the dynamics of each state variable only depend on the action applied locally and on the current values of the neighbouring state variables. We then introduce an extension of the ALP method, dedicated to solving Graph-based MDP. The methods complexity is linear in the number of variables in the GMDP, and exponential in the width of the dependency graph. To illustrate the method, we use a forest management example involving several treatment units, which will be referred to as stands.

2 MARKOV DECISION PROCESSES

2.1 Problem formulation

In its classical formulation [7], a stationary *Markov Decision Process* (MDP) is defined by a four-tuple $\langle \mathcal{X}, \mathcal{A}, p, r \rangle$, where \mathcal{X} represents the finite set of admissible states of the system, \mathcal{A} the finite set of applicable actions, $p : \mathcal{X} \times \mathcal{A} \times \mathcal{X} \rightarrow [0, 1]$ the transition probabilities between states, and $r : \mathcal{X} \times \mathcal{A} \rightarrow \mathbb{R}$ an “immediate” reward function. Note that both $p(x'|x, a)$ and $r(x, a)$ are independent of the decision stage t .

A function $\delta : \mathcal{X} \rightarrow \mathcal{A}$ assigning at each time step an action to every state, is called a (stationary) *policy*. The *value function* of a policy $v_\delta : \mathcal{X} \rightarrow \mathbb{R}$ is defined so that $v_\delta(x)$ represents the infinite horizon, discounted cumulative reward attached to a policy δ applied to a MDP, with initial state x . This value can be computed as:

$$v_\delta(x) = E \left[\sum_{t=0}^{\infty} \gamma^t r(x^t, \delta(x^t)) | x^0 = x \right]. \quad (1)$$

The expectation is taken over all possible trajectories $\tau = \langle x^0, a^0, x^1, \dots, x^t, a^t, \dots \rangle$, where from the initial state x , the policy δ is applied. The factor which ensures that the above infinite sum converges is the discount factor $0 \leq \gamma < 1$.

The problem of finding an optimal policy with respect to the discounted criterion (1) can be written as:

$$\text{Find } \delta^* : \mathcal{X} \rightarrow \mathcal{A}, \text{ so that: } v_{\delta^*}(x) \geq v_\delta(x), \forall x \in \mathcal{X}, \forall \delta \in \mathcal{A}^\mathcal{X}.$$

This problem is classically solved by Stochastic Dynamic Programming algorithms [7]. In the next section we present a method based on *linear programming* (see e.g. [7]).

2.2 Linear Programming Solution for MDP

In this paper, we will use the following definition of the *Bellman operator* \mathcal{B} operating on any value function v .

Definition 1 (Bellman operator) Let $v : \mathcal{X} \rightarrow \mathbb{R}$, the Bellman transform $\mathcal{B}(v) : \mathcal{X} \rightarrow \mathbb{R}$ is defined as:

$$\mathcal{B}(v)(x) = \max_{a \in \mathcal{A}} \left\{ r(x, a) + \gamma \sum_{x' \in \mathcal{X}} p(x'|x, a)v(x') \right\}, \forall x \in \mathcal{X}.$$

Let v^* denote the value function attached to an optimal policy δ^* ($v^* = v_{\delta^*}$). It has been shown (see, e.g. [7]) that v^* can be computed as the unique solution of the system of non-linear equations $v^* = \mathcal{B}(v^*)$:

$$v^*(x) = \max_{a \in \mathcal{A}} \left\{ r(x, a) + \gamma \sum_{x' \in \mathcal{X}} p(x'|x, a)v^*(x') \right\}, \forall x \in \mathcal{X}.$$

The optimal policy δ^* can then be obtained *greedily* from v^* :

$$\delta^*(x) = \arg \max_{a \in \mathcal{A}} \left\{ r(x, a) + \gamma \sum_{x' \in \mathcal{X}} p(x'|x, a) v^*(x') \right\}, \forall x \in \mathcal{X}.$$

There exist several methods for computing v^* . We will focus our discussion on the *linear programming* approach. This method defines v^* as the solution of the following linear programming problem:

$$\begin{aligned} \min & \quad \sum_{x \in \mathcal{X}} c(x)v(x) \\ \text{s.t.} & \quad v(x) \geq r(x, a) + \gamma \sum_{x' \in \mathcal{X}} p(x'|x, a)v(x') \\ & \quad \forall x \in \mathcal{X}, \forall a \in \mathcal{A} \\ & \quad v(x) \text{ free, } \forall x \in \mathcal{X}. \end{aligned} \quad (2)$$

where $c(x), \forall x \in \mathcal{X}$ are arbitrary strictly positive numbers. This formulation of the problem contains $|\mathcal{X}|$ variables, $|\mathcal{X}| \times |\mathcal{A}|$ constraints and is commonly referred to as the *exact LP*. Note that any values for $c(x_1), \dots, c(x_{|\mathcal{X}|})$, will lead to the same optimal value function v^* .

2.3 Approximate Linear Programming (ALP)

For many practical problems, a state is described by the values of several state variables. Related to this gain in the power of expression, is the fact that the size of the state space grows exponentially with the number of state variables. In order to solve practical problems with more than a few variables (and thus of considerable size), using the Linear Programming method, the number of variables and constraints has to be decreased. The *approximate linear programming* (ALP) approach to MDP [3], looks for a *parameterised value function* v_w , which is an approximation of the optimal value function v^* . The parameterised value function v_w , is defined as a linear combination of a set of given basis functions $H = \{h_1, \dots, h_k\}$, $h_i : \mathcal{X} \rightarrow \mathbb{R}$, that can be written as:

$$v_w(x) = \sum_{i=1}^k w_i h_i(x), \forall x \in \mathcal{X}. \quad (3)$$

where $w = (w_1, \dots, w_k)$ is a vector of real-valued weights. Restricting the search of a solution of the LP (2), to the set of parameterised value functions (3), leads to a new *approximate LP model*:

$$\begin{aligned} \min & \quad \sum_{x \in \mathcal{X}} (c(x) \sum_{i=1}^k w_i h_i(x)) \\ \text{s.t.} & \quad \sum_{i=1}^k w_i h_i(x) \geq \\ & \quad r(x, a) + \gamma \sum_{x' \in \mathcal{X}} (p(x'|x, a) (\sum_{i=1}^k w_i h_i(x'))), \\ & \quad \forall x \in \mathcal{X}, \forall a \in \mathcal{A} \\ & \quad w_i \text{ free, } i = 1, \dots, k. \end{aligned} \quad (4)$$

The variables of the LP (4) are now the weights w_i . The problem has been transformed into the problem of finding a set of parameters values $w^* = (w_1^*, \dots, w_k^*)$, so that v_{w^*} be a close approximation of v^* . The advantage of this representation is that the number of variables has been decreased from $|\mathcal{X}|$ to k , the number of basis functions. Thus, the complexity of the problem has been reduced, to the price of the loss of the optimality of the obtained solution. Unfortunately the number of constraints is still $|\mathcal{X}| \times |\mathcal{A}|$, which means that a direct application of LP solution methods is still inefficient for solving really large problems. Several algorithms have been suggested for dealing with the exponential number of constraints induced by the ALP formulation of large MDP. For example [3], use the fact that most of the constraints in (4) are not active. They study an approximation of (4) in which a randomly chosen subset of constraints of tractable size is considered. They also provide probabilistic bounds

on the quality of the returned solution. [4], instead, use a factored representation of the constraints of the LP and a form of *variable elimination* for solving this factored LP.

In the following sections we will describe a specific class of problems for which we apply ALP techniques. Considering this restricted class, we will avoid the problem of facing exponential sets of constraints by *decomposing* the ALP model. The factorisation properties of the class of problems we study allow a further approximation of the ALP model. This in turn allows a replacement of the unique ALP model with a set of *independent* ALP models, of reasonable size.

3 GRAPH-BASED MARKOV DECISION PROCESSES

Factored MDP offer a compact representation of MDP with multidimensional state space, structured transition probabilities and structured reward functions. For solving factored MDP, a number of efficient algorithms relying on the structure of the problem, have been proposed. They are variants of either *value iteration* or *policy iteration* [1] or of ALP approaches [3, 4]. For example [4], propose an ALP-based algorithm relying on the structure of factored MDP in order to solve (4). However, one should note that in general the action spaces are supposed to be “flat” and the possible structure of the action space is not used in the solution algorithm. In this section we present a specific class of factored MDP, called *Graph-based Markov Decision Processes*. Even though it is a subclass of factored MDP, the multidimensionality of the action space is explicitly described and will be exploited by the ALP type of solution algorithms which will be described in the next section.

3.1 Definitions

The *Graph-based Markov Decision Process* (GMDP) is defined by a tuple $\langle \mathcal{X}, \mathcal{A}, p, r, G \rangle$. The state and action spaces are now Cartesian products $\mathcal{X} = \mathcal{X}_1 \times \dots \times \mathcal{X}_n$, and $\mathcal{A} = \mathcal{A}_1 \times \dots \times \mathcal{A}_n$, where \mathcal{X} and \mathcal{A} have the same dimensionality. The reason for \mathcal{X} and \mathcal{A} to have the same dimensionality, is for the transition and rewards to be defined as local (see definitions below). The *directed graph* $G = (V, E)$ expresses *local* dependencies among state and action variables.

A *neighbourhood function* N over V is defined as:

Definition 2 (Neighbourhood function) $N : V \rightarrow 2^V$ is defined as: $N(i) = \{j \in V | (j, i) \in E\}, \forall i \in V$.

Transitions and rewards are said to be *local* iff:

Definition 3 (Local transitions)

$$p(x'|x, a) = \prod_{i=1}^n p_i(x'_i | x_{N(i)}, a_i), \forall x' \in \mathcal{X}, x \in \mathcal{X}, a \in \mathcal{A}$$

where: $x_I = \{x_j | j \in I\}, \forall I \subseteq \{1, \dots, n\}$.

Definition 4 (Local rewards)

$$r(x, a) = \sum_{i=1}^n r_i(x_{N(i)}, a_i), \forall x \in \mathcal{X}, \forall a \in \mathcal{A}$$

In the general case, policies for a GMDP take the form $\delta = (\delta_1, \dots, \delta_n)$, where $\delta_i : \mathcal{X} \rightarrow \mathcal{A}_i$. Nevertheless, global policies can take space in $O(n\alpha^{\sigma^n})$ where $\alpha = \max_i |\mathcal{A}_i|$ and $\sigma = \max_i |\mathcal{X}_i|$.

Except for problems of very small dimension, this clearly prohibits the computation of global policies. Some special policies, called *local policies* are therefore of interest:

Definition 5 (Local policy) A policy $\delta : \mathcal{X} \rightarrow \mathcal{A}$, is said to be local iff $\delta = (\delta_1, \dots, \delta_n)$, where $\delta_i : \mathcal{X}_{N(i)} \rightarrow \mathcal{A}_i$.

Even though the optimal policy of a GMDP may not be local³, it is interesting to look for "good" local policies. This since they are both easy to express (space complexity in $O(n\alpha^\sigma)$) and implement. We have also observed that in practice they can perform very well. Furthermore, as will be shown in Section 4, it is possible to find an efficient algorithm, based on ALP, for finding efficient local policies.

3.2 Example GMDP

In some areas of the world, damage to forests due to wind is considered a major problem. This since recent and earlier gales have wind-felled massive amounts of forests. For example, a storm in 2005, wind-fell approximately 75 millions cubic meter of wood in the southern parts of Sweden. This corresponds to the total normal harvest in Sweden per annum. Forest management activities performed in the stands composing the forest, and the spatial arrangements of the stands can influence the risk of a stand being wind-thrown. Thus, the selection of a forest management policy is an important economic matter. We propose to model the selection of a forest management policy as a GMDP. The graphical part of this example GMDP model is shown in Figure 1. The forest is divided into geographical contiguous parcels of land, called *stands*. Each stand is represented by a state variable (right part of the figure). Each stand variable represents the age of the stand, which can be used to describe both the timber value of the stand, and the protection from storms it provides to neighbour stands. Two actions can be applied to each stand node at each time step: "clear-cutting" and "do-nothing". An additional node (middle) represents the occurrence of a storm at a given time step. The dynamics of the process has a deterministic component linked to the natural age evolution, and to the clear-cutting actions (replacing all trees in a stand with new, "zero-aged", ones). It also has a stochastic component, linked to the probabilistic occurrence of a storm, which may damage stands and necessitate their (maybe unplanned) clear-cutting.

Now, the transition probabilities for a given stand depend on the action locally applied, and the occurrence of a storm. When a storm occurs, the probability of a stand being damaged is dependent on the state of the stand and the "shelter effect" provided by its neighbour stands. This since stands can block the wind and thereby decrease the risk of other stands being wind-thrown. The sheltering effect provided by a stand, depends on the age of the stand. It is assumed that the wind direction of the storms is always the same, in the considered area. Figure 1 shows the probabilistic dependencies between the state variables. Note that the neighbourhood relation is not symmetric, and that the size of a neighbourhood is linked to the number of parent nodes, not child nodes. Thus, even if the storm variable has many children (every stands), the size of its neighbourhood is zero⁴.

Finally, local rewards are attached to each stand and are obtained when "clear-cutting" is applied and increase with the age of the stand.

³ [2] claim that there always exist local policies which are optimal, however, the proof for this claim is wrong, and furthermore it is possible to find examples for which no local policy is globally optimal. Still, in practice, the best local policies often perform well.

⁴ We assume that storm probability is not influenced by the occurrence of a storm the previous year.

A fixed residual reward is obtained when "do-nothing" is applied. We consider than when a storm occurs, forced salvage harvest of damaged stands only benefits the compensate costs and does not change the residual reward.

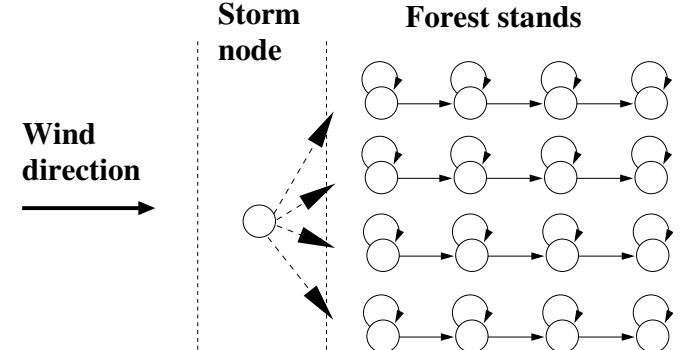

Figure 1. A GMDP representing the forest example, with one specific "storm event" node influencing all other stand-level state variable nodes.

4 APPROXIMATE LINEAR PROGRAMMING SOLUTION FOR GMDP

In this section we describe how the GMDP structure can be exploited for designing an efficient approximate linear programming algorithm. More precisely, we will show how the choice of specific basis functions can be used for finding an approximate solution of (4) in reasonable computation time. We will furthermore show how to compute a bound on the quality loss of the computed solution. We first describe a variation, providing a worst-case error bound, of the ALP approach that was presented in Section 2.

4.1 A generic ALP algorithm providing a bound on the measure of the worst-case error

A problem with the ALP algorithm described in Section 2 is that the quality of the approximate solution depends on the values chosen for the parameters $c(x)$. Furthermore, there are no guarantees that the approximate policy δ_{w^*} obtained from the solution w^* of the ALP, actually minimises the worst-case distance $\|v^* - v_{\delta_{w^*}}\|_\infty$.

With this problem in mind, [4] proposed an approximate *policy iteration* algorithm, in which they use an ALP method for computing an approximation of the value of a fixed policy. The algorithm explicitly minimises the worst-case error on the *measure* of the value of the policy. We suggest a variation of their algorithm which efficiently computes a set of parameter values w^* for which an *upper bound* on the worst-case distance to the optimal value function $\|v^* - v_{\delta_{w^*}}\|_\infty$ is minimised, instead of the worst-case distance itself.

Let us denote $\varepsilon_w = \|v^* - v_{\delta_w}\|_\infty = \max_{x \in \mathcal{X}} |v_{\delta_w}(x) - \mathcal{B}(v^*)(x)|$ the worst-case distance to the optimal value function associated to the parameters w of policy δ_w . Note that [8] showed that:

$$\|v^* - v\|_\infty \leq \frac{2\gamma}{1-\gamma} (\|v - \mathcal{B}(v)\|_\infty), \forall v : \mathcal{X} \rightarrow \mathbb{R}.$$

Using this result, we get the following bound on ε_w :

$$\varepsilon_w \leq \frac{2\gamma}{1-\gamma} (\|v_w - \mathcal{B}(v_w)\|_\infty). \quad (5)$$

Let $\phi_w = \|v_w - \mathcal{B}(v_w)\|_\infty$. Note that ϕ_w is called the *Bellman error* associated with v_w [8]. Furthermore, by finding the vector w which minimises ϕ_w we get a solution policy δ_{w^*} which approximates the optimal policy δ^* . Also, equation (5) provides us with an upper bound on ε_{w^*} , the worst-case distance from v_{w^*} to the optimal value function v^* .

The problem of minimising ϕ_w can be expressed by the following (non-linear) program:

$$\begin{aligned} \min \quad & \phi \\ \text{s.t.} \quad & \phi \geq v_w(x) - \mathcal{B}(v_w)(x), \forall x \in \mathcal{X} \\ & \phi \geq \mathcal{B}(v_w)(x) - v_w(x), \forall x \in \mathcal{X} \\ & w = (w_1, \dots, w_k) \text{ free}, \phi \text{ free}. \end{aligned} \quad (6)$$

4.2 Approximation in the GMDP case

Let $< \mathcal{X}, \mathcal{A}, p, r, G >$ be a GMDP, with $\mathcal{X} = \mathcal{X}_1 \times \dots \times \mathcal{X}_n$, and $\mathcal{A} = \mathcal{A}_1 \times \dots \times \mathcal{A}_n$. In the following, the state space $\mathcal{X}_i \in \mathcal{X}$ of variable i is identified with the set $\{1, \dots, |\mathcal{X}_i|\}$ of integers.

Let us consider a parameterised approximation of the value function, similar to that of (3). Let us also define the basis functions in the GMDP framework as :

Definition 6 (GMDP basis functions) Let $< \mathcal{X}, \mathcal{A}, p, r, G >$ be a GMDP, with $\mathcal{X} = \mathcal{X}_1 \times \dots \times \mathcal{X}_n$, and $\mathcal{A} = \mathcal{A}_1 \times \dots \times \mathcal{A}_n$. The basis functions: $h_{ij}, i \in 1, \dots, n, j \in 1, \dots, |\mathcal{X}_i|$ are defined as $h_{ij}(x_i) = 1$ if $x_i = j$ and 0 otherwise.

