

ECAI 2006

Frontiers in Artificial Intelligence and Applications

FAIA covers all aspects of theoretical and applied artificial intelligence research in the form of monographs, doctoral dissertations, textbooks, handbooks and proceedings volumes. The FAIA series contains several sub-series, including "Information Modelling and Knowledge Bases" and "Knowledge-Based Intelligent Engineering Systems". It also includes the biannual ECAI, the European Conference on Artificial Intelligence, proceedings volumes, and other ECCAI – the European Coordinating Committee on Artificial Intelligence – sponsored publications. An editorial panel of internationally well-known scholars is appointed to provide a high quality selection.

Series Editors:

J. Breuker, R. Dieng, N. Guarino, J.N. Kok, J. Liu, R. López de Mántaras,
R. Mizoguchi, M. Musen and N. Zhong

Volume 141

Preface

In the summer of 1956, John McCarthy organized the famous Dartmouth Conference which is now commonly viewed as the founding event for the field of Artificial Intelligence. During the last 50 years, AI has seen a tremendous development and is now a well-established scientific discipline all over the world. Also in Europe AI is in excellent shape, as witnessed by the large number of high quality submissions we received. About 600 papers and posters were registered for ECAI-06, out of which 550 were actually reviewed (501 paper submissions and 49 poster submissions). The program committee decided to accept 131 full papers, which amounts to an acceptance rate of 26.1%, and 75 posters (authors of full papers had the possibility to opt for acceptance as poster in case of rejectance as full paper).

We received submissions from 43 different countries, and accepted papers from 25 countries. The following table shows the number of submissions and accepted papers per country, based on the contact author affiliation:

Algeria	5	0	Greece	15	4	Romania	4	1
Australia	19	9	Hungary	1	0	Russia	3	0
Austria	9	5	India	1	0	Singapore	4	4
Belgium	4	2	Iran	5	1	Spain	32	5
Brazil	12	0	Ireland	14	9	Slovenia	2	2
Bulgaria	1	0	Israel	8	2	Slovakia	3	3
Canada	13	4	Italy	83	36	Sweden	5	5
China	4	0	Japan	9	1	Switzerland	5	3
Cyprus	1	0	Luxemburg	5	3	Thailand	2	0
Czechia	4	0	Mexico	2	0	Turkey	3	0
Egypt	1	0	Netherlands	26	12	UK	49	22
Estonia	2	0	New Zealand	3	0	USA	22	5
France	111	46	Pakistan	1	0	Venezuela	1	1
Finland	3	2	Poland	3	0			
Germany	47	19	Portugal	1	0			

It is also interesting to look at the areas of the submitted and accepted papers/posters. We show both absolute numbers and percentage. The area information is based on the first two key words chosen by the authors:

	# submitted	%	# accepted	%
Case-Based Reasoning	10.5	1.9	0.5	0.2
Cognitive Modelling	33.5	6.1	13	6.3
Constraints & Search	54.5	10.0	26	12.6
Distributed AI/Agents	107	19.6	36.5	17.7
KR & Reasoning	141.5	25.9	55.5	26.9
Machine Learning	83	15.2	29	14.1
Model-Based Reasoning	32	5.9	8	3.9
Natural Language	21.5	3.9	7.5	3.6
Perception/Vision	6	1.1	2	1.0
Planning and Scheduling	27	4.9	12	5.8
Robotics	12.5	2.3	5	2.4
PAIS	18	3.3	11	5.3

In comparison with ECAI 2004, we see a strong increase in the relative number of submissions from Distributed AI/Agents and Cognitive Modelling. Knowledge Representation & Reasoning is traditionally strong in Europe and remains the biggest area of ECAI-06. One reason the figures for Case-Based Reasoning are rather low is that much of the high quality work in this area has found its way into prestigious applications and is thus represented under the heading of PAIS.

The ECAI-06 best paper award, sponsored by Elsevier, goes to a machine learning paper:

A Real Generalization of Discrete AdaBoost, by Richard Nock and Frank Nielsen

Congratulations! The best poster award, sponsored by IOS Press, will be decided after the poster sessions in Riva. The 10 best papers are invited to a fast track of the Artificial Intelligence Journal.

A conference of the size of ECAI needs a lot of support from many people. At this point we would like to thank all those who helped to make ECAI-06 a tremendous success: the poster, workshop, PAIS and area chairs faced a heavy workload and they all did an excellent job. The PC members and additional reviewers came up with timely, high quality reviews and made the life of the PC chair as easy as it can be. Thanks also to Alex Nittka who ran the conference management software, to the PC chair's great relief. We also want to thank the many people involved in the local organization of the conference: there would be no conference without you.

Our very special thanks go to a person who is no longer with us. Rob Milne, chair of ECAI-06 until he died of a heart attack close to the summit of Mount Everest on June 5th, 2005. He shaped this conference from the beginning, and we did our best to organize ECAI-06 in his spirit.