Notice that there are exactly $(\sum_{i=1}^n |\mathcal{X}_i|)$ basis functions. We can then write v_w as:

$$v_w(x) = \sum_{i=1}^n v_w^i(x_i) = \sum_{i=1}^n \sum_{j=1}^{|\mathcal{X}_i|} w_{ij} h_{ij}(x_i), \forall x \in \mathcal{X} \quad (7)$$

The Bellman transform $\mathcal{B}(v_w)$ can then be decomposed as:

Proposition 1 (GMDP Bellman operator)

$$\mathcal{B}(v_w)(x) = \sum_{i=1}^n \mathcal{B}_i(v_w^i)(x_{N(i)}), \forall x \in \mathcal{X}$$

$$\text{where: } \mathcal{B}_i(v_w^i)(x_{N(i)}) = \max_{a_i \in \mathcal{A}_i} \left\{ r_i(x_{N(i)}, a_i) + \gamma \sum_{x'_i \in \mathcal{X}_i} p_i(x'_i | x_{N(i)}, a_i) v_w^i(x'_i) \right\}, \forall x_{N(i)} \in \mathcal{X}_{N(i)}$$

Using the GMDP basis functions and the GMDP Bellman operator, (6) can be written as:

$$\begin{aligned} \min \quad & \phi \\ \text{s.t.} \quad & \phi \geq \sum_{i=1}^n (v_w^i(x_i) - \mathcal{B}_i(v_w^i)(x_{N(i)})), \forall x \in \mathcal{X} \\ & \phi \geq \sum_{i=1}^n (\mathcal{B}_i(v_w^i)(x_{N(i)}) - v_w^i(x_i)), \forall x \in \mathcal{X} \\ & w = (w_{11}, \dots, w_{n|\mathcal{X}_n|}) \text{ free}, \phi \text{ free} \end{aligned} \quad (8)$$

The NLP (8) is still intractable (it has $O(|\mathcal{X}| \times |\mathcal{A}|)$ constraints). We suggest to consider a first approximation of (8), in which the constraints that are of the form $\phi \geq |\sum_{i=1}^n \varphi_i(x_{N(i)})|$ are replaced by the following constraints :

Approximation 1:

$$\begin{aligned} \phi &= \sum_{i=1}^n \phi_i, \\ \phi_i &\geq |\varphi_i(x_{N(i)})|, \forall i, \forall x_{N(i)}. \end{aligned}$$

By making this approximation, the NLP (8) is replaced by a NLP that furthermore can be divided into n independent non-linear programs NLP_i , each of the following form:

$$\begin{aligned} \min \quad & \phi_i \\ \text{s.t.} \quad & \phi_i \geq v_w^i(x_i) - \mathcal{B}_i(v_w^i)(x_{N(i)}), \forall x_{N(i)} \in \mathcal{X}_{N(i)} \\ & \phi_i \geq \mathcal{B}_i(v_w^i)(x_{N(i)}) - v_w^i(x_i), \forall x_{N(i)} \in \mathcal{X}_{N(i)} \\ & w_i = (w_{i1}, \dots, w_{i|\mathcal{X}_i|}) \text{ free}, \phi_i \text{ free} \end{aligned} \quad (9)$$

A tractable approximation of linear program (6) can then be found by solving the n independent problems (9). Each independent non-linear program NLP_i , only contains $|\mathcal{X}_i| + 1$ variables and $2 \times |\mathcal{X}_{N(i)}| \times |\mathcal{A}_i|$ constraints, in comparison with the original approximate NLP model (4), that with the proposed basis function contains $|\mathcal{X}| \times |\mathcal{A}|$ constraints, and $\sum_{i=1}^n |\mathcal{X}_i|$ variables.

The question that remains now is how are the n independent problems solved? Note that the second set of constraints of (9) can be expressed in the following form: $\phi_i \geq \max_{a_i \in \mathcal{A}_i} \psi(x_{N(i)}, a_i), \forall x_{N(i)} \in \mathcal{X}_{N(i)}$. Which, equivalently can be expressed as: $\phi_i \geq \psi(x_{N(i)}, a_i), \forall x_{N(i)} \in \mathcal{X}_{N(i)}, \forall a_i \in \mathcal{A}_i$. So, the second set of non-linear constraints in (9) can be replaced by an equivalent set of linear constraints.

The first set of constraints can be expressed as: $\phi_i \geq -\max_{a_i \in \mathcal{A}_i} \psi(x_{N(i)}, a_i)$, which is obviously not equivalent to: $\phi_i \geq -\psi(x_{N(i)}, a_i), \forall x_{N(i)} \in \mathcal{X}_{N(i)}, \forall a_i \in \mathcal{A}_i$. Indeed, the second form is more restrictive than the first one, since it involves constraints which should be satisfied by every actions, while in the first form the constraints should be satisfied by at least one action. However, our second approximation consists in using this second form so as to recover a set of linear constraints.

Approximation 2:

By replacing the first set of constraints in the non-linear programs NLP_i (9) by the following more restrictive set of constraints: $\phi_i \geq -\psi(x_{N(i)}, a_i), \forall x_{N(i)} \in \mathcal{X}_{N(i)}, \forall a_i \in \mathcal{A}_i$, we create new set of independent linear programs $LP_i, i \in 1, \dots, n$:

$$\begin{aligned} \min \quad & \phi_i \\ \text{s.t.} \quad & \phi_i \geq \sum_{j=1}^{|\mathcal{X}_i|} w_{ij} h_{ij}(x_i) - r_i(x_{N(i)}, a_i) \\ & -\gamma \sum_{x'_i \in \mathcal{X}_i} (p_i(x'_i | x_{N(i)}, a_i) \sum_{j=1}^{|\mathcal{X}'_i|} w_{ij} h_{ij}(x'_i)), \\ & \forall x_{N(i)} \in \mathcal{X}_{N(i)}, \forall a_i \in \mathcal{A}_i \\ & \phi_i \geq r_i(x_{N(i)}, a_i) - \sum_{j=1}^{|\mathcal{X}_i|} w_{ij} h_{ij}(x_i) \\ & + \gamma \sum_{x'_i \in \mathcal{X}_i} (p_i(x'_i | x_{N(i)}, a_i) \sum_{j=1}^{|\mathcal{X}'_i|} w_{ij} h_{ij}(x'_i)), \\ & \forall x_{N(i)} \in \mathcal{X}_{N(i)}, \forall a_i \in \mathcal{A}_i \\ & w_{ij} \text{ free, for } j = 1, \dots, |\mathcal{X}_i|, \phi_i \text{ free} \end{aligned}$$

Which can be written as:

$$\begin{aligned} \min \quad & \phi_i \\ \text{s.t.} \quad & \phi_i \geq \sum_{j=1}^{|\mathcal{X}_i|} w_{ij} (h_{ij}(x_i) - \gamma p_i(x'_i = j | x_{N(i)}, a_i)) \\ & - r_i(x_{N(i)}, a_i), \forall x_{N(i)} \in \mathcal{X}_{N(i)}, \forall a_i \in \mathcal{A}_i \\ & \phi_i \geq r_i(x_{N(i)}, a_i) - \sum_{j=1}^{|\mathcal{X}_i|} w_{ij} (h_{ij}(x_i) \\ & - \gamma p_i(x'_i = j | x_{N(i)}, a_i)), \forall x_{N(i)} \in \mathcal{X}_{N(i)}, \forall a_i \in \mathcal{A}_i \\ & w_{ij} \text{ free, for } j = 1, \dots, |\mathcal{X}_i|, \phi_i \text{ free} \end{aligned}$$

Note that in the expression of the LP_i , the parameters w_{ij} now appear explicitly. The advantage of this approach is that the solution $\tilde{w}_i = (\tilde{w}_{i1}, \dots, \tilde{w}_{i|\mathcal{X}_i|})$ of each subsystem LP_i , can be used to determine the parameter values of $\tilde{w} = (\tilde{w}_1, \dots, \tilde{w}_n)$. This in turn, defines a parameterised approximation $v_{\tilde{w}}$ of the optimal value function v^* . Another advantage of this approximation is that the greedy policy $\tilde{\delta}$ associated with $v_{\tilde{w}}$ is local, since the following holds for all

$x \in \mathcal{X}$:

$$\tilde{\delta}(x) = \arg \max_{a \in \mathcal{A}} \left\{ \sum_{i=1}^n r_i(x_{N(i)}, a_i) + \gamma \sum_{x'_i \in \mathcal{X}_i} p_i(x'_i | x_{N(i)}, a_i) v_{\tilde{w}}^i(x'_i) \right\}$$

where $v_{\tilde{w}}^i$ are defined as in (7). So, the local components $(\tilde{\delta}_1(x_{N(1)}), \dots, \tilde{\delta}_n(x_{N(n)}))$ of $\tilde{\delta}$ can be computed as:

$$\forall i \in 1, \dots, n, \forall x_{N(i)} \in \mathcal{X}_{N(i)}$$

$$\begin{aligned} \tilde{\delta}_i(x_{N(i)}) &= \arg \max_{a_i \in \mathcal{A}_i} \left\{ r_i(x_{N(i)}, a_i) + \right. \\ &\quad \left. \gamma \sum_{x'_i \in \mathcal{X}_i} p_i(x'_i | x_{N(i)}, a_i) v_{\tilde{w}}^i(x'_i) \right\}. \end{aligned}$$

Thus, solving the n linear programs allows a computation of the approximate local policy $\tilde{\delta}$ which is an approximation of δ^* . A bound on the worst case error $\|v^* - v_{\tilde{\delta}}\|_\infty$ can of course easily be computed by applying (5).

5 EXPERIMENTAL RESULTS

In order to assess the new Approximate Linear Programming algorithm, it was tested on the wind-throw problem described in section 3.2. The tests were performed with increasing number n of stands in the forest. The value of $|\mathcal{X}_i|$ and $|\mathcal{A}_i|$ were fixed to $|\mathcal{X}_i| = 4$ and $|\mathcal{A}_i| = 2, \forall i = 1, \dots, n, \forall i = 1, \dots, n$. The cpu run times of the ALP algorithm and an exact Policy Iteration (PI) algorithm (when available), for increasing values of n can be seen in table 1:

Table 1

n	ALP	PI
4	0.78	2151.23
9	2.09	
16	4.03	
25	6.54	
36	9.69	

In order to asses the policy obtained by the ALP algorithm, it was compared to the exact PI algorithm, a heuristic *greedy* policy⁵, and a heuristic *random* policy⁶. As for large problems, the computation of the value function of a specific policy is very time consuming. The value functions of the policies were evaluated using Monte Carlo simulations. The Monte Carlo simulations were used to compute the average value of a policy, for a number of randomly chosen starting points. The average value of the different policies for increasing values of n can be seen in Table 2:

Table 2

n	ALP	PI	Greedy Policy	Random Policy
4	45.23	45.37	32.20	17.79
9	109.12		70.14	44.08
16	192.47		120.81	81.06
25	295.68		186.06	127.95
36	418.58		266.12	182.82

These tests show the advantage of our new ALP algorithm as for fixed sizes of the neighbourhood function, the run times only increase linearly in the number of stands, n . This while generating a better approximation of the optimal policy than both heuristic greedy policy and heuristic random policy and very close to the exact PI results, when available.

⁵ The greedy policy is local and simply consists in taking in each node the action $\delta_i(x_{N(i)}) = a_i^*$ maximising $r_i(x_{N(i)}, a_i)$.

⁶ The random policy is local and simply consists in taking in each node a random action.

6 CONCLUDING REMARKS

In this paper, we have described a specific form of factored MDP (FMDP) which uses a graph-based representation of local dependencies: the GMDP framework. An important feature of GMDP is that they admit problem and approximately optimal solution representations in space linear in the number n of nodes of the underlying graph. We have proposed an *approximate linear programming* (ALP) algorithm which, by a simplification of the spatio-temporal dependence structure of the model, requires only linear space and time, provided that the maximum number of neighbours remains small. Experiments on toy models inspired by real life decision problems showed that the loss in quality of the policy returned is limited. In particular, the approximate algorithm greatly improves the greedy short-term solution which is usually the only one available in problems of high dimension.

Our approach should be contrasted to that of [1, 4] which can only handle problems with a small number of decision variables and are thus inadequate to solve GMDP. One exception is [5], in which *collaborative multi-agent factored MDP* are studied (chap. 8 and 9) and a dedicated approximation algorithm is proposed. The empirical comparison between this algorithm and ours has not been performed yet, but the complexity of this algorithm is quadratic in the number of decision variables while ours is linear. Note still that *collaborative multi-agent factored MDP* are more general than GMDP. [3] also propose a method to tackle FMDP with multiple decision variables based on the idea of sampling the (exponential size) set of constraints generated by a linear programming (LP) modelling of a FMDP. However, to keep acceptable probabilistic bounds on the quality of the returned policy, the sample size should remain proportional to the number of possible actions, i.e. exponential in the number of decision variables. [5] points out experiments in which his method outperforms that of [3] when the same computation time is allowed to both methods. Finally, [6] propose an alternative *Approximate Policy Iteration* method for solving GMDP, based on the *mean-field approximation* of a stochastic process *occupation measure*. Their method is also of complexity linear in the number of variables. The experimental studies led so far show that even if the two approaches are different, the returned policies have similar values, and the CPU times are linearly related.

Mean Field Approximation of the Policy Iteration Algorithm for Graph-based Markov Decision Processes

Nathalie Peyrard¹ and Régis Sabbadin²

Abstract. In this article, we consider a compact representation of multidimensional Markov Decision Processes based on Graphs (GMDP). The states and actions of a GMDP are multidimensional and attached to the vertices of a graph allowing the representation of local dynamics and rewards. This approach is in the line of approaches based on *Dynamic Bayesian Networks*. For policy optimisation, a direct application of the *Policy Iteration* algorithm, of exponential complexity in the number of nodes of the graph, is not possible for such high dimensional problems and we propose an approximate version of this algorithm derived from the GMDP representation. We do not try to approximate directly the value function, as usually done, but we rather propose an approximation of the *occupation measure* of the model, based on the *mean field* principle. Then, we use it to compute the value function and derive approximate policy evaluation and policy improvement methods. Their combination yields an approximate *Policy Iteration* algorithm of linear complexity in terms of the number of nodes of the graph. Comparisons with the optimal solution, when available, and with a naive short-term policy demonstrate the quality of the proposed procedure.

1 Introduction

Markov Decision Processes (MDP, [9]) have become a standard model for decision-theoretic planning. However, they reach their limits when dealing with spatial applications (e.g. control in ecology, epidemiology, computer networks...). In such contexts, the size of the problem induces two difficulties: the representation and the time complexity for the MDP resolution. To circumvent the first one, factored representations have been developed. Several methods of aggregation/decomposition for large problems have been proposed in the AI community. These methods ([2, 7]) use a compact representation of probability and reward functions involved in the MDP description and propose algorithms adapted for these factored descriptions. However, these representations and algorithms usually only consider the structure of the states space, not of the actions space. In this article, we exploit a particular form of compact representation of MDP, based on graphs modelling both states and actions spaces in a common structure, that we will refer to as Graph MDP (GMDP). In this framework, several states and actions variables are attached to the vertices of a graph allowing the representation of local dependencies. The dynamics of each state variable only depends on the action applied locally and on the current values of the neighbouring state variables. The classical *Policy Iteration* algorithm for policy optimisation does not scale to the size of factored MDP or GMDP: the time complexity is exponential in the number of nodes in the graph.

² INRA, Toulouse - France, email: sabbadin@toulouse.inra.fr

We propose an approximate version of the *Policy Iteration* algorithm derived from the GMDP representation and from a *mean field* approximation of the stochastic model, leading to an approximation of the *occupation measure* of the model. Then, we propose approximate policy evaluation and policy improvement steps, based on the occupation measure. Their combination yields an approximate *Policy Iteration* algorithm and we discuss the computational complexity of the proposed method. Then we assess its performance in terms of precision by comparing experimentally the method to the exact *Policy Iteration* algorithm when possible, and to a greedy policy when not, on toy examples.

2 Graph-Based Markov Decision Processes

2.1 Definitions

In its classical formulation [9], a finite stationary MDP is described by a four-tuple $\langle \mathcal{X}, \mathcal{A}, p, r \rangle$, where \mathcal{X} represents the finite set of admissible states of the system, \mathcal{A} the finite set of applicable actions, $p : \mathcal{X} \times \mathcal{A} \times \mathcal{X} \rightarrow [0, 1]$ the transition probabilities between states and $r : \mathcal{X} \times \mathcal{A} \rightarrow \mathbb{R}$ an “immediate” reward function. In a MDP, the state $x' \in \mathcal{X}$ at step $t + 1$ depends only on the state $x \in \mathcal{X}$ at time t and on the action $a \in \mathcal{A}$ applied at this instant (Markov property). The transition probability from x to x' given a is $p(x'|x, a)$. In addition, a *reward* function r is defined as the reward obtained when action a is applied on the system in the current state. When the process is stationary, both $p(x'|x, a)$ and $r(x, a)$ are independent of t . In this article, we consider the situation where the state $x \in \mathcal{X}$ is multidimensional, and the coordinates are not independent. They are locally interacting and the interaction network can be represented by a graph. The transition probabilities and the rewards are local according to the graph structure. This representation has already been exploited in [4]: a GMDP is defined by a 5-tuple $\langle \mathcal{X}, \mathcal{A}, p, r, G \rangle$, the state space is a Cartesian product $\mathcal{X} = \mathcal{X}_1 \times \dots \times \mathcal{X}_n$, and the action space is a Cartesian product $\mathcal{A} = \mathcal{A}_1 \times \dots \times \mathcal{A}_n$. $G = (V, E)$ is an oriented graph, defined by a set of vertices $V = \{1, \dots, n\}$ and a set of (oriented) edges $E \subseteq V^2$. An edge (i, j) means that node i influences node j (i is a *parent* of j). A neighbourhood function N is defined over V by the set of parents of a given node :

Definition 1 (Neighbourhood function)

$N : V \rightarrow 2^V$ is defined by : $\forall i \in V, N(i) = \{j \in V, (j, i) \in E\}$.

We also introduce the following characteristics of the GMDP: $\sigma = \max_i |\mathcal{X}_i|$, $\alpha = \max_i |\mathcal{A}_i|$ and $\nu = \max_i |N(i)|$ (ν is the maximum degree of a node in the graph).