Preface	xiii

Gerhard Brewka, Silvia Coradeschi, Anna Perini and Paolo Traverso

I. Invited Talks

Socially Intelligent Robots <i>Cynthia Breazeal</i>	3
Managing Diversity in Knowledge <i>Fausto Giunchiglia</i>	4
The Truth About Defaults <i>Hector Levesque</i>	5
SmartWeb: Getting Answers on the Go <i>Wolfgang Wahlster</i>	6

II. Papers

1. Cognitive Modelling

Background Default Knowledge and Causality Ascriptions <i>Jean-François Bonnefon, Rui Da Silva Neves, Didier Dubois and Henri Prade</i>	11
Comparing Sets of Positive and Negative Arguments: Empirical Assessment of Seven Qualitative Rules <i>Jean-François Bonnefon and Hélène Fargier</i>	16
A Similarity and Fuzzy Logic-Based Approach to Cerebral Categorisation <i>Julien Erny, Josette Pastor and Henri Prade</i>	21
Imitation of Intentional Behaviour <i>Bart Jansen</i>	26
Dramatization Meets Narrative Presentations <i>Rossana Damiano, Vincenzo Lombardo, Antonio Pizzo and Fabrizio Nunnari</i>	31
MAMA: An Architecture for Interactive Musical Agents <i>David Murray-Rust, Alan Smaill and Michael Edwards</i>	36
Bayesian Modelling of Colour's Usage Impact to Web Credibility <i>Eleftherios Papachristos, Nikolaos Tselios and Nikolaos Avouris</i>	41
Evaluating Perception of Interaction Initiation in Virtual Environments Using Humanoid Agents <i>Christopher Peters</i>	46
Cognitive Situated Agents Learn to Name Actions <i>Julien Poudade, Lionel Landwerlin and Patrick Paroubek</i>	51

Tracking the Lexical *Zeitgeist* with WordNet and Wikipedia*Tony Veale*

56

2. Constraints and Search

Enhancing Constraints Manipulation in Semiring-Based Formalisms <i>Stefano Bistarelli and Fabio Gadducci</i>	63
Evaluating ASP and Commercial Solvers on the CSPLib <i>Marco Cadoli, Toni Mancini, Davide Micaletto and Fabio Patrizi</i>	68
Automatic Generation of Implied Constraints <i>John Charnley, Simon Colton and Ian Miguel</i>	73
Maintaining Generalized Arc Consistency on Ad-Hoc n -Ary Boolean Constraints <i>Kenil C.K. Cheng and Roland H.C. Yap</i>	78
A Study on the Short-Term Prohibition Mechanisms in Tabu Search <i>Luca Di Gaspero, Marco Chiarandini and Andrea Schaerf</i>	83
Random Subset Optimization <i>Boi Faltings and Quang-Huy Nguyen</i>	88
Search for Compromise Solutions in Multiobjective State Space Graphs <i>Lucie Galand and Patrice Perny</i>	93
MINION: A Fast Scalable Constraint Solver <i>Ian P. Gent, Chris Jefferson and Ian Miguel</i>	98
Asynchronous Forward-Bounding for Distributed Constraints Optimization <i>Amir Gershman, Amnon Meisels and Roie Zivan</i>	103
Distributed Log-Based Reconciliation <i>Yek Loong Chong and Youssef Hamadi</i>	108
Extracting MUCs from Constraint Networks <i>Fred Hemery, Christophe Lecoutre, Lakhdar Sais and Frédéric Boussemart</i>	113
Preference-Based Inconsistency Proving: When the Failure of the Best Is Sufficient <i>Ulrich Junker</i>	118
Return of the JTMS: Preferences Orchestrate Conflict Learning and Solution Synthesis <i>Ulrich Junker and Olivier Lhomme</i>	123
Multi-Objective Propagation in Constraint Programming <i>Emma Rollon and Javier Larrosa</i>	128
Last Conflict Based Reasoning <i>Christophe Lecoutre, Lakhdar Sais, Sébastien Tabary and Vincent Vidal</i>	133
Dynamic Orderings for AND/OR Branch-and-Bound Search in Graphical Models <i>Radu Marinescu and Rina Dechter</i>	138
Compact Representation of Sets of Binary Constraints <i>Jussi Rintanen</i>	143
Pessimistic Heuristics Beat Optimistic Ones in Real-Time Search <i>Aleksander Sadikov and Ivan Bratko</i>	148

Inverse Consistencies for Non-Binary Constraints <i>Kostas Stergiou and Toby Walsh</i>	153
Guiding Search Using Constraint-Level Advice <i>Radoslaw Szymanek and Barry O'Sullivan</i>	158
Beyond Singleton Arc Consistency <i>Marc van Dongen</i>	163
Symmetry Breaking Using Value Precedence <i>Toby Walsh</i>	168
3. Distributed AI/Agents	
Coordination Through Inductive Meaning Negotiation <i>Alessandro Agostini</i>	175
Reaching Agreements for Coalition Formation Through Derivation of Agents' Intentions <i>Samir Aknine and Onn Shehory</i>	180
Cheating Is Not Playing: <i>Methodological Issues of Computational Game Theory</i> <i>Bruno Beaujalis and Philippe Mathieu</i>	185
Mediation in the Framework of Morpho-Logic <i>Isabelle Bloch, Ramón Pino-Pérez and Carlos Uzcátegui</i>	190
Strengthening Admissible Coalitions <i>Guido Boella, Luigi Sauro and Leendert van der Torre</i>	195
Advanced Policy Explanations on the Web <i>Piero Bonatti, Daniel Olmedilla and Joachim Peer</i>	200
Prevention of Harmful Behaviors Within Cognitive and Autonomous Agents <i>Caroline Chopinaud, Amal El Fallah Seghrouchni and Patrick Taillibert</i>	205
Coalition Structure Generation in Task-Based Settings <i>Viet Dung Dang and Nicholas R. Jennings</i>	210
Programming Agents with Emotions <i>Mehdi Dastani and John-Jules Ch. Meyer</i>	215
Goal Types in Agent Programming <i>Mehdi Dastani, M. Birna van Riemsdijk and John-Jules Ch. Meyer</i>	220
Alternating-Offers Bargaining Under One-Sided Uncertainty on Deadlines <i>Francesco Di Giunta and Nicola Gatti</i>	225
A Logic-Based Framework to Compute Pareto Agreements in One-Shot Bilateral Negotiation <i>Azzurra Ragone, Tommaso Di Noia, Eugenio Di Sciascio and Francesco M. Donini</i>	230
Towards ACL Semantics Based on Commitments and Penalties <i>Leila Amgoud and Florence Dupin de Saint-Cyr</i>	235
Computational Opinions <i>Felix Fischer and Matthias Nickles</i>	240
A New Semantics for the FIPA Agent Communication Language Based on Social Attitudes <i>Benoit Gaudou, Andreas Herzig, Dominique Longin and Matthias Nickles</i>	245

Contouring of Knowledge for Intelligent Searching for Arguments <i>Anthony Hunter</i>	250
On the Inability of Gathering by Asynchronous Mobile Robots with Initial Movements <i>Branislav Katreňák and Jana Katreňáková</i>	255
Testing the Limits of Emergent Behavior in MAS Using Learning of Cooperative Behavior <i>Jordan Kidney and Jörg Denzinger</i>	260
Boolean Games Revisited <i>Elise Bonzon, Marie-Christine Lagasquie-Schiex, Jérôme Lang and Bruno Zanuttini</i>	265
An Automated Agent for Bilateral Negotiation with Bounded Rational Agents with Incomplete Information <i>Raz Lin, Sarit Kraus, Jonathan Wilkenfeld and James Barry</i>	270
Self-Organizing Multiagent Approach to Optimization in Positioning Problems <i>Sana Moujahed, Olivier Simonin, Abderrafiâ Koukam and Khaled Ghédira</i>	275
Arguing with Confidential Information <i>Nir Oren, Timothy J. Norman and Alun Preece</i>	280
Auction Mechanisms for Efficient Advertisement Selection on Public Displays <i>Terry Payne, Ester David, Nicholas R. Jennings and Matthew Sharifi</i>	285
Verifying Interlevel Relations Within Multi-Agent Systems <i>Alexei Sharpanskykh and Jan Treur</i>	290
Flexible Provisioning of Service Workflows <i>Sebastian Stein, Nicholas R. Jennings and Terry R. Payne</i>	295
Heuristic Bidding Strategies for Multiple Heterogeneous Auctions <i>David C.K. Yuen, Andrew Byde and Nicholas R. Jennings</i>	300
Are Parallel BDI Agents Really Better? <i>Huiliang Zhang and Shell Ying Huang</i>	305
Dynamic Control of Intention Priorities of Human-Like Agents <i>Huiliang Zhang and Shell Ying Huang</i>	310

4. Knowledge Representation and Reasoning

Knowing Minimum/Maximum n Formulae <i>Thomas Ågotnes and Natasha Alechina</i>	317
Modal Logics for Communicating Rule-Based Agents <i>Natasha Alechina, Mark Jago and Brian Logan</i>	322
Causation as Production <i>John Bell</i>	327

Socially Intelligent Robots

Cynthia Breazeal, MIT Media Lab, MA, USA

No longer restricted to the factory floor or hazardous environments, autonomous robots are making their way into human environments. Although current commercial examples of domestic robots are more akin to toys, smart appliances, or supervised tools, the need to help ordinary people as capable partners and interact with them in a socially appropriate manner poses new challenges and opens new opportunities for robot applications in the home, office, school, entertainment locales, healthcare institutions, and more. Many of these applications require robots to play a long-term role in people's daily lives.