In a GMDP, transition probabilities and rewards are local according to G :

Definition 2 (Local transitions) Let $\langle \mathcal{X}, \mathcal{A}, p, r, G \rangle$ be a GMDP. Transitions are said to be local iff for all $x = (x_1 \dots x_n), x' = (x'_1 \dots x'_n) \in \mathcal{X}, a = (a_1 \dots a_n) \in \mathcal{A}$,

$$p(x'|x, a) = \prod_{i=1}^n p_i(x'_i|x_{N(i)}, a_i),$$

where $\forall I \subseteq \{1, \dots, n\}$, $x_I = \{x_i\}_{i \in I}$. With this factored representation, the space complexity of the representation of p is now $O(n \cdot \sigma^{\nu+1} \cdot \alpha)$, instead of $O((\sigma^2 \cdot \alpha)^n)$ for a classical MDP.

Definition 3 (Local rewards) Let $\langle \mathcal{X}, \mathcal{A}, p, r, G \rangle$ be a GMDP. Rewards are said to be local when $\forall x = (x_1 \dots x_n) \in \mathcal{X}, \forall a = (a_1 \dots a_n) \in \mathcal{A}$,

$$r(x, a) = \sum_{i=1}^n r_i(x_{N(i)}, a_i).$$

A function $\delta : \mathcal{X} \rightarrow \mathcal{A}$ assigning an action to every state is called a policy. In the general case, policies for a GMDP take the form $\delta = (\delta_1, \dots, \delta_n)$, where $\delta_i : \mathcal{X} \rightarrow \mathcal{A}_i$. Nevertheless, global policies can take space in $O(n \cdot \sigma^n)$ at most to be expressed, which can be prohibitive, except for very low dimensionality problems. Some special policies, called *local policies* are of special interest since they take space in $O(n \cdot \sigma^\nu)$.

Definition 4 (Local policy) In a GMDP $\langle \mathcal{X}, \mathcal{A}, p, r, G \rangle$, a policy $\delta : \mathcal{X} \rightarrow \mathcal{A}$ is said to be local iff $\delta = (\delta_1, \dots, \delta_n)$ where $\delta_i : \mathcal{X}_{N(i)} \rightarrow \mathcal{A}_i$.

2.2 GMDP example

Let us consider the graph in Figure 1, representing crop fields infected or not by a disease. Each node i , representing a field, has two possible states : $x_i = 1$ if uninfected and $x_i = 2$ if infected ($\mathcal{X}_i = \{1, 2\}$). Edges represent possible paths for contamination from neighbour locations. The disease passes through an edge with fixed probability p (in this case the graph is non-oriented). In addition, every location has probability ε of being infected through long range contamination (from another region). Decisions are taken yearly and two actions are possible for each node : $a_i = 1$ if a normal culture mode is used, and $a_i = 2$ if the field is left fallow and treated ($\mathcal{A}_i = \{1, 2\}$). Yields are affected by the state of the field and the applied action: the disease halves the yearly yield, while leaving the crop fallow generates no yield. Transition probabilities and rewards are summarised in Table 1. The objective in such context is to optimise the choice of a long-term policy in terms of expected yield.

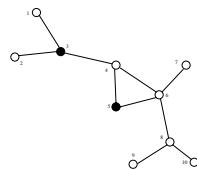

Figure 1. An epidemiological problem state: white (resp. black) nodes represent uninfected (resp. infected) fields.

2.3 Search for an optimal policy

Let $\langle \mathcal{X}, \mathcal{A}, p, r, G \rangle$ be a GMDP, discounted with discount factor γ . In the stationary case, the problem of searching an optimal policy

		$p(x'_i x_{N(i)}, a_i)$			
		$a_i = 1$		$a_i = 2$	
		$x_i = 1$	$x_i = 2$	$x_i = 1$	$x_i = 2$
$x'_i = 1$		$1 - P(\varepsilon, p)$	0	1	q
$x'_i = 2$		$P(\varepsilon, p)$	1	0	$1 - q$

		$r(x_i, a_i)$	
		$a_i = 1$	$a_i = 2$
		$x_i = 1$	$x_i = 2$
$x_i = 1$		r	0
$x_i = 2$		$r/2$	0

Table 1. Epidemiological problem: transition probabilities and rewards, $P(\varepsilon, p) = \varepsilon + (1 - \varepsilon)(1 - (1 - p)^{n_i})$, with n_i the number of parents of i which are infected.

with respect to the infinite horizon-discounted value of a policy δ , $V_\delta(x) = E \left[\sum_{t=0}^{+\infty} \gamma^t r(X^t, \delta(X^t)) \mid X^0 = x \right]$, can be written as:

$$\text{Find } \delta^*, \mathcal{X} \rightarrow \mathcal{A}, V_{\delta^*}(x) \geq V_\delta(x), \forall x \in \mathcal{X}, \forall \delta \in \mathcal{A}^\mathcal{X}$$

(NB: In this section and in the following, we will use upper case letters to represent random variables, and lower case ones for realisations of these random variables.)

This problem is classically solved by Stochastic Dynamic Programming methods [9] such as the *Backwards Induction*, *Policy Iteration* and *Value Iteration* algorithms.

The *Policy Iteration* (PI) algorithm consists in the alternation of an *evaluation* phase of the current policy and an *improvement* phase of this policy.

Policy Evaluation step: Solve

$$V_\delta(x) = r(x, \delta(x)) + \gamma \cdot \sum_{x' \in \mathcal{X}} p(x'|x, \delta(x)) \cdot V_\delta(x'), \forall x.$$

Policy improvement step: Update the current policy δ into a policy δ' by applying for all x :

$$\delta'(x) = \arg \max_{a \in \mathcal{A}} \left(r(x, a) + \gamma \cdot \sum_{x' \in \mathcal{X}} p(x'|x, a) \cdot V_\delta(x') \right).$$

It is guaranteed that $V_{\delta'}(x) \geq V_\delta(x), \forall x$, after the improvement phase. Furthermore when $V_{\delta'}(x) = V_\delta(x), \forall x$ we have the guarantee that δ is an optimal policy [9].

Generally, the PI algorithm converges within a very small number of iterations, but each iteration is costly since policy evaluation needs solving a system of equations (complexity in $O(\sigma^{3n})$) and policy improvement has complexity in $O((\sigma^2 \cdot \alpha)^n)$. This exponential complexity limits severely the size of GMDP that can be efficiently solved. In this paper we propose an approximation of the two steps of the PI algorithm for a GMDP, based on the search of an (a priori sub-optimal) policy among the local ones, which leads to a time complexity linear in n (but exponential in ν).

3 Approximate PI for GMDP

3.1 Policy Value and Occupation Measures

There exists an alternative way of expressing a policy value, based on the occupation measure, which has been used for instance in [1]. The occupation measure is related to the time a stochastic process spends in a given state, knowing the initial state. By extension, occupation measures have also been used in the framework of discounted MDP.

Definition 5 (Occupation measure) Let $\langle \mathcal{X}, \mathcal{A}, p, r \rangle$ be a stationary MDP, γ a discount factor. Let $\delta : \mathcal{X} \rightarrow \mathcal{A}$ be a policy and

$x^0 \in \mathcal{X}$ an initial state. The occupation measure $P_{x^0, \delta, \gamma} : \mathcal{X} \rightarrow [0, 1]$ is defined as:

$$\forall y \in \mathcal{X}, P_{x^0, \delta, \gamma}(y) = (1 - \gamma) \sum_{t=0}^{+\infty} \gamma^t \cdot P_\delta(X^t = y | X^0 = x^0).$$

The value function V_δ of any policy can be computed from the probability distribution $P_{x^0, \delta, \gamma}$ as

$$\forall x^0 \in \mathcal{X}, V_\delta(x^0) = \frac{1}{1 - \gamma} \cdot \sum_{y \in \mathcal{X}} P_{x^0, \delta, \gamma}(y) \cdot r(y, \delta(y)).$$

In particular, $\forall \delta$ a local policy, the value function can be decomposed as $V_\delta(x^0) = \sum_{i=1}^n V_\delta^i(x^0)$, where

$$V_\delta^i(x^0) = \sum_{t=0}^{+\infty} \gamma^t \cdot \sum_{y \in \mathcal{X}} P_\delta(X^t = y | X^0 = x^0) \cdot r_i(y_{N(i)}, \delta_i(y_{N(i)})). \quad (1)$$

As such, this expression does not help to compute efficiently optimal or near optimal policies. However, we propose to look for an approximation \hat{C} of the conditional probability $P_\delta(X^t = y | X^0 = x^0)$ with simpler structure, which will result in an approximation of $V_\delta^i(x^0)$ by a function depending only on $x_{N(i)}^0$. Conditional probabilities (from time 0 to time t) can be derived from the transition probabilities $p_i(x_i^t | x_{N(i)}^{t-1}, \delta(x_{N(i)}^{t-1}))$. If we are able to find approximate transition probabilities of the form $\hat{Q}_\delta^{t,i}(x_i^t | x_i^{t-1})$ then the corresponding approximate conditional probability will be, $\forall t \geq 2$,

$$\begin{aligned} \hat{C}_\delta^t(y|x^0) &= \sum_{x^{t-1}} \hat{Q}_\delta^t(y|x^{t-1}) \cdot \hat{C}_\delta^{t-1}(x^{t-1}|x^0) \\ &= \prod_{i=1}^n \sum_{x_i^{t-1}} \hat{Q}_\delta^{t,i}(y_i|x_i^{t-1}) \cdot \hat{C}_\delta^{t-1,i}(x_i^{t-1}|x_i^0). \end{aligned} \quad (2)$$

the recursive definition being initialised by $\hat{C}_\delta^1(y|x^0) = \prod_i \hat{Q}_\delta^{1,i}(y_i|x_i^0)$. And by induction, $\forall t, \hat{C}_\delta^t(y|x^0) = \prod_{i=1}^n \hat{C}_\delta^{t,i}(y_i|x_i^0)$, so that we get $V_\delta^i(x^0) \approx \hat{V}_\delta^i(x_{N(i)}^0)$ where

$$\hat{V}_\delta^i(x_{N(i)}^0) = \sum_{t=0}^{+\infty} \gamma^t \cdot \sum_{y_{N(i)}} \left(\prod_{j \in N(i)} \hat{C}_\delta^{t,j}(y_j|x_j^0) \cdot r_i(y_{N(i)}, \delta_i(y_{N(i)})) \right).$$

The main contribution of this work is to propose a solution for the choice of $\hat{Q}_\delta^{t,i}(x_i^t | x_i^0)$, derived from the mean field principle, as detailed in the next section.

3.2 Mean field approximation of the transition probabilities

The mean field principle arises from statistical mechanics [3] and the study of systems of particles in interaction and Gibbs distributions. It has since been successfully used in other domains such as image analysis, graphical models, epidemiology, ecology. The mean field approximation of a multidimensional distribution $P(u_1, \dots, u_m)$ is defined as the best approximation by a system of independent variables in the sense of the Kullback-Leibler divergence, $KL(Q|P) = E_Q[\log(Q/P)]$. The minimum of $KL(Q|P)$ is thus looked for among the distributions Q with factorisation property: $Q(u_1, \dots, u_m) = \prod_{i=1}^m Q_i(u_i)$.

In the GMDP framework, the model complexity lies in the spatio-temporal dependence between sites' states. More specifically, if

$X^t = \{X_1^t, \dots, X_n^t\}$ is the random variable corresponding to the system's state at time t then, given a policy δ , the variable X_i^t depends on the variables in its neighborhood at the previous time step, $X_{N(i)}^{t-1}$ through the transition probabilities. So, we propose to apply the mean field principle to the joint distribution of X^{t-1} and X^t , which is fully defined by the distribution of X^{t-1} , and the transition probability of X^t knowing X^{t-1} .

Let us start the iterative approximation procedure at time $t = 1$. We will use the notation P for the exact distributions and the notation Q for the approximate ones. Assuming an initial, factored, distribution P^0 on \mathcal{X}^0 (for sake of simplicity and also to ensure the repeatability of the approximation method from one time step to the next one) we have the following forms for the exact and the approximate distributions:

$$\begin{aligned} P^0(x^0) &= \prod_{i=1}^n P^{0,i}(x_i^0), & P_\delta(x^1|x^0) &= \prod_{i=1}^n p_i(x_i^1|x_{N(i)}^0, \delta_i(x_{N(i)}^0)) \\ Q^0(x^0) &= P^0(x^0), & Q_\delta^1(x^1|x^0) &= \prod_{i=1}^n Q_\delta^{1,i}(x_i^1|x_i^0) \end{aligned} \quad (3)$$

With the approximate model, given δ , $X^{1,i}$ depends only on $X^{0,i}$. Let us denote \mathcal{Q} the set of all joint distributions of X^{t-1} and X^t which can be decomposed as (3). Among all the elements of \mathcal{Q} , we are looking for the best approximation of the exact joint distribution, according to the Kullback-Leibler divergence. Since $Q^0 = P^0$, the approximation is only on Q_δ^1 .

Proposition 1 (Mean field approximation of the transitions) The mean field approximation \hat{Q}_δ^1 , defined as the solution of

$$\hat{Q}_\delta^1 = \arg \min_{Q_\delta^1 \in \mathcal{Q}} KL(Q_\delta^1(X^1|X^0).P^0(X^0)|P_\delta(X^1|X^0).P^0(X^0))$$

is

$$\hat{Q}_\delta^{1,i}(x_i^1|x_i^0) \propto \exp E_{P^0} [\log p_i(x_i^1|x_i^0, X_{N(i)\setminus\{i\}}^0, \delta_i(x_i^0, X_{N(i)\setminus\{i\}}^0))] \quad (4)$$

Proof: Indeed, we have

$$\begin{aligned} &KL(Q_\delta^1(X^1|X^0).P^0(X^0)|P_\delta(X^1|X^0).P^0(X^0)) \\ &= \sum_{x^0, x^1 \in \mathcal{X}^2} Q_\delta^1(x^1|x^0).P^0(x^0). \log \frac{Q_\delta^1(x^1|x^0)}{P_\delta(x^1|x^0)} \end{aligned}$$

Setting the derivates according to the $Q_\delta^{1,i}(x_i^1|x_i^0)$ to zero, we obtain the mean field solution. \square

By switching the expectation and the logarithm, we obtain the approximation

$$\hat{Q}_\delta^{1,i}(x_i^1|x_i^0) = E_{P^0} [p_i(x_i^1|x_i^0, X_{N(i)\setminus\{i\}}^0, \delta_i(x_i^0, X_{N(i)\setminus\{i\}}^0))]$$

It is easy to check that this quantity is normalized. It is easier to compute and more intuitive than expression (4). We will use this approximation in the following as the mean field approximation of the transition probabilities. Note that this factored expression relies on an initial factored a priori distribution P^0 . This initial distribution is necessary for technical reasons, but can also help representing a priori knowledge about the initial distribution of the process. If no a priori knowledge is available, we simply chose P^0 as a product of independent uniform laws on the \mathcal{X}_i 's.

Given the approximate transition probabilities between time 0 and

time 1, and given P^0 , we can derive the approximate probability distribution of X^1 for a given policy δ :

$$\hat{Q}_\delta^1(x^1) = \sum_{x^0} \hat{Q}_\delta^1(x^1|x^0).P^0(x^0) = \prod_{i=1}^n \sum_{x_i^0} \hat{Q}_\delta^{1,i}(x_i^1|x_i^0).P^{0,i}(x_i^0)$$

This approximate distribution at time 1 has also the factorisation property. Thus we can iterate the approximation method (minimisation of the Kullback-Leibler divergence) and obtain for each time step $t \geq 2$ an approximation of the transition probabilities, $\hat{Q}_\delta^{t+1}(x^{t+1}|x^t)$. Note that they depend on t (and on P^0) while this is not the case in the initial model.

3.3 Approximate Policy Evaluation

Using the mean field approximation of the occupation measure to perform the evaluation step, we recall that we obtain an approximation of each component of the policy value of the following form:

$$\begin{aligned} \hat{V}_\delta^i(x) &\approx \hat{V}_\delta^i(x_{N(i)}) \\ &\approx \sum_{t=0}^{+\infty} \gamma^t \cdot \sum_{y_{N(i)}} \left(\prod_{j \in N(i)} \hat{C}_\delta^{t,j}(y_j|x_j) \right) \cdot r_i(y_{N(i)}, \delta_i(y_{N(i)})) \end{aligned}$$

In this approximation, each component \hat{V}_δ^i depends on $x_{N(i)}$ only. This results in a reduced time complexity, exponential in the maximum number of neighbours of a node, as opposed to exponential in the number of nodes for the exact PI.

Proposition 2 (Complexity of the Approximate Policy Evaluation) *Let ϵ be the stopping threshold in the computation of the infinite sum over time. Then the complexity of the Approximate Policy Evaluation step is in $O(\ln(1/\epsilon) \cdot n \cdot \sigma^{3\nu} \cdot \nu^2)$.*

Proof: There are $n \cdot \sigma^\nu$ quantities $\hat{V}_\delta^i(x_{N(i)})$ to compute. Then, for a given site i and a given configuration $x_{N(i)}$, the computation of $\gamma^t \sum_{y_{N(i)}} \left(\prod_{j \in N(i)} \hat{C}_\delta^{t,j}(y_j|x_j) \right) \cdot r_i(y_{N(i)}, \delta_i(y_{N(i)}))$ requires at most σ^ν summations, ν products, and the evaluation of $\hat{C}_\delta^{t,j}(y_j^t|x_j)$. This last evaluation is of complexity $\nu \cdot \sigma \cdot \sigma^{\nu-1}$: sum over each possible state of site j at the previous time step and computation of the approximated transition probabilities as expectations of products of $\nu+1$ terms. The discount factor γ^t ensures that the precision required is reached for a time $t > K \frac{\ln(\epsilon)}{\ln(\gamma)}$. Finally, the complexity of the Approximate Policy Evaluation is $O(\ln(1/\epsilon) \cdot n \cdot \sigma^{3\nu} \cdot \nu^2)$. \square

3.4 Approximate Policy Improvement

In order to reduce the search space, we limit the search of approximately optimal policies among local ones (even if in general there is no guarantee that there exist a local policy which is optimal). This allows a reduction in representation space and in time complexity. Using the mean field approximation of V_δ and the local properties of rewards and transition probabilities, the exact maximisation

$$\delta'(x) = \arg \max_{a \in \mathcal{A}} \left(r(x, a) + \gamma \cdot \sum_{y \in \mathcal{X}} p(y|x, a) \cdot V_\delta(y) \right), \forall x.$$

is replaced by the search of the arguments of the maximum of the expressions :

$$\sum_i r_i(x_{N(i)}, a_i) + \gamma \sum_{y_{N(i)}} \left(\prod_{j \in N(i)} p_j(y_j|x_{N(j)}, a_j) \hat{V}_\delta^i(y_{N(i)}) \right).$$

Let us consider a particular site i . The terms which depend on a_i are

$$r_i(x_{N(i)}, a_i) + \gamma \sum_{k \in N(i)} \sum_{y_{N(k)}} \left(\prod_{j \in N(k)} p_j(y_j|x_{N(j)}, a_j) \cdot \hat{V}_\delta^i(y_{N(k)}) \right).$$

In order to ensure that the argument of the maximum is local, first we adopt a parallel scheme, initialised by δ , to compute each component of the improved policy:

$$\begin{aligned} \forall i, \tilde{\delta}_i^{n+1}(x) &= \arg \max_{a_i \in \mathcal{A}_i} r_i(x_{N(i)}, a_i) + \gamma \sum_{k \text{ s.t. } i \in N(k)} \sum_{y_{N(k)}} \left[\right. \\ &\quad \left. \left(\prod_{j \in N(k), j \neq i} p_j(y_j|x_{N(j)}, \tilde{\delta}_j^n(y_{N(j)})) \right) \cdot p_i(y_i|x_{N(i)}, a_i) \cdot \hat{V}_\delta^i(y_{N(k)}) \right]. \end{aligned}$$

This is not enough since the i th component of the solution still depend on $x_{N(N(i))}$. So, we replace the transition probabilities p_j by appropriate mean values, in order to restrict dependencies, as follows

$$\begin{aligned} p_i(y_i|x_{N(i)}, a_i) &\approx \frac{\sum_{x_{N(i)} \setminus \{i\}} p_i(y_i|x_{N(i)}, a_i)}{\text{card}(\mathcal{X}_{N(i)} \setminus \{i\})} \\ \text{if } j \in N(i): \\ p_j(y_j|x_{N(j)}, \delta(x_{N(j)})) &\approx \frac{\sum_{x_{N(j)} \setminus \{j\}} p_j(y_j|x_{N(j)}, \delta_j(x_{N(j)}))}{\text{card}(\mathcal{X}_{N(j)} \setminus \{j\})} \\ \text{if } j \notin N(i): \\ p_j(y_j|x_{N(j)}, \delta(x_{N(j)})) &\approx \frac{\sum_{x_j} p_j(y_j|x_{N(j)}, \delta_j(x_{N(j)}))}{\text{card}(\mathcal{X}_j)} \end{aligned}$$

Proposition 3 (Complexity of Approximate Policy Update) *The Approximate Policy Update step is of complexity $O(n \cdot \alpha \cdot \nu^2 \cdot \sigma^{2\nu})$.*

Proof: The maximisation is performed for all sites, and is over α terms at most. The computation of the approximate version of expression (5) requires at most $\nu \cdot \sigma^\nu$ summations and ν products. One element of the product is computed either in σ^ν or in σ operations. This leads to a complexity of at most $O(n \cdot \alpha \cdot \nu^2 \cdot \sigma^{2\nu})$. \square

3.5 Experimental evaluation of API

We first tested the mean field approximation of the Policy Iteration (MF-PI) algorithm on problems of small size, where the exact solution of the PI algorithm for standard MDP is available, in order to assess the quality of the approximate policies returned by MF-PI. The first toy example used is the one presented in Section 2.2. The parameters were set to $p = 0.2, \epsilon = 0.01, q = 0.9$. The second example is an extension to four states per node: the state 'healthy' and three states of increasing severity in the case of an infected field.

Example 1				Example 2			
n	error	CPU MF	CPU PI	n	error	CPU MF	CPU PI
3	0%	1.44	10.11	3	0%	21.4	646
4	6.5%	5.75	65.52	4	3.6%	574	21200
5	3.3%	6.78	454.54	40	4380		
6	10.1%	9.07	3485.6				

Table 2. Mean relative error (in percentage) between the optimal policy and the estimated one, and computation time.

In both cases, the graphs were generated randomly, with a maximum size of $N(i)$ of 3. For varying values of n , we observed a limited loss in the quality of the optimal policy (with a mean relative error no more than 10 %, see Table 2) and a significant gain in time complexity (see Figure 2). We observe a linear progression of the CPU time required by MF-PI with respect to the number of nodes (see Figure 2). Implementation was done in Scilab, on a quadriprocessor PC with four Intel 2.40 GHz processors with 512 Ko of cache.

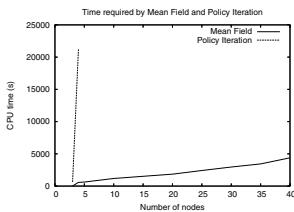

Figure 2. CPU times required by MF-PI and by exact PI

In a second set of experiments, we compared the relative performance of the MF-PI and the greedy (maximising the local immediate rewards) policies for graphs of larger size, on the problem of epidemiology control (version with three states of disease severity). Graph of dependencies were generated randomly and the MF-PI and the greedy policies were computed and their values were estimated using Monte Carlo simulations. Figure 3 illustrates the gain in the empirical value using MF-PI instead of the greedy policy, as a average over 5 problems, 10 initial states per problem, and simulation of 100 trajectories of length 20.

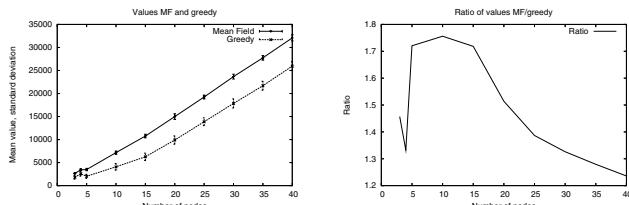

Figure 3. Left: estimated mean values of the MF-PI and the greedy policies, Right: estimated mean value of the ratio of the MF-PI policy value over the greedy policy value.

4 Concluding remarks

In this paper, we described a specific form of factored MDP (FMDP) which uses a graph-based representation of local dependencies: the GMDP framework. The specificities are: first, each decision node is the parent of exactly one state and no two decision nodes are attached to the same state node. second, the scope of each reward node is included in the set of parents of one state variable and no two reward nodes are attached to the same state variable.

An important feature of GMDP is that they admit problem and approximately optimal solution representations in space linear in the size of the underlying graph. However, classical Dynamic Programming algorithms use space and time exponential in the size of the graph to compute optimal solutions. We have proposed an approximate *Policy Iteration* algorithm which requires only linear space and

time provided that the graph width remains small. The quality loss associated with this gain in time complexity is not known yet. However, experiments showed that it is limited. In particular, the approximate algorithm greatly improves the greedy short-term solution which is usually the only one available in problems of high dimension.

Our approach should be contrasted to [2, 7, 5] which are also devoted to FMDP. [2] uses *algebraic decision diagrams* (ADD) to model and solve FMDP and [7, 5] use a *linear programming* approach. [5] propose a method to tackle FMDP with multiple decision variables based on the idea of sampling the (exponential size) set of constraints generated by a linear programming (LP) modelling of a FMDP. However, to keep acceptable probabilistic bounds on the quality of the returned policy, the sample size should remain proportional to the number of possible actions, i.e. exponential in the number of decision variables. [7] instead consider the exact LP, but propose a specific *variable elimination* method which take the structure of the LP into account in order to solve it exactly. [7] points out experiments in which his method outperforms that of [5] when the same computation time is allowed to both methods.

[2, 7, 5] can only handle problems with a small number of decision variables and are thus inadequate to solve GMDP. In [8], *collaborative multi-agent factored MDP*, which are more general than GMDP, are studied and approximately solved by a dedicated algorithm. The empirical comparison between this algorithm and ours has not been performed yet, but the complexity of this algorithm is quadratic in the number of decision variables, while ours is linear.

Finally, [6] propose a LP-based method for solving GMDP, derived from the method of [7]. Experiments led so far show that even if this approach differs from ours, the returned policies have similar values, and the CPU times are linearly related. We are currently investigating the benefits of each method, in particular their ability to face the following generalisation of GMDP. An important assumption of the GMDP framework is that the action space \mathcal{A} is a cross product of *independent* local action spaces \mathcal{A}_i . However, this assumption should be relaxed (\mathcal{A} becoming a strict subset of $\prod_i \mathcal{A}_i$), as soon as we want to model resource allocation or local constraints between the actions. Relaxing this independence assumption clearly affects the approximation method suggested in this paper and we are currently exploring the effects of this relaxation.

Unified Definition of Heuristics for Classical Planning

Jussi Rintanen¹

Abstract. In many types of planning algorithms distance heuristics play an important role. Most of the earlier works restrict to STRIPS operators, and their application to a more general language with disjunctivity and conditional effects first requires an exponential size reduction to STRIPS operators.

I present direct formalizations of a number of distance heuristics for a general operator description language in a uniform way, avoiding the exponentiality inherent in earlier reductive approaches. The formalizations use formulae to represent the conditions under which operators have given effects. The exponentiality shows up in satisfiability tests with these formulae, but would appear to be a minor issue because of the small size of the formulae.

1 Introduction

Much of planning research has been carried out in the context of STRIPS operators, named after the famous planning system [3]. A STRIPS operator consists of three sets of facts: a precondition, an *add* list, and a *delete* list. There are many actions that cannot be expressed in terms of STRIPS operators only, for example anything with context-dependent effects, but it is well known that any classical planning problem (one initial state, deterministic actions) can be translated into an equivalent one with STRIPS operators only. However, this translation may increase the size of the planning problem exponentially, and therefore it is not desirable.

In this paper we use a general language for expressing classical planning problems, including conditional effects and disjunctive preconditions. We show that for many purposes a small toolbox of definitions based on the propositional logic is sufficient for handling a general operator definition rather elegantly. Specifically, we consider a number of *distance heuristics* developed for STRIPS planning, and generalize them to a much more expressive planning language.

Anecdotal evidence from the planning community tells that handling conditional effects and disjunctive preconditions elegantly is difficult. Indeed, no clear formalizations of the above heuristics – or many planning algorithms and other planning techniques – in the full generality of conditional effects and disjunctive preconditions have been published. Related works and planning system implementations rely on *ad hoc* techniques, for example on an exponential translation of all formulae into DNF and on eliminating conditional effects. We show how general operator definitions can be handled concisely and elegantly without an exponential blow up in size or processing time.

The outline of this paper is as follows. In Section 4.1 we generalize Bonet and Geffner's [1] max heuristic to operators with conditional effects and arbitrary disjunctive preconditions. A novelty here is that the heuristic is not defined as a cyclic recursion equation. In Section 4.2 we do the same to Bonet and Geffner's [1] additive heuristic, and in Section 4.3 to Hoffmann and Nebel's [7] relaxed plan heuristic.

2 Preliminaries

We give a definition of operators that corresponds to ADL/PDDL operators [4] that have been grounded which means that quantifiers *forall* and *exists* have been eliminated and all parameters have been instantiated with objects of appropriate types in all possible ways.

We use the classical propositional logic with the connectives \vee, \wedge, \neg and the constant symbols *true* \top and *false* \perp . The state variables of a planning problem are the atomic propositions of the logic. State variables $a \in A$ and their negations are *literals*. The *complement* \bar{l} of a literal l is defined by $\bar{a} = \neg a$ and $\bar{\neg a} = a$ for all $a \in A$.

Definition 1. Let A be a set of state variables. An operator over A is a pair $\langle c, e \rangle$ where c is a formula over A describing the precondition and e is an effect over A . Effects are recursively defined as follows.

1. \top is an effect (the dummy effect).
2. a and $\neg a$ for state variables $a \in A$ are effects.
3. $e_1 \wedge \dots \wedge e_n$ is an effect if e_1, \dots, e_n are effects over A (the special case with $n = 0$ is defined as the dummy effect \top .)
4. $c \triangleright e$ is an effect if c is a formula and e is an effect over A .

Conditional effects $c \triangleright e$ mean that e is executed if c is true.

Definition 2 (Operator execution). Let $o = \langle c, e \rangle$ be an operator over A and s a state (an assignment of truth values to A). The operator is executable in s if $s \models c$ and $\{a, \neg a\} \not\subseteq [e]_s$ for all $a \in A$. The set $[e]_s$ of literals (the active effects of e in s) is defined as follows.

1. $[\top]_s = \emptyset$
2. $[a]_s = \{a\}$ for $a \in A$
3. $[\neg a]_s = \{\neg a\}$ for $a \in A$
4. $[e_1 \wedge \dots \wedge e_n]_s = [e_1]_s \cup \dots \cup [e_n]_s$
5. $[c \triangleright e]_s = [e]_s$ if $s \models c$ and $[c \triangleright e]_s = \emptyset$ otherwise.

The successor state $app_o(s)$ of s under o is obtained from s by making the literals in $[e]_s$ true and retaining the values of state variables not occurring in $[e]_s$. For sequences $\sigma = o_1; o_2; \dots; o_n$ of operators we define $app_\sigma(s) = app_{o_n}(\dots app_{o_2}(app_{o_1}(s))\dots)$.

Example 1. Consider the operator $\langle a, e \rangle$ where $e = \neg a \wedge (\neg c \triangleright b)$ and a state s such that $s \models a \wedge b \wedge c$. The operator is executable because $s \models a$. Now $[e]_s = \{\neg a\}$ and $app_{\langle a, e \rangle}(s) \models \neg a \wedge b \wedge c$. ■

A *problem instance* is a quadruple $\langle A, I, O, G \rangle$ where A is the set of state variables, I is the initial state, O is the set of operators and G is the goal formula. A sequence $\sigma = o_1; \dots; o_n$ of operators is a *plan* for the problem instance if $app_\sigma(I) \models G$.

The formula $EPC_I(e)$ expresses the conditions under which the literal l is assigned *true* when the effect e is executed.

¹ National ICT Australia, Canberra Research Laboratory, Canberra, Australia

Definition 3. Define the formula $EPC_l(e)$ recursively as follows.

$$\begin{aligned} EPC_l(\top) &= \perp \\ EPC_l(l) &= \top \\ EPC_l(l') &= \perp \text{ when } l \neq l' \text{ (for literals } l') \\ EPC_l(e_1 \wedge \dots \wedge e_n) &= EPC_l(e_1) \vee \dots \vee EPC_l(e_n) \\ EPC_l(c \triangleright e) &= c \wedge EPC_l(e) \end{aligned}$$

The case $EPC_l(e_1 \wedge \dots \wedge e_n) = EPC_l(e_1) \vee \dots \vee EPC_l(e_n)$ is defined as a disjunction because it is sufficient that at least one of the effects e_1, \dots, e_n makes l true. For example, $EPC_a(a \wedge b) \equiv \top$, $EPC_a(b) \equiv \perp$ and $EPC_a((b \triangleright a) \wedge (c \triangleright a)) \equiv b \wedge c$.

We define a formula that indicates when an operator is executable so that a given literal becomes true.

Definition 4. Let A be the set of state variables and $o = \langle c, e \rangle$ an operator over A . Define

$$EPC_l(o) = c \wedge EPC_l(e) \wedge \bigwedge_{a \in A} \neg(EPC_a(e) \wedge EPC_{\neg a}(e)).$$

There is a connection between $EPC_l(e)$ and the definition of $[e]_s$.

Lemma 1. Let A be the set of state variables, s a state over A , l a literal over A , and o an operator over A with the effect e . Then

1. $l \in [e]_s$ if and only if $s \models EPC_l(e)$, and
2. $app_o(s)$ is defined and $l \in [e]_s$ if and only if $s \models EPC_l(o)$.

The proof of this lemma and some that follow are by structural induction and can be found in a technical report [9].

3 Reachability and Distances

The notion of reachability is important in defining whether a planning problem is solvable and in deriving techniques that speed up search for plans. Distances between states are closely related to reachability and will be defined next. Heuristics in Section 4 are approximations of distances. Define $img_o(S) = \{app_o(s) | s \in S\}$.

Definition 5. Let I be an initial state and O a set of operators. Define the distance sets D_i^{fwd} for I, O which consist of those states that are reachable from I by executing at most i operators.

$$\begin{aligned} D_0^{fwd} &= \{I\} \\ D_i^{fwd} &= D_{i-1}^{fwd} \cup \{s | o \in O, s \in img_o(D_{i-1}^{fwd})\} \text{ for all } i \geq 1 \end{aligned}$$

Definition 6. Given a state I , a set O of operators and the distance sets $D_0^{fwd}, D_1^{fwd}, \dots$ for I, O , the distance of a state s from I is

$$\delta_I^{fwd}(s) = \begin{cases} 0 & \text{if } s = I \\ i & \text{if } s \in D_i^{fwd} \setminus D_{i-1}^{fwd}. \end{cases}$$

If $s \notin D_i^{fwd}$ for all $i \geq 0$ then $\delta_I^{fwd}(s) = \infty$. States that have a finite distance are reachable (from I with O).

Distances can also be defined for formulae.

Definition 7. The distance $\delta_I^{fwd}(\phi)$ of a formula ϕ is $i \geq 1$ if there is a state s such that $s \models \phi$ and $\delta_I^{fwd}(s) = i$ and there is no state s' such that $s' \models \phi$ and $\delta_I^{fwd}(s') < i$. If $I \models \phi$ then $\delta_I^{fwd}(\phi) = 0$.

A formula ϕ has a finite distance iff $\langle A, I, O, \phi \rangle$ has a plan.

Reachability and distances are useful for implementing efficient planning systems. We mention two applications. First, if the precondition of an operator is not reachable, the operator can never be applied and can be ignored. Second, having an oracle that could tell the distances of states for free would directly yield a planning algorithm: step by step choose a sequence of operators that decrease the distance of the goal formula from the current state by one.

Computing distances is in the worst case just as difficult as planning itself (PSPACE-complete), and hence it is usually not useful to use exact distances. Instead, different kinds of *approximations* of distances and reachability can be used.

4 Distance Heuristics

Many approximations of distances are based on the following idea. Instead of considering the number of operators required to reach individual states, we compute approximate numbers of operators to reach states in which certain literals are true. So instead of distances of states, we use distances of literals. Within the computation of distances of literals, distances of formulae are estimated in terms of the distances of literals, which introduces an inaccuracy because the dependencies between literals are ignored. The heuristics therefore may underestimate the actual distance and only yield a lower bound for it.

4.1 Admissible Max Heuristic

Effective heuristics were presented by McDermott [8], Bonet et al. [2, 1] and Haslum and Geffner [6]. We first describe a generalization of the Bonet et al. *max* heuristics to our definition of operators.

We give a procedure that computes a lower bound on the number of operator applications that are needed for reaching from a state I a state in which certain literals are true. Sets D_i^{max} consist of literals that are true in all states that have a distance $\leq i$.

Definition 8. Let $L = A \cup \{\neg a | a \in A\}$ be the set of literals over A and I a state. For all $i \geq 1$ define the max-distance sets

$$\begin{aligned} D_0^{max} &= \{l \in L | I \models l\}, \text{ and} \\ D_i^{max} &= D_{i-1}^{max} \setminus \{l \in L | o \in O, D_{i-1}^{max} \cup \{EPC_l(o)\} \text{ is satisfiable}\}. \end{aligned}$$

The computation starts from D_0^{max} which consists of all literals that are true in the initial state I . This set therefore characterizes those states that have distance 0 from the initial state.