Developing robots with social and emotional intelligence is a critical step towards enabling them to be intelligent and capable in their interactions with humans, intuitive to communicate with people, able to work cooperatively with people, and able to learn quickly and effectively from natural human instruction.

This talk presents recent progress in these areas and outlines several “grand challenge” problems of social robotics. Specific research projects and applications are highlighted to illustrate how robots with social capabilities are being developed to learn, assist, entertain, or otherwise benefit their human counterparts.

Managing Diversity in Knowledge

Fausto Giunchiglia, Università di Trento, Italy

We are facing an unforeseen growth of the complexity of (data, content and) knowledge. Here we talk of complexity meaning the size, the sheer numbers, the spatial and temporal pervasiveness of knowledge, and the unpredictable dynamics of knowledge change, unknown at design time but also at run time. The obvious example is the Web and all the material, also multimedia, which is continuously made available on line.

Our goal in this talk is to propose a novel approach which deals with this level of complexity and that, hopefully, will overcome some of the scalability issues shown by the existing data and knowledge representation technology. The key idea is to propose a bottom-up approach where diversity is considered as a feature which must be maintained and exploited and not as a defect that must be absorbed in some general schema. The proposed solution amounts to making a paradigm shift from the view where knowledge is mainly assembled by combining basic building blocks to a view where new knowledge is obtained by the design or run-time adaptation of existing knowledge.

Typically, we will build knowledge on top of a landscape of existing highly interconnected knowledge parts. Knowledge will no longer be produced ab initio, but more and more as adaptations of other, existing knowledge parts, often performed in runtime as a result of a process of evolution. This process will not always be controlled or planned externally but induced by changes perceived in the environment in which systems are embedded. The challenge is to develop design methods and tools that enable effective design by harnessing, controlling and using the effects of emergent knowledge properties. This leads to the proposal of developing adaptive and, when necessary, self-adaptive knowledge systems and to the proposal of developing a new methodology for knowledge engineering and management, that we call "Managing Diversity in Knowledge by Adaptation".

We will present and discuss the ideas above considering, as an example, the use of ontologies in the formalization of knowledge (for instance in the SemanticWeb).

The Truth about Defaults

Hector Levesque, University of Toronto, Canada

Virtually all of the work on defaults in AI has concentrated on default reasoning: given a theory T containing facts and defaults of some sort, we study how an ideal agent should reason with T , typically in terms of constructs like fixpoints, or partial orders, or nonmonotonic entailment relationships.

In this talk, we investigate a different question: under what conditions should we consider the theory T to be true, or believed to be true, or all that is believed to be true? By building on truth in this way, we end up with a logic of defaults that is classical, that is, a logic with an ordinary monotonic notion of entailment. And yet default reasoning emerges naturally from these ideas.

We will show how to characterize the default logic of Reiter and the autoepistemic logic of Moore in purely truth-theoretic terms. We will see that the variant proposed by Konolige is in fact a link between the two, and that all three fit comfortably within a single logical language, that we call O3L. Finally, we will present first steps towards a proof theory (with axioms and rules of inference) for O3L. Among other things, this allows us to present ordinary sentence-by-sentence derivations that correspond to different sorts of default reasoning.

This is joint work with Gerhard Lakemeyer.

SmartWeb: Getting Answers on the Go

Wolfgang Wahlster, Universität des Saarlandes - DFKI, Saarbrücken, Germany

The appeal of being able to ask a spoken question to a mobile internet terminal and receive an audible answer immediately has been renewed by the broad availability of always-on Web access, which allows users to carry the internet in their pockets. Ideally, a multimodal dialogue system that uses the Web as its knowledge base would be able to answer a broad range of spoken questions. Practically, the size and dynamic nature of the Web and the fact that the content of most web pages is encoded in natural language makes this an extremely difficult task.

Recent progress in semantic web technology is enabling innovative open-domain question answering engines that use the entire Web as their knowledge base and offer much higher retrieval precision than current web search engines. Our SmartWeb system is based on the fortunate confluence of three major research efforts that have the potential of forming the basis for the next generation of Web-based answer engines. The first effort is the semantic Web, which provides the formalisms, tools and ontologies for the explicit markup of the content of Web pages; the second effort is the development of semantic Web services, which results in a Web where programs act as autonomous agents to become the producers and consumers of information and enable automation of transactions. The third important effort is information extraction from huge volumes of rich text corpora available on the web exploiting language technology and machine learning.

SmartWeb provides a context-aware user interface, so that it can support the mobile user in different roles, e.g. as a car driver, a motor biker, a pedestrian or a sports spectator. One of the demonstrators of SmartWeb is a personal guide for the 2006 FIFA world cup in Germany, that provides mobile infotainment services to soccer fans, anywhere and anytime.