Then we compute sets of literals characterizing states with distance 1, 2 and so on. Each set D_i^{max} is computed from the preceding set D_{i-1}^{max} by testing for each operator o whether it is executable in one of the distance $i - 1$ states and whether it could make a literal l false. This is by testing whether $EPC_l(o)$ is true in one of the distance $i - 1$ states. If it is, l will not be included in D_i^{max} .

Since we consider only finite sets A of state variables and $|D_0^{max}| = |A|$ and $D_{i+1}^{max} \subseteq D_i^{max}$ for all $i \geq 0$, necessarily $D_i^{max} = D_j^{max}$ for some $i \leq |A|$ and all $j > i$.

Every state with distance $\leq i$ satisfies D_i^{max} .

Theorem 9. Let $D_i^{fwd}, i \geq 0$ be the distance sets and D_i^{max} the max-distance sets for I and O . Then for all $i \geq 0$, $D_i^{fwd} \subseteq \{s \in S | s \models D_i^{max}\}$ where S is the set of all states.

The sets D_i^{max} can be used for estimating the distances of formulae. The distance of a formula is the minimum of the distances of states that satisfy it.

Definition 10. Let ϕ be a formula. Define

$$\delta_I^{\max}(\phi) = \begin{cases} 0 & \text{iff } D_0^{\max} \cup \{\phi\} \text{ is satisfiable} \\ d & \text{iff } D_d^{\max} \cup \{\phi\} \text{ is satisfiable and} \\ & D_{d-1}^{\max} \cup \{\phi\} \text{ is not satisfiable, for } d \geq 1. \end{cases}$$

Lemma 2. Let I be a state, O a set of operators, and $D_0^{\max}, D_1^{\max}, \dots$ the max-distance sets for I and O . Then $\text{app}_{o_1, \dots, o_n}(I) \models D_n^{\max}$ for any operators $\{o_1, \dots, o_n\} \subseteq O$.

The next theorem shows that the distance estimates are a lower bound on the actual distances.

Theorem 11. Let I be a state, O a set of operators, ϕ a formula, and $D_0^{\max}, D_1^{\max}, \dots$ the max-distance sets for I and O . If $\text{app}_{o_1, \dots, o_n}(I) \models \phi$, then $D_n^{\max} \cup \{\phi\}$ is satisfiable.

Proof. By Lemma 2 $\text{app}_{o_1, \dots, o_n}(I) \models D_n^{\max}$. By assumption $\text{app}_{o_1, \dots, o_n}(I) \models \phi$. Hence $D_n^{\max} \cup \{\phi\}$ is satisfiable. \square

Corollary 12. For a formula ϕ and a state I , if o_1, \dots, o_n is a sequence of operators and $\text{app}_{o_1, \dots, o_n}(I) \models \phi$ then $n \geq \delta_I^{\max}(\phi)$.

The estimate $\delta_s^{\max}(\phi)$ never overestimates the distance from s to ϕ and it is therefore an admissible heuristic. It may severely underestimate the distance, as discussed in Section 4.2. A family h^m of stronger admissible heuristics has been proposed by Haslum and Geffner [6]. The heuristic h^1 is the max heuristic. There is an algorithm for computing m -literal invariant clauses that generalizes the sets D^{\max} to sets of m -literal clauses [9] and yields the h^m heuristic.

4.1.1 Distance Estimation in Polynomial Time

The computation of the sets D_i^{\max} and the distances $\delta_I^{\max}(\phi)$ is polynomial time except for the NP-complete satisfiability tests for $D \cup \{\phi\}$ where D is a set of literals. Here $\phi = \text{EPC}_I(o)$ for a literal l and an operator o . The size of ϕ is in the worst case quadratic in the size of o , and hence the formulae ϕ are typically small. The cost of the satisfiability test is exponential in the size of ϕ and linear in D , and hence the NP-completeness is almost never an issue.

However, to show that our approach is feasible even in the unrealistic case of huge operators we give a simple polynomial time approximation $\text{asat}(D, \phi)$ of the satisfiability tests with the property that if $D \cup \{\phi\}$ is satisfiable then $\text{asat}(D, \phi) = \text{true}$. The proof of Theorem 9 works when the satisfiability tests of $D \cup \{\phi\}$ are replaced by $\text{asat}(D, \phi)$. The approximation never leads to overestimating the distances, only underestimating, and for STRIPS operators the approximation never makes a difference and for general operators rarely. Define $\text{asat}(D, \phi)$ as follows.

$$\begin{aligned} \text{asat}(D, \perp) &= \text{false} \\ \text{asat}(D, \top) &= \text{true} \\ \text{asat}(D, a) &= \text{true iff } \neg a \notin D \text{ (for } a \in A\text{)} \\ \text{asat}(D, \neg a) &= \text{true iff } a \notin D \text{ (for } a \in A\text{)} \\ \text{asat}(D, \neg\neg\phi) &= \text{asat}(D, \phi) \\ \text{asat}(D, \phi_1 \vee \phi_2) &= \text{asat}(D, \phi_1) \text{ or } \text{asat}(D, \phi_2) \\ \text{asat}(D, \phi_1 \wedge \phi_2) &= \text{asat}(D, \phi_1) \text{ and } \text{asat}(D, \phi_2) \\ \text{asat}(D, \neg(\phi_1 \vee \phi_2)) &= \text{asat}(D, \neg\phi_1) \text{ and } \text{asat}(D, \neg\phi_2) \\ \text{asat}(D, \neg(\phi_1 \wedge \phi_2)) &= \text{asat}(D, \neg\phi_1) \text{ or } \text{asat}(D, \neg\phi_2) \end{aligned}$$

The cases for $\neg(\phi_1 \wedge \phi_2)$ and $\neg(\phi_1 \vee \phi_2)$ are respectively obtained from the cases for $\phi_1 \vee \phi_2$ and $\phi_1 \wedge \phi_2$ by the De Morgan laws.

The inaccuracy of the satisfiability tests stems from the fact that for formulae $\phi_1 \wedge \phi_2$ (respectively $\neg(\phi_1 \vee \phi_2)$) we make recursively

two satisfiability tests that do not require that ϕ_1 and ϕ_2 (respectively $\neg\phi_1$ and $\neg\phi_2$) are simultaneously satisfiable. For example, $\text{asat}(\emptyset, a \wedge \neg a) = \text{true}$ although $a \wedge \neg a$ is unsatisfiable.

Lemma 3. Let ϕ be a formula and D a set of literals. If $D \cup \{\phi\}$ is satisfiable, then $\text{asat}(D, \phi)$ returns true.

4.2 Inadmissible Additive Heuristic

The max heuristic is very optimistic about the distances, and in many cases it seriously underestimates them. If there are two goal literals, the maximum of the goal costs (distances) is taken to be the combined cost. This however is only accurate when the easier goal is achieved for free while achieving the more difficult one. Goals are often independent and then a more accurate estimate would be the sum of the individual costs. To fix this problem Bonet and Geffner [1] proposed a more practical variant of the max heuristic.

Our definition is based on an auxiliary definition for the cost of achieving a formula. The cost of a literal is the number of steps it takes to achieve it, in a similar approximative sense as in the max heuristic. The cost of a disjunction is the minimum cost of the disjuncts. The cost of a conjunction is the sum of the costs of the conjuncts. This is the difference to the max heuristic where the cost of a conjunction is the maximum of the costs of the conjuncts.

Definition 13. Let I be a state and $L = A \cup \{\neg a | a \in A\}$ the set of literals. Define the sets D_i^+ for $i \geq 0$ as follows.

$$\begin{aligned} D_0^+ &= \{l \in L | I \models l\} \\ D_i^+ &= D_{i-1}^+ \setminus \{l \in L | o \in O, \text{cost}(EP\bar{C}_I(o), i) < i\} \text{ for all } i \geq 1 \end{aligned}$$

We define $\text{cost}(\phi, i)$ as follows.

$$\begin{aligned} \text{cost}(\perp, i) &= \infty \\ \text{cost}(\top, i) &= 0 \\ \text{cost}(a, i) &= 0 \text{ if } \neg a \notin D_0^+, \text{ for } a \in A \\ \text{cost}(\neg a, i) &= 0 \text{ if } a \notin D_0^+, \text{ for } a \in A \\ \text{cost}(a, i) &= j \text{ if } \neg a \in D_{j-1}^+ \setminus D_j^+ \text{ for some } j < i \\ \text{cost}(\neg a, i) &= j \text{ if } a \in D_{j-1}^+ \setminus D_j^+ \text{ for some } j < i \\ \text{cost}(a, i) &= \infty \text{ if } \neg a \in D_j^+ \text{ for all } j < i \\ \text{cost}(\neg a, i) &= \infty \text{ if } a \in D_j^+ \text{ for all } j < i \\ \text{cost}(\phi_1 \vee \phi_2, i) &= \min(\text{cost}(\phi_1, i), \text{cost}(\phi_2, i)) \\ \text{cost}(\phi_1 \wedge \phi_2, i) &= \text{cost}(\phi_1, i) + \text{cost}(\phi_2, i) \\ \text{cost}(\neg\phi, i) &= \text{cost}(\phi, i) \\ \text{cost}(\neg(\phi_1 \wedge \phi_2), i) &= \min(\text{cost}(\neg\phi_1, i), \text{cost}(\neg\phi_2, i)) \\ \text{cost}(\neg(\phi_1 \vee \phi_2), i) &= \text{cost}(\neg\phi_1, i) + \text{cost}(\neg\phi_2, i) \end{aligned}$$

The above definitions would appear to be cyclic but the definition of D_i^+ refers to $\text{cost}(\phi, j)$ for $j \leq i$ only and the definition of $\text{cost}(\phi, i)$ refers to D_j^+ for $j < i$ only.

The definition of $\text{cost}(\phi, i)$ ignores dependencies between conjuncts in the same way as the definition $\text{asat}(D, \phi)$.

Definition 14. Let ϕ be a formula. Define

$$\delta_I^+(\phi) = \text{cost}(\phi, n)$$

where n is the smallest i such that $D_i^+ = D_{i-1}^+$.

The following theorem shows that the distance estimates of the additive heuristic are never lower than those of the max heuristic.

Theorem 15. Let $D_i^+, i \geq 0$ be the sets defined in terms of the approximate tests $\text{asat}(D, \phi)$. Then $D_i^{\max} \subseteq D_i^+$ for all $i \geq 0$.

Proof. The proof is by induction on i .

Base case $i = 0$: By definition $D_0^+ = D_0^{max}$.

Inductive case $i \geq 1$: By the induction hypothesis $D_{i-1}^{max} \subseteq D_{i-1}^+$. To show $D_{i-1}^{max} \setminus \{l \in L \mid o \in O, \text{asat}(D_{i-1}^{max}, EPC_{\bar{l}}(o))\} \subseteq D_{i-1}^+ \setminus \{l \in L \mid o \in O, \text{cost}(EPC_{\bar{l}}(o), i) < i\}$ it is sufficient to show that $\text{cost}(EPC_{\bar{l}}(o), i) < i$ implies $\text{asat}(D_{i-1}^{max}, EPC_{\bar{l}}(o))$.

We show this by induction on the structure of $\phi = EPC_{\bar{l}}(o)$.

Induction hypothesis: $\text{cost}(\phi, i) < i$ implies $\text{asat}(D_{i-1}^{max}, \phi) = \text{true}$.

Base case 1, $\phi = \perp$: $\text{cost}(\perp, i) = \infty$ and $\text{asat}(D_i^{max}, \perp) = \text{false}$.

Base case 2, $\phi = \top$: $\text{cost}(\top, i) = 0$ and $\text{asat}(D_i^{max}, \top) = \text{true}$.

Base case 3, $\phi = a$: If $\text{cost}(a, i) < i$ then $\neg a \notin D_j^+$ for some $j < i$ or $\neg a \notin D_0^+$. Hence $\neg a \notin D_{i-1}^+$. By the outer induction hypothesis $\neg a \notin D_{i-1}^{max}$ and consequently $\neg a \notin D_i^{max}$. Hence $\text{asat}(D_i^{max}, a) = \text{true}$.

Base case 4, $\phi = \neg a$: Analogous to the case $\phi = a$.

Inductive case 5, $\phi = \phi_1 \vee \phi_2$: Assume $\text{cost}(\phi_1 \vee \phi_2, i) < i$. Since $\text{cost}(\phi_1 \vee \phi_2, i) = \min(\text{cost}(\phi_1, i), \text{cost}(\phi_2, i))$, either $\text{cost}(\phi_1, i) < i$ or $\text{cost}(\phi_2, i) < i$. By the induction hypothesis $\text{cost}(\phi_1, i) < i$ implies $\text{asat}(D_{i-1}^{max}, \phi_1)$, and $\text{cost}(\phi_2, i) < i$ implies $\text{asat}(D_{i-1}^{max}, \phi_2)$. Hence either $\text{asat}(D_{i-1}^{max}, \phi_1)$ or $\text{asat}(D_{i-1}^{max}, \phi_2)$. Therefore by definition $\text{asat}(D_{i-1}^{max}, \phi_1 \vee \phi_2)$.

Inductive case 6, $\phi = \phi_1 \wedge \phi_2$: Assume $\text{cost}(\phi_1 \wedge \phi_2, i) < i$. Since $i \geq 1$ and $\text{cost}(\phi_1 \wedge \phi_2, i) = \text{cost}(\phi_1, i) + \text{cost}(\phi_2, i)$, both $\text{cost}(\phi_1, i) < i$ and $\text{cost}(\phi_2, i) < i$. By the induction hypothesis $\text{cost}(\phi_1, i) < i$ implies $\text{asat}(D_{i-1}^{max}, \phi_1)$, and $\text{cost}(\phi_2, i) < i$ implies $\text{asat}(D_{i-1}^{max}, \phi_2)$. Hence both $\text{asat}(D_{i-1}^{max}, \phi_1)$ and $\text{asat}(D_{i-1}^{max}, \phi_2)$. Therefore by definition $\text{asat}(D_{i-1}^{max}, \phi_1 \wedge \phi_2)$.

Inductive case 7, $\phi = \neg\neg\phi_1$: By the induction hypothesis $\text{cost}(\phi_1, i) < i$ implies $\text{asat}(D_{i-1}^{max}, \phi_1)$. By definition $\text{cost}(\neg\neg\phi_1, i) = \text{cost}(\phi_1, i)$ and $\text{asat}(D, \neg\neg\phi) = \text{asat}(D, \phi)$. By the induction hypothesis $\text{cost}(\neg\neg\phi_1, i) < i$ implies $\text{asat}(D_{i-1}^{max}, \neg\neg\phi_1)$.

Inductive case 8, $\phi = \neg(\phi_1 \vee \phi_2)$: Analogously to $\phi = \phi_1 \wedge \phi_2$.

Inductive case 9, $\phi = \neg(\phi_1 \wedge \phi_2)$: Analogously to $\phi = \phi_1 \vee \phi_2$. \square

That the additive heuristic gives higher estimates than the max heuristic could in many cases be viewed as an advantage because the estimates would be more accurate. However, sometimes this leads to overestimating the actual distance, and the heuristic is therefore not admissible (but see recent work by Haslum et al. [5].)

Example 2. Consider an initial state such that $I \models \neg a \wedge \neg b \wedge \neg c$ and the operator $\langle \top, a \wedge b \wedge c \rangle$. A state satisfying $a \wedge b \wedge c$ is reached by this operator in one step but $\delta_I^+(a \wedge b \wedge c) = 3$. \blacksquare

4.3 Inadmissible Relaxed Plan Heuristic

The max heuristic and the additive heuristic represent two extremes. The first assumes that sets of operators required for reaching the different goal literals maximally overlap in the sense that the operators for the most difficult goal literal include the operators for all the remaining ones. The second assumes that these sets are completely disjoint. In some cases the first is better and in others the second.

To estimate the distances more accurately the operators should be better taken into account, which suggests yet another approach to computing a heuristic: attempt to find a set of operators that in a very loose sense reaches the goals. This idea has been considered by Hoffmann and Nebel [7]. A *relaxed plan* is computed as follows (see the algorithm in Figure 1.) We first choose a set of goal literals the truth of which is sufficient for the truth of the goal formula G . These literals must be reachable in the sense of the sets D_i^{max} from Section 4.1. Then we identify the goal literals l with the highest distance

(in the D_i^{max} sense) and a set of operators making them true. These operators form the last step of the relaxed plan. A new goal formula represents the conditions under which these operators can make the literals true. Then a new set of goal literals is produced by a form of regression from the new goal formula. The computation is repeated until we have a set of goal literals that are true in the initial state. Along the way we have constructed a relaxed plan.

The function $\text{goals}(D, \phi)$ recursively finds a set M of literals such that $M \models \phi$ and each literal in M is consistent with D . Note that M itself is not necessarily consistent, for example for $D = \emptyset$ and $\phi = a \wedge \neg a$ we get $M = \{a, \neg a\}$. If a set M is found $\text{goals}(D, \phi) = \{M\}$ and otherwise $\text{goals}(D, \phi) = \emptyset$.

Definition 16. Let D be a set of literals.

$$\begin{aligned} \text{goals}(D, \perp) &= \emptyset \\ \text{goals}(D, \top) &= \{\emptyset\} \\ \text{goals}(D, a) &= \{\{a\}\} \text{ if } \neg a \notin D \\ \text{goals}(D, a) &= \emptyset \text{ if } \neg a \in D \\ \text{goals}(D, \neg a) &= \{\{\neg a\}\} \text{ if } a \notin D \\ \text{goals}(D, \neg a) &= \emptyset \text{ if } a \in D \\ \text{goals}(D, \neg\neg\phi) &= \text{goals}(D, \phi) \\ \text{goals}(D, \phi_1 \vee \phi_2) &= \begin{cases} \text{goals}(D, \phi_1) \text{ if } \text{goals}(D, \phi_1) \neq \emptyset \\ \text{goals}(D, \phi_2) \text{ otherwise} \end{cases} \\ \text{goals}(D, \phi_1 \wedge \phi_2) &= \begin{cases} \{L_1 \cup L_2\} \text{ if } \text{goals}(D, \phi_1) = \{L_1\} \\ \quad \text{and } \text{goals}(D, \phi_2) = \{L_2\} \\ \emptyset \quad \text{otherwise} \end{cases} \\ \text{goals}(D, \neg(\phi_1 \wedge \phi_2)) &= \begin{cases} \text{goals}(D, \neg\phi_1) \text{ if } \text{goals}(D, \neg\phi_1) \neq \emptyset \\ \text{goals}(D, \neg\phi_2) \text{ otherwise} \end{cases} \\ \text{goals}(D, \neg(\phi_1 \vee \phi_2)) &= \begin{cases} \{L_1 \cup L_2\} \text{ if } \text{goals}(D, \neg\phi_1) = \{L_1\} \\ \quad \text{and } \text{goals}(D, \neg\phi_2) = \{L_2\} \\ \emptyset \quad \text{otherwise} \end{cases} \end{aligned}$$

If both ϕ_1 and ϕ_2 yield goal literals for $\phi_1 \vee \phi_2$ the set for ϕ_1 is chosen. A practically better choice is the smaller of the two sets.