This talk presents the anatomy of SmartWeb and explains the distinguishing features of its multimodal interface and its answer engine. In addition, the talk gives an outlook on the French-German mega project Quaero and its relation to SmartWeb.

Background default knowledge and causality ascriptions

Jean-François Bonnefon and Rui Da Silva Neves¹ and Didier Dubois and Henri Prade²

Abstract. A model is defined that predicts an agent's ascriptions of causality (and related notions of facilitation and justification) between two events in a chain, based on background knowledge about the normal course of the world. Background knowledge is represented by nonmonotonic consequence relations. This enables the model to handle situations of poor information, where background knowledge is not accurate enough to be represented in, e.g., structural equations. Tentative properties of causality ascriptions are explored, i.e., preference for abnormal factors, transitivity, coherence with logical entailment, and stability with respect to disjunction and conjunction. Empirical data are reported to support the psychological plausibility of our basic definitions.

1 INTRODUCTION

Models of causal ascriptions crucially depend on the choice of an underlying representation for the causality-ascribing agent's knowledge. Unlike standard diagnosis problems (wherein an unobserved cause must be inferred from observed events and known causal links), causality ascription is a problem of describing as 'causal' the link between two observed events in a sequence. The first step in modeling causal ascription is to define causality in the language chosen for the underlying representation of knowledge. In this article, we define and discuss a model of causal ascription that represents knowledge by means of nonmonotonic consequence relations.³ Indeed, agents often must cope with poor knowledge about the world, under the form of default rules. Clearly, this type of background knowledge is less accurate than, e.g., structural equations. It is nevertheless appropriate to predict causal ascriptions in situations of restricted knowledge. Section 2 presents the logical language we will use to represent background knowledge. Section 3 defines our main notions of causality and facilitation ascriptions. Empirical data are reported to support the distinction between these two notions. Section 4 establishes some formal properties of the model. Section 5 distinguishes the notion of epistemic justification from that of causality. Section 6 relates our model to other works on causality in AI.

2 MODELING BACKGROUND KNOWLEDGE

The agent is supposed to have observed or learned of a sequence of events, e.g.: $\neg B_t, A_t, B_{t+1}$. This expresses that B was false at time t , when A took place, and that B became true afterwards ($t + 1$ denotes a time point after t). There is no uncertainty about these events.

Besides, the agent maintains a knowledge-base made of conditional statements of the form 'in context C , if A takes place then B '

¹ LTC-CNRS and DSVP, respectively, 5 allées A. Machado 31058 Toulouse Cedex 9, France. E-mail: {bonnefon,neves}@univ-tlse2.fr.

² IRIT-CNRS, 118 Route de Narbonne, 31062 Toulouse Cedex, France. E-mail: {dubois,prade}@irit.fr

³ This model was advocated in a recent workshop paper [9].

is generally true afterwards', or 'in context C , B is generally true'. These will be denoted by $A_t \wedge C_t \succsim B_{t+1}$, and by $C_t \succsim B_t$, respectively. (Time indices will be omitted when there is no risk of confusion.) The conditional beliefs of an agent with respect to B when an action A takes place or not in context C can take three forms: (i) If A takes place B is generally true afterwards: $A_t \wedge C_t \succsim B_{t+1}$; (ii) If A takes place B is generally false afterwards: $A_t \wedge C_t \succsim \neg B_{t+1}$; (iii) If A takes place, one cannot say whether B is generally true or false afterwards: $A_t \wedge C_t \not\succsim B_{t+1}$ and $A_t \wedge C_t \not\succsim \neg B_{t+1}$.

We assume that the nonmonotonic consequence relation \succsim satisfies the requirements of 'System P' [18]; namely, \succsim is reflexive and the following postulates and characteristic properties hold (\models denotes classical logical entailment):

<i>Left Equivalence</i>	$E \succsim G$ and $E \equiv F$	imply	$F \succsim G$
<i>Right Weakening</i>	$E \succsim F$ and $F \models G$	imply	$E \succsim G$
<i>AND</i>	$E \succsim F$ and $E \succsim G$	imply	$E \succsim F \wedge G$
<i>OR</i>	$E \succsim G$ and $F \succsim G$	imply	$E \vee F \succsim G$
<i>Cautious Monotony</i>	$E \succsim F$ and $E \succsim G$	imply	$E \wedge F \succsim G$
<i>Cut</i>	$E \succsim F$ and $E \wedge F \succsim G$	imply	$E \succsim G$

In addition, we assume $\not\succsim$ to obey the property of Rational Monotony, a strong version of Cautious Monotony[19]:

$$\text{Rational Monotony} \quad E \not\succsim \neg F \text{ and } E \succsim G \quad \text{imply} \quad E \wedge F \succsim G$$

Empirical studies repeatedly demonstrated [1, 2, 5, 10, 24] that System P and Rational Monotony provide a psychologically plausible representation of background knowledge and default inference. Arguments for using nonmonotonic logics in modeling causal reasoning were also discussed in the cognitive science literature [26].

3 ASCRIBING CAUSALITY OR FACILITATION

In the following definitions, A , B , C , and F are either reported actions or statements describing states of affairs, even though notations do not discriminate between them, since the distinction does not yet play a crucial role in the model. When nothing takes place, the persistence of the truth status of statements is assumed in the normal course of things, i.e., $B_t \succsim B_{t+1}$ and $\neg B_t \succsim \neg B_{t+1}$.

Assume that in a given context C , the occurrence of event B is known to be exceptional (i.e., $C \succsim \neg B$). Assume now that F and A are such that $F \wedge A \not\succsim \neg B$ on the one hand, and $A \wedge F \wedge C \succsim B$ on the other hand; we will say that in context C , A together with F are perceived as the *cause* of B (denoted $C : A \wedge F \Rightarrow_{ca} B$), while F alone is merely perceived to have *facilitated* the occurrence of B (denoted $C : F \Rightarrow_{fa} B$).

Definition 1 (Facilitation ascription). An agent that, in context C , learns of the sequence $\neg B_t, F_t, B_{t+1}$ will judge that $C : F \Rightarrow_{fa} B$ if it believes that $C \succsim \neg B$, and that both $F \wedge A \not\succsim \neg B$ and $F \wedge C \not\succsim \neg B$.

Definition 2 (Causality ascription). An agent that, in context C , learns of the sequence $\neg B_t, A_t, B_{t+1}$ will judge that $C : A \Rightarrow_{ca} B$ if it believes that $C \vdash \neg B$, and $A \wedge C \vdash B$.

Example 1 (Driving while intoxicated). When driving, one has generally no accident, $Drive \vdash \neg Accident$. This is no longer true when driving while drunk, which is not as safe, $Drive \wedge Drunk \not\vdash \neg Accident$; moreover, fast driving while drunk will normally lead to an accident, $Drive \wedge Fast \wedge Drunk \vdash Accident$. Suppose now that an accident took place after the driver drove fast while being drunk. $Fast \wedge Drunk$ will be perceived as the cause of the accident, while $Drunk$ will only be judged as having facilitated the accident.

Note that Def. 1 is weaker than saying F ‘prevents’ $\neg B$ from persisting: $\not\vdash$ does not allow the jump from ‘not having $\neg B$ ’ to ‘ B ’. In Def. 2, the fact that B is exceptional in context C precludes the possibility for C to be the cause of B – but not the possibility that $B \models C$, i.e., that C is a necessary condition of B . Thus, context can be a necessary condition of B without being perceived as its cause.

An interesting situation arises when an agent only knows that $C \vdash \neg B$ and $F \wedge C \not\vdash \neg B$, and learns of the sequence of events $\neg B_t$ (in context C), F_t , B_{t+1} . Although this situation should lead the agent to judge that $C : F_t \Rightarrow_{fa} B_{t+1}$, it may be tempting to judge that $C : F_t \Rightarrow_{ca} B_{t+1}$, as long as no other potential cause reportedly took place. Another interesting situation arises when, in context C , an agent learns of the sequence $\neg B_t, A_t$, and B_{t+1} , while it believes that $\neg B_t \wedge C \vdash \neg B_{t+1}$, and that $A_t \wedge C \vdash \neg B_{t+1}$. Then the agent cannot consider that $C : A_t \Rightarrow_{ca} B_{t+1}$, and it may suspect some fact went unreported: finding about it would amount to a diagnosis problem.

There is no previous empirical support to the distinction we introduce between ascriptions of cause and facilitation. To check whether this distinction has intuitive appeal to lay reasoners, we conducted two experiments in which we presented participants with different sequences of events. We assessed their relevant background knowledge, from which we predicted the relations of cause and facilitation they should ascribe between the events in the sequence. We then compared these predictions to their actual ascriptions.

3.1 Experiment 1

Methods Participants were 46 undergraduate students. None was trained in formal logic or in philosophy. Participants read the stories of three characters, and answered six questions after reading each story. The three characters were described as constantly feeling very tired (an uncommon feeling for them) after two recent changes in their lives: working at night and having a stressful boss (for the first character), working at night and becoming a dad (for the second character), and having a stressful boss and becoming a dad (for the third character). The first three questions assessed participants’ background knowledge with respect to (i) the relation between the first event and feeling constantly tired; (ii) the second event and feeling constantly tired; and (iii) the conjunction of the two events and feeling constantly tired. For example:

What do you think is the most common, the most normal: Working at night and feeling constantly tired, or working at night and not feeling constantly tired? or are those equally common and normal?