Lemma 4. Let D be a set of literals and ϕ a formula.

1. $\text{goals}(D, \phi) \neq \emptyset$ if and only if $\text{asat}(D, \phi) = \text{true}$.
2. If $\text{goals}(D, \phi) = \{M\}$ then $\{\bar{l} \mid l \in M\} \cap D = \emptyset$ and $\text{asat}(D, \bigwedge_{l \in M} l) = \text{true}$.

Proof. 1. This is an easy induction proof on the structure of ϕ based on the definitions of $\text{asat}(D, \phi)$ and $\text{goals}(D, \phi)$.

2. This is because $\bar{l} \notin D$ for all $l \in M$. This can be shown by a simple induction proof. \square

Lemma 5. Let D and $D' \subseteq D$ be sets of literals. If $\text{goals}(D, \phi) = \emptyset$ and $\text{goals}(D', \phi) = \{M\}$, then there is $l \in M$ such that $\bar{l} \in D \setminus D'$.

Definition 17. Define $\delta_I^{rlx}(\phi) = \text{relaxedplan}(A, I, O, \phi)$.

The additive and the relaxed plan heuristic are incomparable and both give estimates at least as high as the max heuristic.

Theorem 18. Let ϕ be a formula and $\delta_I^{max}(\phi)$ the max-distance defined in terms of $\text{asat}(D, \phi)$. Then $\delta_I^{rlx}(\phi) \geq \delta_I^{max}(\phi)$.

Proof. We have to show that for any formula G the procedure call $\text{relaxedplan}(A, I, O, G)$ returns a number $\geq \delta_I^{max}(G)$.

The procedure returns ∞ if and only if $\text{asat}(D_0^{max}, G) = \text{false}$ for all $i \geq 0$. In this case by definition $\delta_I^{max}(G) = \infty$. Otherwise $t = \delta_I^{max}(G)$. Now $t = 0$ if and only if $\text{asat}(D_0^{max}, G) = \text{true}$. In this case the procedure returns 0 without iterating the loop (line 9.)

```

1: procedure relaxedplan(A,I,O,G);
2:    $L := A \cup \{\neg a | a \in A\}$ ; (* Set of all literals *)
3:   compute sets  $D_i^{\max}$  as in Definition 8;
4:   if asat( $D_i^{\max}, G$ ) = false for all  $i \geq 0$  then return  $\infty$ ;
5:    $t := \delta_I^{\max}(G)$ ;
6:    $L_{t+1}^G := \emptyset$ ; (* Goal literals initially *)
7:    $N_{t+1} := \emptyset$ ;
8:    $G_t := G$ ; (* Initial goal formula *)
9:   for  $i := t$  downto 1 do
10:     $L_i^G := (L_{i+1}^G \setminus N_{i+1}) \cup \{l \in M | M \in \text{goals}(D_i^{\max}, G_i)\}$ ;
11:     $N_i := \{l \in L_i^G | l \in D_{i-1}^{\max}\}$ ; (* Goals becoming true at i *)
12:     $T_i := \text{a minimal subset of } O$  (* Operators making  $N_i$  true *)
13:    so that  $N_i \subseteq \{l \in L_i | o \in T_i, \text{asat}(D_{i-1}^{\max}, EPC_l(o))\}$ ;
14:     $G_{i-1} := \bigwedge_{l \in N_i} \bigvee \{EPC_l(o) | o \in T_i\}$ ; (* New goal *)
15:   end do
16:   return  $|T_1| + |T_2| + \dots + |T_t|$ ;

```

Figure 1. Algorithm for finding a relaxed plan

We show that if $t \geq 1$ then $T_i \neq \emptyset$ for every $i \in \{1, \dots, t\}$, entailing $|T_1| + \dots + |T_t| \geq t = \delta_I^{\max}(G)$. This is by induction from t to 1. We use the following auxiliary result. If $\text{asat}(D_{i-1}^{\max}, G_i) = \text{false}$ and $\text{asat}(D_i^{\max}, G_i) = \text{true}$ and $\bar{l} \notin D_i^{\max}$ for all $l \in L_i^G$ then T_i is well-defined and $T_i \neq \emptyset$. The proof is as follows.

By Lemma 4 $\text{goals}(D_{i-1}^{\max}, G_i) = \emptyset$ and $\text{goals}(D_i^{\max}, G_i) = \{M\}$ for some M . By Lemma 5 there is $l \in M$ such that $\bar{l} \in D_{i-1}^{\max}$ and hence $N_i \neq \emptyset$. By definition $\bar{l} \in D_{i-1}^{\max}$ for all $l \in N_i$. By $N_i \subseteq L_i^G$ and the assumption about L_i^G $\bar{l} \notin D_i^{\max}$ for all $l \in N_i$. Hence $\bar{l} \in D_{i-1}^{\max} \setminus D_i^{\max}$ for all $l \in N_i$. Hence by definition of D_i^{\max} for every $l \in N_i$ there is $o \in O$ such that $\text{asat}(D_{i-1}^{\max}, EPC_l(o))$. Hence there is $T_i \subseteq O$ so that $N_i \subseteq \{l \in L_i | o \in T_i, \text{asat}(D_{i-1}^{\max}, EPC_l(o))\}$ and the value of T_i is defined. As $N_i \neq \emptyset$ also $T_i \neq \emptyset$.

In the induction proof we establish the assumptions of the auxiliary result and then invoke the auxiliary result itself.

Induction hypothesis: For all $j \in \{i, \dots, t\}$

1. $\bar{l} \notin D_j^{\max}$ for all $l \in L_j^G$,
2. $\text{asat}(D_j^{\max}, G_j) = \text{true}$ and $\text{asat}(D_{j-1}^{\max}, G_j) = \text{false}$, and
3. $T_j \neq \emptyset$.

Base case $i = t$:

1. $\bar{l} \notin D_t^{\max}$ for all $l \in L_t^G$ by (2) of Lemma 4 because $L_t^G = \{l \in \text{goals}(D_t^{\max}, G_t)\}$.
2. As $t = \delta_I^{\max}(G_t)$ by definition $\text{asat}(D_{t-1}^{\max}, G_t) = \text{false}$ and $\text{asat}(D_t^{\max}, G_t) = \text{true}$.
3. By the auxiliary result from the preceding case.

Inductive case $i < t$:

1. We have $\bar{l} \notin D_i^{\max}$ for all $l \in L_i^G$ because $L_i^G = (L_{i+1}^G \setminus N_{i+1}) \cup \{l \in \text{goals}(D_i^{\max}, G_i)\}$ and by the induction hypothesis $\bar{l} \notin D_{i+1}^{\max}$ for all $l \in L_{i+1}^G$ and by (2) of Lemma 4 $\bar{l} \notin D_i^{\max}$ for all $l \in M$ for $M \in \text{goals}(D_i^{\max}, G_i)$.
2. By definition $G_i = \bigwedge_{l \in N_{i+1}} \bigvee \{EPC_l(o) | o \in T_{i+1}\}$. By definition of T_{i+1} for every $l \in N_{i+1}$ there is $o \in T_{i+1}$ such that $\text{asat}(D_i^{\max}, EPC_l(o)) = \text{true}$. By definition of $\text{asat}(D_i^{\max}, \phi_1 \vee \phi_2)$ and $\text{asat}(D_i^{\max}, \phi_1 \wedge \phi_2)$ also $\text{asat}(D_i^{\max}, G_i) = \text{true}$. Then we show that $\text{asat}(D_{i-1}^{\max}, G_i) = \text{false}$. By definition of D_i^{\max} , $\text{asat}(D_{i-1}^{\max}, EPC_{\bar{l}}(o)) = \text{false}$ for all $l \in D_i^{\max}$ and $o \in O$. Hence $\text{asat}(D_{i-1}^{\max}, EPC_l(o)) = \text{false}$ for all $l \in N_{i+1}$ and $o \in O$.

because $\bar{l} \in D_i^{\max}$. Hence $\text{asat}(D_{i-1}^{\max}, EPC_l(o)) = \text{false}$ for all $l \in N_{i+1}$ and $o \in T_{i+1}$ because $T_{i+1} \subseteq O$. By definition $G_i = \bigwedge_{l \in N_{i+1}} \bigvee \{EPC_l(o) | o \in T_{i+1}\}$. Hence by definition of $\text{asat}(D, \phi)$ also $\text{asat}(D_{i-1}^{\max}, G_i) = \text{false}$.

3. By the auxiliary result from the preceding case. \square

5 Conclusions

We have shown how a number of distance heuristics can be elegantly generalized to an expressive planning language with conditional effects and arbitrary formulae. In comparison to the reductive approach for handling general operators, our approach does not suffer from the problem of exponential size of operator sets. The only exponentiality is in the satisfiability tests, but as the structure of formulae $EPC_l(o)$ is usually very simple even in cases that are difficult to the reductive approach, the worst-case exponentiality is not a serious issue, and can be completely avoided by approximate satisfiability tests.

We have also clarified relations between different heuristics. Hoffmann and Nebel [7] do not elaborate on the close connection between their Graphplan-based relaxed plan heuristic and Bonet and Geffner's max heuristic. Our formalization of the former makes the connection very clear: a relaxed plan is a set of operator occurrences that in a certain sense covers the changes between sets D_i^{\max} and D_{i+1}^{\max} that are relevant for reaching the goals. Planning graphs are not needed for defining the relaxed plan heuristic.

Applying Trip@dvice Recommendation Technology to www.visiteurope.com

Adriano Venturini¹ and Francesco Ricci²

Abstract. Implementing decision support technologies in a real commercial tourism destination portal is challenging. First of all, the peculiar problems related to the tourism domain, which have been studied in the recent years in eCommerce and tourism research, must be considered. But, to provide an effective and useful tool, one must tackle additional requirements arising from the technical and operational environment, which influence not only the software development and architectural issues, but also methodological aspects. This paper describes the main choices we taken and the approach we followed to integrate the Trip@dvice recommendation technology in www.visiteurope.com, the major European tourism portal launched in March 2006, with the goal of promoting Europe as a tourist destination.

1 INTRODUCTION

There is a growing number of web sites that support a traveller in the selection of travel destinations or travel products and services (e.g., events, attractions, flight, hotel). Travellers enter tourism portals searching for information about destinations and related topics, such as, points of interests, historical data, weather conditions, travel packages, flights and hotels. This wide spectrum of information is currently provided by a number of web actors belonging to different categories: on-line travel agencies; tour operators; cruise operators; destination management organizations (multi-destination, regional, city); airlines; hotel chains; convention and visitors bureau [2, 15].

To help visitors to find the information they need and plan their vacation, decision aid technologies are being adopted by tourism portals. These tools must take into account the complexity of the tourist decision process, that has already been described in several studies (see [5] for a survey). A destination is a complex concept, it is an aggregation of more elementary components, such as attractions or cultural themes, more than a geographic area. In addition, a "travel plan", i.e., the output of the decision process, may vary greatly in the structure and content, it could be a flight and hotel, or a complete day by day schedule of the holiday. Because of this, the straightforward implementation of general decision aid and recommendation technologies, already proved to be successful in other sectors [12, 1], cannot be successfully applied to travel planning and destination choice [10].

To overcome these limitations, we have developed Trip@dvice, a travel recommendation methodology that incorporates a human choice model derived from specialized literature on traveler's behavior [4], and extends recommender systems designed for simpler products, and in particular those based on Case Base Reasoning [6].

Trip@dvice supports the selection of travel products (e.g., a hotel or a visit to a museum or a climbing school) and the building of a *travel plan*. In our approach the case base is composed of travel plans built by a community of users. A case is structured hierarchically including components that represent the search/decision problem definition, i.e. the travel's and travellers' characteristics, and the problem solution, that is, the set of products and services included in the plan [11].

Trip@dvice has been chosen by the European Union and by the European Travel Commission (ETC) to provide personalized travel recommendations in the European tourism destination portal, www.visiteurope.com. The main goal of [visiteurope.com](http://www.visiteurope.com), which has been launched on March 2006, is to promote Europe as a tourist destination. The Travel Planner tool, based on Trip@dvice technology, is an advanced service allowing tourists to self-bundle their travel plan by receiving personalized recommendations about interesting places and activities that can be practiced in Europe.

To integrate a recommendation technology such as Trip@dvice in a real portal we faced several challenges, normally not considered when dealing with research tools. A tourism destination portal is a complex system composed of a wide set of components and services designed to help the user to find, examine and select the tourist products she is looking for. Supporting the portal visitors in their decisional process means to integrate the recommendation process in the portal concept itself, sharing content, functions and tools of the overall portal. Visitors should be able to bundle their travel plan at any time in their preferred way, either browsing the content through the classical navigation functions, or by selecting the preferred tourist products shown on the home page, or by accepting a suggestion which has been sent via email by a friend.

Therefore the recommender system should exploit the same content repository available in the portal. The European tourism destination portal, stores content related to the 34 European official national tourism organization belonging to ETC, and supports a weakly structured content model representing a wide sets of concepts. Recommendation functions must be adapted to deal with items represented with semi-structured models annotated with metadata information. Furthermore, the tourist target market of the portal is the whole world, thus the portal has to support a wide spectrum of visitors with different characteristics and decision styles [16]. Most of [visiteurope.com](http://www.visiteurope.com) visitors do not know much about Europe and they are supposed to increase their "destination" knowledge with the portal support.

This paper is organized as follows: Section 2 describes the functions implemented by Travel Planner service and the typical interaction supported by the tool. Section 3 summarizes the methodology implemented by Trip@dvice and how it has been adapted to [visiteurope.com](http://www.visiteurope.com).

¹ eCTRL Solutions, Italy, email: venturini@ectrlsolutions.com

² ITC-irst, Italy, email: ricci@itc.it

rope.com. Section 4 gives an overview of the architecture we adopted to integrate the recommendation technologies within the portal. Section 5 deals with some open questions and next research activities.

2 THE TRAVEL PLANNER SERVICE AND SUPPORTED SCENARIO

The Travel Planner service provides a set of functions that allow users to plan their vacation in Europe. It manages the current user travel plan, which is a set of tourist items (e.g. regions, cities, attractions, activities, events) selected by the user to self-bundle the travel. Tourist items can be selected from any section of the portal and added to the user's personal travel plan: each tourist item shown by any information service of the portal can be selected and added to the user's personal travel plan. All the items that the user has added to his personal travel plan contribute to create his user model (of the current travel) and will be exploited by the recommendation functions to provide relevant recommendations (see Section 3).

Figure 1. Specifying Travel Preferences

The initial step of the recommendation process consists in collecting the user's travel preferences, as shown in Figure 1. Here the user can enter general needs and preferences about the travel he is going to plan. Users are not forced to answer all these questions to get recommendations or to use the travel planner services, since this is not the unique source of information for recommendations. Moreover, users can at anytime refine their preferences to better specify their profile. It is important to highlight that the features that the user can here specify (e.g. themes and regions of interests) are not predefined by the recommender system. In fact, they belong to the classification trees used to classify items in the content management system of the portal. Features can be added and removed by the portal content manager, adapting the tool to the evolving needs of the tourism organization. Travel preferences become part of the current case and will be exploited by the Search Activity and by the Seeking for Inspiration functions to deliver product recommendations.

In the Search Activity function the user further specifies detailed preferences about the activities sought (Figure 2). Additional criteria can also be set, like the preferred countries and themes of interests. Note that the top level categories (e.g. Nature) already selected in the Travel Preference section are automatically expanded to allow the user to select children categories (e.g. Natural Park, Landscape) and refine her interests definition. By pushing the search button, activities matching the detailed preferences are ranked and shown to the user, who can add the preferred ones to his travel plan (Figure 3).

Figure 2. Specifying Detailed Preferences

The recommendation functions we have implemented in [visit-europe.com](http://www.visit-europe.com) are the followings:

- **Search Activity.** Exploiting the information and preferences acquired during the user-system interaction and the experiences contained in past recommendation sessions, the system identifies and recommends ranked tourist items.
- **Seeking for Inspiration.** This function is intended for those users that rather than specifying preferences and constraints, prefer to browse the portal content, looking and rating proposals made by the system. Each system proposal is a coherent bundle of tourist items. If the user is interested in one proposal, she can either add all or some of its components to the travel plan, or get additional proposals similar to the one that she likes.

The other main recommendation function which has been implemented is called "Seeking for Inspiration" (Figure 4). Here the system initially proposes some alternative bundles of tourist items. The user can examine each proposal in details and add all or part of it to her travel plan, or can get additional recommendations by selecting one bundle ("My favorite is this"). In this case, the system, exploiting the whole history of alternative bundles preferred by the user, proposes new bundles that are supposed to be closer to the user ideal travel.

Results of your search

The screenshot shows a search results page with three items:

- Glacier walking**: Rating 5 stars. Description: "Norway still shows traces of the Ice Age, when the entire country was covered by ice." Buttons: "Suggested experiences" and "add to your Travel Plan".
- Reindeer sledding**: Rating 5 stars. Description: "Reindeer sledding is a unique way of experiencing the Norwegian countryside." Buttons: "Suggested experiences" and "add to your Travel Plan".
- Nature trails**: Rating 5 stars. Description: "If you like learning about the features of the route while you are walking, a nature trail is an excellent option." Buttons: "Suggested experiences" and "add to your Travel Plan".

Figure 3. Search Results

Seeking Inspirations

The screenshot shows a section titled "Seeking Inspirations" with six alternatives:

- ALTERNATIVE 1**: Switzerland Food, Wines. Description: "Gastronomy & Wine in Switzerland". Buttons: "detail" and "My favourite is this!".
- ALTERNATIVE 2**: Switzerland, Germany Food, Wines. Description: "Gastronomy & Wine in Switzerland". Buttons: "detail" and "My favourite is this!".
- ALTERNATIVE 3**: Mediterranean, Cyprus Sightseeing, Culture. Description: "Beaches". Buttons: "detail" and "My favourite is this!".
- ALTERNATIVE 4**: Switzerland Golfing, Skating. Description: "Golf". Buttons: "detail" and "My favourite is this!".
- ALTERNATIVE 5**: Switzerland Culture, History. Description: "Art Basel". Buttons: "detail" and "My favourite is this!".
- ALTERNATIVE 6**: Switzerland Alpine skiing, Snowboarding. Description: "Winter in Switzerland". Buttons: "detail" and "My favourite is this!".