Participants who chose the first, second, and third answer were assumed to endorse $WorkNight \vdash Tired$; $WorkNight \vdash \neg Tired$; and $(WorkNight \not\vdash Tired) \wedge (WorkNight \not\vdash \neg Tired)$, respectively. The fourth, fifth, and sixth questions assessed participants’ ascriptions of causality or facilitation between (i) the first event and feeling constantly tired; (ii) the second event and feeling constantly tired; and

(iii) the conjunction of the two events and feeling constantly tired. E.g., one of these questions read:

Fill in the blank with the word ‘caused’ or ‘facilitated’, as seems the most appropriate. If neither seems appropriate, fill in the blank with ‘xxx’: Working at night ... the fact that Julien feels constantly tired.

Results Out of the 116 ascriptions that the model predicted to be of facilitation, 68% indeed were, 11% were of causality, and 21% were neither. Out of the 224 ascriptions that the model predicted to be of causality, 46% indeed were, 52% were of facilitation, and 2% were neither. The global trend in the results is thus that background knowledge that theoretically matches a facilitation ascription indeed largely leads people to make such an ascription, while background knowledge that theoretically matches a causality ascription leads people to divide equally between causality and facilitation ascriptions. This trend is statistically reliable for almost all ascriptions required by the task. Relevant statistics (χ^2 scores) are higher than 7.7 for 7 out of the 9 ascriptions ($p < .05$, one-tailed, in all cases), and higher than 3.2 for the remaining two ascriptions ($p < .10$, one-tailed, in both cases). From these results, it appears that the notion of facilitation does have intuitive appeal to lay reasoners, and that it is broadly used as defined in our model. In particular, it clearly has a role to play in situations where an ascription of causality sounds too strong a conclusion, but no ascription at all sounds too weak.

3.2 Experiment 2

Experiment 2 was designed to consolidate the results of Experiment 1 and to answer the following questions: Does the fact that background knowledge match Def. 1 or Def. 2 affect the strength of the link participants perceive between two reported events, and does this perceived strength in turn determine whether they make an ascription of causality or facilitation?

Methods Participants were 41 undergraduates. Elements of their background knowledge were assessed as in Exp. 1, in order to select triples of propositions $<Context, Factor, Effect>$ that matched either Def. 1 or Def. 2. E.g., a participant might believe that one has generally no accident when driving, but that one will generally have an accident when driving after some serious drinking; for this participant, $<Drive, SeriousDrinking, Accident>$ is a match with Def. 2. Participants then rated on a 9-point scale how strongly *Factor* and *Effect* were related. Finally, as a measure of ascription, they chose an appropriate term to describe the relation between *Factor* and *Effect*, from a list including ‘causes’ and ‘facilitates’.

Results Out of the 16 ascriptions that the model predicted to be of facilitation, 14 were so, and 2 were of causality. Out of the 25 ascriptions that the model predicted to be of causality, 11 were so, and 14 were of facilitation. Beliefs thus had the expected influence on ascriptions, $\chi^2 = 4.5$, $p < .05$. The trend observed in Experiment 1 is replicated in Experiment 2. We also conducted a *mediation analysis* of our data, which consists in a series of 3 regression analyzes. The direct effect of background knowledge on ascription was significant, $\beta = .33$, $p < .05$. The effect of background knowledge on perceived strength was also significant, $\beta = .41$, $p < .01$. In the third regression, background knowledge and perceived strength were entered simultaneously. Perceived strength was a reliable predictor of ascription, $\beta = .29$, $p < .05$, which was no longer the case for background knowledge, $\beta = .23$, $p > .05$. Data thus meet the requirement

of a mediational effect: Whether the background knowledge of participants matches Def. 1 or Def. 2 determines their final ascription of $C : \text{Factor} \Rightarrow_{\text{fa}} \text{Effect}$ or $C : \text{Factor} \Rightarrow_{\text{ca}} \text{Effect}$ through its effect on the perceived strength of the link between *Factor* and *Effect*.

4 PROPERTIES OF CAUSAL ASSCRIPTIONS

4.1 Impossibility of mutual causality

Proposition 1. *If $C : A \Rightarrow_{\text{ca}} B$, then it cannot hold that $C : B \Rightarrow_{\text{ca}} A$.*

Proof. If $C : A \Rightarrow_{\text{ca}} B$, it holds that $C \succ \neg A$, $C \wedge A \succ B$, and the sequence $\neg B_i, A_i, B_{i+1}$ has been observed. This is not inconsistent with $C \succ \neg A$, $C \wedge B \succ A$ (the background knowledge part of $C : B \Rightarrow_{\text{ca}} A$), but it is inconsistent with the sequence $\neg A_i, B_i, A_{i+1}$ that would allow the ascription $C : B \Rightarrow_{\text{ca}} A$. \square

4.2 Preference for abnormal causes

Psychologists established that abnormal conditions are more likely to be selected by human agents as the cause of an event [17] and more so if this event is itself abnormal [12] (see also [16] in the area of legal philosophy). Our model reflects this preference: Only what is abnormal in a given context can be perceived as facilitating or causing a change in the normal course of things in this context.