Figure 4. Seeking Inspiration

3 TRIP@DEVICE RECOMMENDATION TECHNOLOGY

Trip@device is a recommendation technology which integrates case base reasoning and cooperative query answering to provide personalized suggestions about interesting tourist products. This section briefly describes the case structure and the methodology exploited in the two implemented recommendation functions, Single Item Recommendations and Seeking for Inspiration. Full details of Trip@device recommendation methodology can be found in [11].

3.1 Case Model

Trip@device bases its recommendations on a case model that captures a unique human-machine interaction session. A case collects: information provided by the user during the session, the products selected, and some long-term preferences and demographic data of the user if he is registered. Recommendation sessions are stored as cases in a repository (case base) [6]. In addition to the case base, product catalogues are stored in a relational database.

In Trip@device, a case represents a user interaction with the system, and it is built incrementally during the recommendation session. A case comprises the following three main components:

- **Collaborative Features (clf)** are features that describe general user's characteristics, wishes, constraints or goals (e.g. desire to relax or to practise sports). They capture general travel preferences and characteristics that are relevant to the decision-making process, but cannot be considered as product features (e.g. the traveller group composition). These features are used to measure case similarity.
- **Content Queries (cnq)** are queries posed over the catalogues of products. Content queries are built by constraining (content) features, i.e., descriptors of the products listed in the catalogues.
- **Cart** contains the set of products and services chosen by the user during the recommendation session. A cart represents a meaningful (from the user's point of view) bundling of different products. For instance, a travel cart may contain some destinations, some accommodations, and some additional attractions.

Figure 5 shows a case example. It represents a user, who is single, has a medium budget, interested in nature and culture and in visiting Scandinavia or Central Europe. These are the collaborative features. Then there is one query, where the user has further specified some countries he is interested in (Norway and Sweden). From the result set of that query, the user has selected the Raindeer sledding and the Trono old church site.

3.2 Single Item Iterative Selection

The overall process supported by Trip@device for the single item iterative selection is shown in Figure 6. The full description of this process can be found in [11], here we provide just a brief summary of the methodology. The user interacts with the recommender system by asking for recommendations about a product type (e.g., an activity)(1: AskRecommendation(q) in Figure 6). The system replies to this query q either recommending some products, or, in case the query fails, suggesting some query refinements. The RecEngine module manages the request. First, it invokes the Evaluate-Query function (2) of the Intelligent Query Manager module (IQM), by passing the query. This function searches the catalogue for products matching the query. If too many or no product matches the input

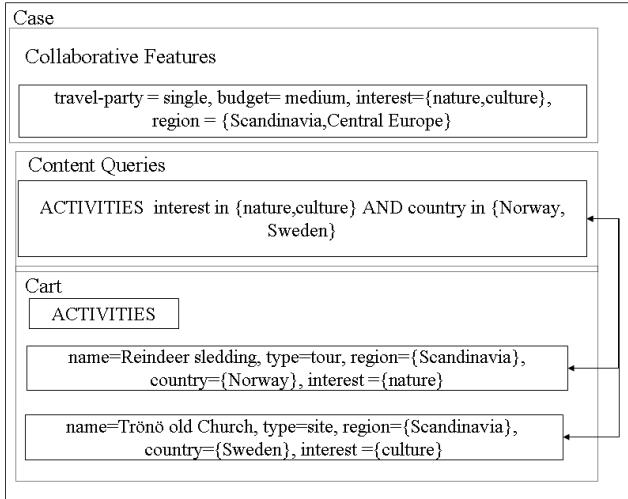

Figure 5. Example of a case

query q , then IQM analyzes q and determines a set of query refinements to suggest.

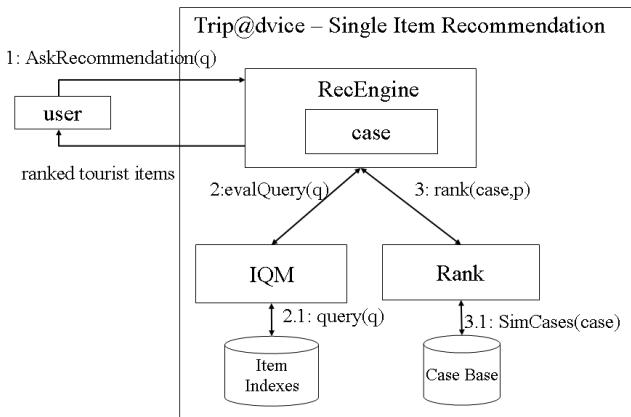

Figure 6. Single item recommendation with Trip@device.

The products selected by the user's query are ranked by invoking the Rank method (3). Rank receives as input the current case and the set of products p to be ranked. The current case is used to retrieve the set of K most similar cases from the case base, and the products contained in these retrieved cases are then used to rank the user selected products p . Finally, the ranked products are returned to the user. Ranking is computed exploiting two similarity metrics: first, the case base is accessed to retrieve the K most similar cases (reference cases) to the current one. Then, the products contained in the carts of the retrieved reference cases (reference products) are used to sort the products selected by the user's query. The basic idea is that among the products in the result set of the query one will get a better score if it is similar/equal to a product chosen by a user with similar needs and preferences. This function implements a hybrid "cascade" recommendation methodology [3], where first a conversational approach is used to select a set of options and then a collaborative via content approach is used for ranking [8].

3.3 Seeking for Inspiration

In this section we describe the seeking for inspiration function, designed for users that would prefer to browse travel options and get inspired by them before taking some decision. The recommendation proceeds according to the following loop (see Figure 7):

- **Retrieval.** The process is started with an initial case c that could be either the current case or a random case taken from the case base. It is the current user's case if the user has already created it in previous stages of the interaction, for instance by specifying his general travel preferences or adding some tourist products to the cart. Conversely, if the current case does not yet contain any useful information, then the recommender does not know anything about the user and could only make an initial random guess of what could be a good travel for the user. The retrieval module searches for the M most similar cases in the case base and passes this set to the next module, the Selection.
- **Case Selection.** In the second step the M cases retrieved from the case base are analyzed to select a very small subset of candidates to be presented to the user (six in the European tourism destination portal). To select this small set of candidates a greedy algorithm is used [14]. It iteratively selects a case starting from the initial case and puts the selected case in the result set. The case added at each iteration is the one that minimizes the sum of the similarities between itself and the cases already in the result set. In this way, it selects from the M cases those that are enough different among themselves to provide a reasonable variety of options to the user.

The selected cases are shown to the user, who can choose the preferred one. The retrieval step is executed again, with some notable changes. The seed case is now the case that received positive feedback from the user, and the number of cases retrieved from the case base, M in the first retrieval, is decreased by a factor $0 < \lambda < 1$. The rationale for decreasing the number of retrieved cases is to stronger focus the retrieval around the input case, since at this new stage we must count on the positive evaluation of the user on the selected case. This recommendation functionality follow the recommendation by proposing and comparison-based recommendation approaches introduced in [13, 7]

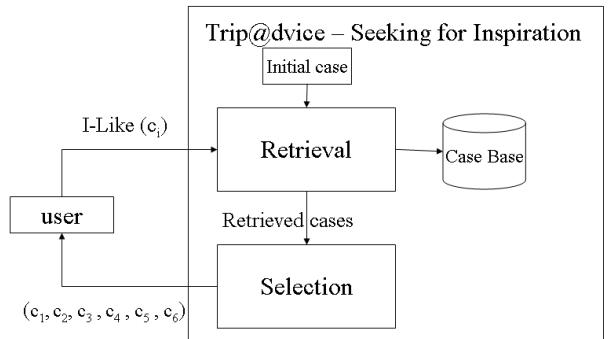

Figure 7. Seeking for inspiration recommendation cycle.

4 INTEGRATION ARCHITECTURE

As already said in the Introduction, integrating the recommendation technology in a full portal presents several issues that should be considered. [9] describes several options for deploying a recommender

system. One, is to build an independent web site, which provides recommendations about products described in a second portal. TripAdvisor is a popular example of this approach, it recommends hotels that are sold by a number of merchant web sites (e.g. expedia and travelocity). Another approach consists of deploying the recommendation technology inside the system itself, and tightly integrate the recommendation functions with the full system. In this way the designer can mix new recommendation functions with more traditional one (e.g. browsing and search), controlling the full human-computer interaction. In visiteurope.com we adopted the second option. Figure 8 shows a high level view of the modules relevant to our discussion. In particular it shows some components which are parts of a typical web portal architecture: the Navigation component, allowing the user to navigate the content of the portal following a navigation tree; the Content Management System (CMS), which is in charge of managing the content items of the portal; and TripAdvisor, providing the recommendation and travel plan management functions and the Travel Planner graphical user interface.

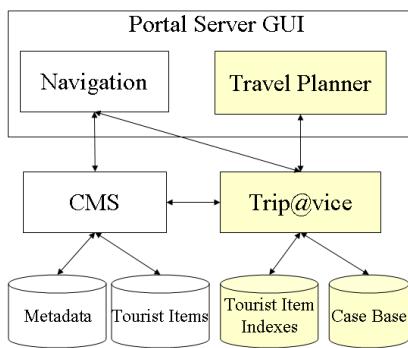

Figure 8. Single item recommendation with TripAdvisor.

These components should communicate among them. The Travel Planner GUI uses the TripAdvisor functions to display the current user travel plan and recommend items to the users. The Navigation service interacts with TripAdvisor to add to the user' travel plan the tourist items that the user chooses navigating in the portal or exploiting the recommendation functions. In this architecture, TripAdvisor must retrieve from the CMS the content items and their metadata to build the recommendations and must refer to them when storing cases.

5 CONCLUSION

In this paper we have illustrated the design and the implementation of a decision aid tool aimed at supporting the traveller's decisional process in the European tourism destination portal www.visiteurope.com. We have presented the main project goals, the interaction we have supported, its methodology and the integration architecture. The proposed recommendation technology, before being deployed in visiteurope.com, has been evaluated in a number of empirical studies involving hundreds of users [16]. The travel plans case base has been initialized with some cases for each country and is now growing, acquiring new travel cases as the system is used by the visitors. A case management tool, supporting the content manager in the validation and selective inclusion of new cases in the repository, has been developed and integrated in the portal infrastructure.

A number of open problems must be still faced in the near future. Techniques to analyze the case base and select a subset of cases among the potentially huge set of those created by the portal visitors must be developed. Moreover, tourism organizations should be supported in better understanding their users and their tourism offers by exploiting the knowledge stored in the case base.

Natural and Intuitive Multimodal Dialogue for In-Car Applications: The SAMMIE System

Tilman Becker¹ and Nate Blaylock² and Ciprian Gerstenberger² and Ivana Kruijff-Korbayová² and Andreas Korthauer³ and Manfred Pinkal² and Michael Pitz⁴ and Peter Poller¹ and Jan Schehl¹

Abstract.

We present SAMMIE, a laboratory demonstrator of an in-car showcase of a multimodal dialogue system developed in the TALK project⁵ in cooperation between DFKI/USAAR/BOSCH/BMW, to show natural, intuitive mixed-initiative interaction, with particular emphasis on multimodal turn-planning and natural language generation. SAMMIE currently supports speech-centered multimodal access for the driver to a MP3-player application including search and browsing, as well as composition and modification of playlists. Our approach to dialogue modeling is based on collaborative problem solving integrated with an extended Information State Update paradigm. A formal usability evaluation of a first baseline system of SAMMIE by naive users in a simulated environment yielded positive results, and the improved final version will be integrated in a BMW research car.

1 Introduction

The TALK project investigates issues in multimodal dialogue systems: multilinguality, adaptivity and learning, dialogue modeling and multimodal turn planning. Our approach is based on an extended Information State Update paradigm. Some of these issues are demonstrated in SAMMIE, an in-car showcase developed in cooperation between DFKI/USAAR/BOSCH/BMW. The design of the SAMMIE system is based on a series of user studies performed in different Wizard-of-Oz settings as well as a usability evaluation of a baseline version of the laboratory demonstrator. SAMMIE will be integrated into a test car at BMW later this year.

The SAMMIE system provides a multimodal interface to an in-car MP3 player through speech and haptic input with a BMW iDrive input device, a button which can be turned, pushed down and sideways in four directions. System output is provided by speech and a graphical display integrated into the car's dashboard. An example of the system display is shown on the right in figure 1.

The MP3 player application offers a wide range of tasks: The user can control the currently playing song, search and browse the database by looking for any of the fields in the MP3 database (song, artist, album, etc.), search and select playlists and even construct and

edit playlists.

SAMMIE supports natural, intuitive mixed-initiative interaction, with particular emphasis on multimodal turn-planning and natural language generation. The system puts the user in control of the interaction. Input can be given through any modality and is not restricted to answers to system queries. On the contrary, the user can provide new tasks as well as any information relevant to the current task at any time. This is achieved through modeling the interaction as a collaborative problem solving process, modeling the tasks and their progression as *recipes* and a multimodal interpretation that fits any user input into the context of the current task. Note that the user is also free in the use of multimodal input, such as deictic references accompanied by pointing gestures ("Play this title" while pushing the BMW iDrive button), and even cross-modal references without pointing as in "Play the third song (on the list)". To support these aspects of dialogue flexibility, we model dialogue context, collaborative problem solving and the driver's attention state by an enriched information state. Table 1 shows a typical interaction with the SAMMIE system, figure 3 shows the current setup for the user environment.

- U: Show me the Beatles albums.
- S: I have these four Beatles albums. [shows a list of album names]
- U: Which songs are on this one? [selects the Red Album]
- S: The Red Album contains these songs [shows a list of the songs]
- U: Play the third one.
- S: [song "From Me To You" plays]

Table 1. A typical interaction with SAMMIE.

The following section describes our system architecture. Section 3 presents our approach to extended multimodal interaction modeling, ontology based modeling and its impact on natural and intuitive dialogues. Section 4 briefly describes our Wizard-of-Oz experiments, the evaluation process and the results. Finally, section 5 summarizes some important lessons learned in development and evaluation of our system.

2 System Architecture

Our system architecture follows the classical approach [5] of a pipelined architecture with multimodal fusion and fission modules encapsulating the dialogue manager. Figure 1 shows the modules and their interaction: Modality-specific recognizers and analysers provide semantically interpreted input to the multimodal fusion module (interpretation manager in fig. 1) that interprets them in the context of the other modalities and the current dialog context. The dialogue manager decides on the next system move, based on its model of the

tasks as collaborative problem solving, on the current context and also on the results from calls to the MP3 database. The turn planning module then generates an appropriate message to the user by planning the actual content, distributing it over the available output modalities and finally co-ordinating and synchronizing the output. Modality-specific output modules generate spoken output and an update of the graphical display. All modules interact with the extended information state in which all context information is stored.

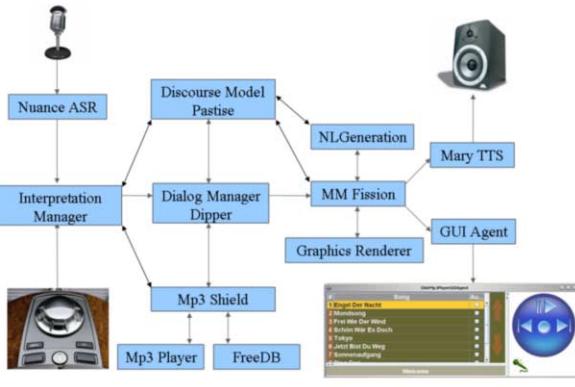

Figure 1. SAMMIE system architecture.

Many tasks in the SAMMIE system are modeled by a plan-based approach. Discourse modeling, interpretation management, dialogue management and linguistic planning, and turn planning in our system are all based on the production rule system PATE⁶ [9], originally developed for the integration of multimodal input. During the implementation of the baseline system, we found that PATE is also adequate for modeling other dialogue system components as it provides an efficient and elegant way of realizing complex processing rules. Section 3.5 elaborates more on PATE and the ontology-based representations it uses. In the following sections we will concentrate on our main areas of research.

3 Modeling Multimodal Interaction

Many dialogue systems that are employed today follow a state-based approach that explicitly models the full (finite) set of dialogue states and all possible transitions between them. The VoiceXML⁷ standard is a prominent example of this approach. This has two drawbacks: on the one hand, this approach is not very flexible and typically allows only so-called system controlled dialogues where the user is restricted to choosing their input from provided menu-like lists and answering specific questions. The user never is in control of the dialogue.⁸ For restricted tasks with a clear structure, such an approach is often sufficient and has been applied successfully. On the other hand, building such applications requires a fully specified model of all possible states and transitions, making larger applications expensive to build and difficult to test.

⁶ PATE is short for (P)roduction rule system based on (A)ctivation and (T)yped feature structure (E)lements.

⁷ <http://www.w3.org/TR/voicexml20>

⁸ It is possible to build state-based systems without presenting a fixed menu hierarchy to the user. The user might even get the impression that they can interact quite flexible. But of course this creates considerable application complexity and implementation effort for all possible states and transitions.

In SAMMIE, we are following an approach that models the interaction on an abstract level as collaborative problem solving and adds application specific knowledge on the possible *tasks*, available *resources* and known *recipes* for achieving the goals. A planner, based on the PATE rule-interpreter [9] dynamically derives the next move of the system and then plans the details of the system output.

In addition, all relevant context information is administered in a central Extended Information State (EIS) module. This is an extension of the Information State Update approach [13] to the multimodal setting.

3.1 Extended Information State

The information state of a multimodal system needs to contain a representation of contextual information about discourse, but also a representation of modality-specific information and user-specific information which can be used to plan system output suited to a given context. The overall information state (IS) of the SAMMIE system is shown in Figure 2.

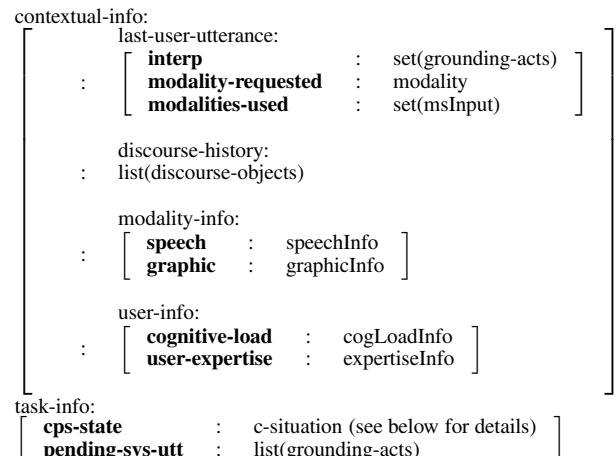

Figure 2. Structure of the SAMMIE Information State

The contextual information partition of the IS represents the multimodal discourse context, i.e., the information communicated through the different modalities. It contains a record of the latest user utterance and preceding discourse history representing in a uniform way the salient discourse entities introduced in the different modalities (we follow the approach adopted in the SmartKom system [10]; the discourse model employs the three-tiered context representation proposed in [7] where the linguistic layer is generalized to a modality layer). The contents of the task partition are explained in the next section.

3.2 Collaborative Problem Solving

We see a dialogue system as a *conversational agent*—an autonomous agent which can communicate with humans through natural language dialogue. In order to support natural and flexible conversation, we need to model dialogue about the range of activities an agent may engage in, including goal selection, planning, execution, monitoring, replanning, and so forth. To achieve this our dialogue manager is based on an agent-based model which views dialogue as collaborative problem-solving (CPS) [4]. CPS follows a process similar to

single-agent problem solving, but the agents negotiate to jointly determine objectives, find and instantiate recipes to accomplish them and execute the recipes and monitoring for success.

The basic building blocks of the formal CPS model are problem-solving (PS) objects, which we represent as typed feature structures. PS object types form a single-inheritance hierarchy, where children inherit or specialize features from parents. Instances of these types are then used in problem solving.

In our CPS model, we define types for the upper level of an ontology of PS objects, which we term *abstract PS objects*. There are six abstract PS objects in our model from which all other domain-specific PS objects inherit: objective, recipe, constraint, evaluation, situation, and resource. These abstract PS objects are used to model problem-solving at a domain-independent level and are taken as arguments by all update operators of the dialogue manager which implement conversation acts [4, 12]. The model is then specialized to a domain by inheriting and instantiating domain-specific types and instances from the PS objects. For example, the domain-specific objective *play-song* in the MP3 domain inherits all attributes from *objective* and adds a has-song slot, which is *single-slot* of type *song*. The operators, however, do not change with domain, which supports reasoning done at a domain-independent level.

3.3 Adaptive Turn Planning

In a multimodal dialogue system, the *fission* component is responsible for realising the planned system response as determined by the dialogue manager through multimodal output in an appropriate combination of the available output channels. This task comprises detailed content planning, media allocation and coordination and synchronization.

In SAMMIE, the fission task is realised by two modules - the *Turn Planner* and the *Output Manager*, whereas user- and modality-specific information which might be necessary for presentation planning can be obtained from another module called *Pastis*. Pastis is designed to provide and store user-, modality- and also discourse-specific information and forms, together with the dialogue manager's embedded information state as the *Extended Information State* of the system.

When the dialogue manager has finished processing the user input, the turn planner (TP) receives a bundle of CPS-specific conversational acts, representing the planned system response on an abstract level. TP then starts planning how to distribute given information over the available modalities, namely speech and graphics, but also determines on which level of detail information is going to be presented. As soon as TP has finished processing, it sends a sorted bundle of output messages, including both speech and graphic messages, to the output manager. The output manager then distributes the messages to the graphics renderer and/or the generation manager and synchronizes their output rendering.

The Turn Planner within the SAMMIE system is responsible for content selection and media allocation. It takes a set of CPS-specific conversational acts generated by the dialogue manager and maps them to modality-specific communicative acts. Therefore, relevant information on how content should be distributed over the available modalities (speech or graphics) can be obtained by

- (a) the EIS/discourse module Pastis, which provides information about
 - (1) the modality on which the user is currently focused, derived by the current discourse context.

- (2) the user's current cognitive load when system interaction becomes a secondary task (e.g., system interaction while driving). This information is modeled as a state variable with the possible states *low, mid, high* or *extreme*.
- (3) the user's expertise, which is represented as a state variable with the possible states *power-user* or *beginner*.

Pastis also contains information about factors that influence the preparation of output rendering for a modality, like the currently used language (German or English) or the display capabilities (e.g., maximum number of displayable objects within a table).⁹

- (b) a set of production rules that determine which kind of information should be presented through which modality. The rule set is divided in two subsets, domain-specific and domain-independent rules which together form the system's multimodal plan library. These rules are used to create the presentation plan for a turn, while dynamically taking the information listed in (a) into account.

Beside determining the best possible distribution of information, the turn planner also transforms domain-specific information that will be presented by speech to a representation we call *Reduced Knowledge Representation* (RKR) that can be interpreted by the Linguistic Planner. Such an RKR structure differs from its source structure through its more general, abstract surface structure which can be seen as an intermediate form between a pure ontological representation of a domain specific object and the logical form representation that the linguistic planner needs for deep generation with OpenCCG. Furthermore, an RKR structure specifies exactly the information that has to be presented to the user. Beside deriving the appropriate input for NLG, the turn planner is also responsible for computing and packaging the appropriate information to be presented by the display. Additionally, if there are alternatives on how to graphically realize content in different ways the turn planner needs to decide which one to take.

3.4 Spoken Natural Language Output Generation

Our goal is to produce output that varies in the surface realization form and is adapted to the context. We opted for using both a template-based and a deep grammar-based module in parallel. On the one hand, deep generation provides linguistically more powerful modeling, in particular it allows for more fine-grained and controlled choices between linguistic expressions in order to achieve contextually appropriate output. On the other hand, the template-based module can be developed faster and thus facilitates incremental development. It is also sufficient for classes of system output that do not need fine-tuned context-driven variation, such as simple cases of feedback. Our template-based generator can also deliver alternative realizations, e.g., alternative syntactic constructions *There are 3 songs by Nena* vs. *I found 3 songs by Nena*, referring expressions *Nena* vs. *the artist Nena*, or lexical items, e.g., *song* vs. *track*; however, the choice among alternative templates is made at random. The template-based generator is implemented by a set of straightforward sentence planning rules in the PATE system to build the templates, and a set of XSLT transformations to yield the output strings. Output in German and English is produced by accessing different dictionaries in a uniform way.

The grammar-based generator uses OpenCCG, an open-source natural language processing environment[3]. We have developed a

⁹ Note, that for points (2) and (3) we haven't yet fully elaborated the rule based processing of these factors as this part of our ongoing work.

German OpenCCG grammar with basic coverage of German phenomena, and gradually extend it with respect to the phenomena encountered in the SAMMIE-1 and SAMMIE-2 corpora (see section 4).

3.5 Modeling with an Ontology

We use a full model of the application in OWL¹⁰ format as the knowledge representation format in the dialogue manager, turn planner and sentence planner. This model includes the entities, properties and relations of the MP3 domain—including the player, data base and playlists. Also, all possible tasks that the user may perform are modeled explicitly. Note that this is a model that is *user centered* and not simply a model of the application’s API. Actually, there is a separate module, the MP3-shield, that maps user tasks into possibly complex interactions with the connected applications, i.e., the database and the MP3 player itself.

The OWL-based model is transformed automatically to the internal format used in the PATE rule-interpreter. PATE employs Typed Feature Structures (TFSs) as basic internal data representation and XML for encoding all incoming and outgoing data as well as knowledge bases (production rules, type definitions). PATE is based on some concepts of the ACT-R 4.0 system [2]. Its main concepts, which PATE makes use of, are the goal-oriented application of production rules, the activation of working memory elements, and the weighting of production rules. In processing TFSs, PATE provides two operations that both integrate data and also are suitable for condition matching in production rule systems, namely a slightly extended version of the general *unification*, but also the discourse-oriented operation *overlay* [1].

Another important feature is the concept of multiple inheritance provided by the type system, as it allows to define different views on ontological concepts. Consider the concept *Song* and the different views our system ontology provides. A *Song* can be seen as a *Browsable-object* which allows generalization within the turn planning library over objects a user can browse. It can also be seen as a *Media-object* or a *Problem-solving-object* which are abstract concepts dialogue management can use for planning and execution. Or it can be seen as a *Mp3-resource* which denotes the domain affiliation of the concept. Thereby PATE provides an efficient and elegant way to create more abstract/generic presentation planning rules.

4 Experiments and Evaluation

To guide system development we have so far conducted two WOZ *data collection* experiments and one *evaluation* experiment with a baseline version of our system. The SAMMIE-1 WOZ experiment involved only spoken interaction, SAMMIE-2 was multimodal, with speech and haptic input, and the subjects had to perform a primary driving task using a Lane Change simulator [8] in a half of the experiment session. The wizard was simulating an MP3 player application with access to a large database of information (but not actual music) of more than 150,000 music albums (almost 1 million songs). The user had to carry out several tasks of two types: searching for a title either in the database or in an existing playlist, and building a playlist satisfying a number of constraints. In order to collect data with a variety of interaction strategies, we used multiple wizards and gave them freedom to decide about their response and its realization. In the multimodal setup in SAMMIE-2, the wizards could also freely decide between mono-modal and multimodal output. There is not

enough time for the wizard to properly design the screen output on the fly. Therefore, we implemented modules supporting the wizard by providing several automatically generated screen output options the wizard could select from and inform the user about the database search results using the visual modality.

The following aspects of the setup were designed to elicit interactions more realistically resembling dialogue with an actual system [6]: The wizard and the user did not directly hear each other, instead, their utterances were immediately transcribed; the wizard’s utterances were then presented to the user via a speech synthesizer, and parts of the user’s utterances were sometimes deleted to simulate acoustic understanding problems and elicit clarifications.

Figure 3. The current setup of the user environment.

To explore the user acceptance, usability, and performance of a first baseline implementation of the SAMMIE multimodal dialogue system we have completed a usability evaluation. The evaluation tested the multimodal interaction of first-time users with the SAMMIE system in a laboratory experiment with a simulated driving task (figure 3 shows the setup). A sample of 20 subjects performed 32 tasks in total out of three scenarios with variation of the different kinds of dialogue modalities (spoken vs. multimodal). The users were asked to perform tasks which tested the system functionality, namely controlling player functions like stop/play/pause, next/previous track, playing a particular/random song/album/playlist, querying the music database (e.g., available songs/albums/artists/playlists) and administration of playlists (create/delete playlists, add/remove songs).

The evaluation analyzed the user’s interaction with the baseline system and combined objective measurements like task completion and speech recognition accuracy observed in the experiments and subjective ratings from the test subjects by means of intermediate interviews during the session and by post-experimental questionnaires. The analysis of the experiments yielded an overall task completion rate (TCR) of about 90% for both spoken and multimodal interaction. Note that we allow up to four repeats for a user input. Relatively small differences in TCR between the dialogue modalities but considerable decrease of TCR for the more complex tasks have been observed. This was partly due to a relatively high out-of-grammar rate and consequently word error rate which showed the need to further increase the ASR grammar coverage.

Spoken dialogue was observed as the preferred interaction modality in the experiments. About 70% of the subjects chose speech when they had the free choice and less than 10% changed the modality during the task. Nevertheless, 40% of all subjects would prefer multimodal interaction in the long run when having more practice with the system. The general impression of the SAMMIE system was rated positively by most of the test subjects and changing the interaction modality was simple or very simple for 95% of the users. Also, the content and extent of the system’s spoken and graphical output messages were rated mostly positively. But a detailed analysis of the ob-

¹⁰ <http://www.w3.org/TR/owl-features>

jective measurements and subjective ratings also revealed some important issues for significant improvement towards the final version of the SAMMIE system.

The following section reflects some of the lessons learned from this evaluation.

5 Lessons Learned

To summarize the current state of our research and development, this section attempts to present the most important lessons learned to date and the biggest challenges for AI in the domain of natural, intuitive multimodal interaction.

- Reliable and robust ASR: When the system does not recognize the user's utterance, the biggest challenge for the user and the system is to know what went wrong. We are addressing this on two fronts: SAMMIE tries to give feedback about partially understood utterances with appropriate clarification requests. Also, we are using the data collection to expand the language covered by the recognition grammars.
- Natural and understandable speech synthesis: We have used the multilingual capabilities of the Mary TTS [11] to pronounce English song titles correctly, even when embedded in a German utterance. Also, markup of the speech output should allow context dependent prosodic cues such as pauses around elements to be clarified. To address users' demands, we need to increase the naturalness and acoustic quality of the TTS.
- System responsiveness: For command and control type interaction, e.g., stopping the MP3 player, time delays should be in the millisecond range. Thus we have added shortcuts directly from speech recognition to the player application, such that the full dialogue system is updated only in parallel or later. However, the context model must be kept synchronized with the course of the dialogue. Overall, reaction times (for complex input) have to be improved to satisfy the requirements of in-car systems.
- Close to real time system feedback: early on, we have added a multimodal microphone state, signaling to the user whether the system is ready and listening or currently processing input. The microphone shown on the GUI (see figure 1) toggles between red and green, accompanied by characteristic acoustic signals.
- Speech-centered multimodality: The evaluation confirmed that speech is the most important modality for our system, however the graphical and haptic modalities were used and valued by users. Since driving as the primary task leaves fewer and sometimes little attention (in particular, visual attention) for interacting with the SAMMIE system, turn planning must assure that core information is conveyed in speech and only additional information is presented on the display. Such additional information must also be accessible through spoken interaction.
- Adaptive, context-sensitive presentation: Natural, intuitive, multimodal interaction can be achieved through true mixed-initiative, collaborative interaction. Our system dynamically adapts its next move to give "intelligent" replies that (i) make the system's understanding transparent and (ii) ask for clarification when necessary and (iii) query for more information by dynamically determining the most informative type of information, e.g. album name rather than artist name¹¹.

The last point represents the ultimate goal of our work: optimize all the above issues in the context of a flexible dialogue paradigm

(Extended Information State Update) to achieve natural and intuitive multimodal interaction.

6 Conclusion

We presented an in-car multimodal dialogue system for an MP3 application developed in the TALK project in cooperation between several academic and industrial partners. The system employs the Information State Update paradigm, extended to model collaborative problem solving and multimodal context. It supports natural, intuitive mixed-initiative interaction, with particular emphasis on multimodal turn-planning and natural language generation to produce output adapted to the context, including the driver's attention state with respect to the primary driving task. We performed extensive user studies in a WOZ setup to guide the system design. A formal usability evaluation of the system's baseline version in a simulated environment has been carried out with overall positive results. A further enhanced version of the system will be integrated and evaluated in a test car, demonstrating the successful transfer of a range of AI techniques towards a real world application.

A Client/Server User-Based Collaborative Filtering Algorithm: Model and Implementation

CASTAGNOS Sylvain and BOYER Anne¹

Abstract. This paper describes a new way of implementing an intelligent web caching service, based on an analysis of usage. Since the cache size in software is limited, and the search for new information is time-consuming, it becomes interesting to automate the process of selecting the most relevant items for each user. We propose a new generic model based on a client/server collaborative filtering algorithm and a behavior modeling process. In order to highlight the benefits of our solution, we collaborated with a company called ASTRA which is specialized in satellite website broadcasting. ASTRA has finalized a system sponsored by advertisement and supplying to users a high bandwidth access to hundreds of websites for free. Our work has been implemented within its software architecture and, in particular, within its recommender system in order to improve the satisfaction of users. Our solution is particularly designed to address the issues of data sparsity, privacy and scalability. Because of the industrial context, we consider the situation where the set of users is relatively stable, whereas the set of items may vary considerably from an execution to another. In addition to the model and its implementation, we present a performance assessment of our technique in terms of computation time and prediction relevancy.

1 INTRODUCTION

With the development of information and communication technologies, the size of information systems all over the world has exponentially increased. This causes at least two problems. First, it becomes difficult for users to identify interesting items in a reasonable time, even if they use a powerful search engine. Secondly, the amount of available data is now much more important than the cache size of some industrial applications on client side. We can quote the examples of strategic awareness tools in big companies or the satellite data transfers. In this paper, we propose a generic collaborative filtering model to cope with these problems. Our approach is suitable for client/server architectures. We designed it to address three main difficulties inherent in an industrial context: the recommender system scalability, the user privacy and the data sparsity.

We implemented our work in the context of satellite website broadcasting. Thus, we run our model in the architecture of Casablanca, which is a product of the ASTRA company². ASTRA conceived a service of satellite website broadcasting service called Sat@once. This service is sponsored by advertisement so that it is free for users, provided that they use a DVB receiver. The satellite bouquet holds 150 websites which are sent to about 120.000 persons through a high-bandwidth and one-way transmission. More-

over, users can inform the server about their preferences by using a standard internet connection. Initially, they only could send the non-numerical votes which appear as a list of favorite websites. Once a week, the preferences of all users are used to make up the bouquet with the most popular websites. Because of this industrial context, we consider the situation where users are relatively stable, whereas the set of items may vary considerably from an execution to another. In addition to the research constraints, we also had to be compliant with the Casablanca architecture and the ASTRA business model.

The next section is dedicated to a short state-of-the-art about collaborative filtering techniques. Afterwards, we will present our model and its implementation in a satellite website broadcasting software. The fourth part offers an evaluation of our algorithm, both in terms of computation time and relevancy recommendations. At last, we will highlight the benefits of this decentralized architecture.

2 RELATED WORK

BREESE *et al* [3] have identified, among existing techniques, two major classes of algorithms to solve this problem : the memory-based and the model-based algorithms.

The memory-based algorithms maintain a database containing votes of all users. A similarity score (RENNICK [9], MAES [11] or BREESE [3]) is determined between active user and each of the others members. Then, each prediction leads to a computation on all of this source of data. The influence of a person is all the stronger in it since his/her degree of similarity with the active user is great.

These memory-based techniques offer the advantage to be very reactive, by integrating immediately modifications of users profiles into the system. However, BREESE *et al* [3] are unanimous in thinking that their scalability is problematic: even if these methods work well with small-sized example, it is difficult to change to situations characterized by a great number of documents or users. Indeed, time and space complexities of algorithms are much too important for big databases.

The model-based algorithms constitute an alternative to the problem of combinatorial complexity. In this approach, collaborative filtering can be seen as the computation of the expected value of a vote, according to preferences of active user. These algorithms create descriptive models correlating persons, resources and associated votes via a learning process. Then, predictions are inferred from these models. The item-item algorithm [10] belongs, among others, to this family. UNGAR and FOSTER [12] have also imagined the possibility to classify users and resources in groups. So, for each category of users, we must estimate the probability that a resource could be chosen.

According to PENNOCK *et al* [8], model-based algorithms minimize the problem of algorithmic time complexity. Furthermore, they

perceive in these models an added value beyond the only function of prediction: they highlight some correlations in data, proposing by that way an intuitive reasoning for recommendations or making simply the hypotheses more explicit. However, these methods are not enough dynamic and they react badly to insertion of new contents in database. Moreover, they require a learning phase at the same time penalizing for the user³ and expensive in computation time for large databases.

Consequently, one of the main difficulty of collaborative filtering remains the scalability of systems. The model proposed in this article is an hybrid approach, combining advantages of memory-based and model-based methods to distribute the computations between the server and the clients.