Proposition 2. *If $C : A \Rightarrow_{\text{ca}} B$ or $C : A \Rightarrow_{\text{fa}} B$, then $C \succ \neg A$.*

Proof. $C \succ \neg A$ is false when either $C \succ A$ or $C \not\succ \neg A$. If $C \succ A$, it cannot be true that both $C \succ \neg B$ and either $A \wedge C \not\succ \neg B$ (the definition of $C : A \Rightarrow_{\text{fa}} B$) or $A \wedge C \succ B$ (the definition of $C : A \Rightarrow_{\text{ca}} B$). This is due to the Cautious Monotony property of \succ , which forces $C \wedge A \succ \neg B$ from $C \succ A$ and $C \succ \neg B$. Likewise, the Rational Monotony of \succ forces $C \wedge A \succ \neg B$ from $C \not\succ \neg A$ and $C \succ \neg B$; thus, it cannot be the case that $C : A \Rightarrow_{\text{fa}} B$ or $C : A \Rightarrow_{\text{ca}} B$ when $C \not\succ \neg A$. \square

Example 2 (The unreasonable driver). *Let us imagine an agent who believes it is normal to be drunk in the context of driving ($\text{Drive} \succ \text{Drunk}$). This agent may think that it is exceptional to have an accident when driving ($\text{Drive} \succ \neg \text{Accident}$). In that case, the agent cannot but believe that accidents are exceptional as well when driving while drunk: $\text{Drive} \wedge \text{Drunk} \succ \neg \text{Accident}$. As a consequence, when learning that someone got drunk, drove his car, and had an accident, this agent will neither consider that $C : \text{Drunk} \Rightarrow_{\text{fa}} \text{Accident}$ nor that $C : \text{Drunk} \Rightarrow_{\text{ca}} \text{Accident}$.*

4.3 Transitivity

Def. 2 does not grant general transitivity to \Rightarrow_{ca} . If $C : A \Rightarrow_{\text{ca}} B$ and $C : B \Rightarrow_{\text{ca}} D$, it does not always follow that $C : A \Rightarrow_{\text{ca}} D$. Formally: $C \succ \neg B$ and $A \wedge C \succ B$ and $C \succ \neg D$ and $B \wedge C \succ D$ do not entail $C \succ \neg D$ and $A \wedge C \succ D$, because \succ itself is not transitive. Although \Rightarrow_{ca} is not generally transitive, it becomes so in one particular case.

Proposition 3. *If $C : A \Rightarrow_{\text{ca}} B$, $C : B \Rightarrow_{\text{ca}} D$, and $B \wedge C \succ A$, then $C : A \Rightarrow_{\text{ca}} D$.*

Proof. From the definition of $C : B \Rightarrow_{\text{ca}} D$, it holds that $B \wedge C \succ D$. From $B \wedge C \succ A$ and $B \wedge C \succ D$, applying Cautious Monotony yields $A \wedge B \wedge C \succ D$, which together with $A \wedge C \succ B$ (from the definition of $C : A \Rightarrow_{\text{ca}} B$) yields by Cut $A \wedge C \succ D$; since it holds from the definition of $C : B \Rightarrow_{\text{ca}} D$ that $C \succ \neg D$, the two parts of the definition of $C : A \Rightarrow_{\text{ca}} D$ are satisfied. \square

Example 3 (Mud on the plates). *Driving back from the countryside, you get a fine because your plates are muddy, $\text{Drive} : \text{Mud} \Rightarrow_{\text{ca}} \text{Fine}$. Let us assume that you perceive your driving to the countryside as the cause for the plates to be muddy, $\text{Drive} : \text{CountrySide} \Rightarrow_{\text{ca}} \text{Mud}$. For transitivity to apply, i.e., to judge that $\text{Drive} : \text{CountrySide} \Rightarrow_{\text{ca}} \text{Fine}$, it must hold that $\text{Mud} \wedge \text{Drive} \succ \text{CountrySide}$: If mud on your plates usually means that you went to the countryside, then the trip can be considered the cause of the fine. If the presence of mud on your plates does not allow to infer that you went to the countryside (perhaps you also regularly drive through muddy streets where you live), then transitivity is not applicable; you will only consider that the mud caused the fine, not that the trip did.*

4.4 Entailment and causality ascriptions

Classical entailment \models does not preserve \Rightarrow_{ca} . If $C : A \Rightarrow_{\text{ca}} B$ and $B \models B'$, one cannot say that $C : A \Rightarrow_{\text{ca}} B'$. Indeed, while $A \wedge C \succ B$ follows by right weakening [18] from $A \wedge C \succ B$, it is not generally true that $C \succ \neg B'$, given that $C \succ \neg B$. Besides, according to Definition 2, if $A' \models A$, the fact that $C : A \Rightarrow_{\text{ca}} B$ does not entail that $C : A' \Rightarrow_{\text{ca}} B$, since $C \succ \neg B$ and $A \wedge C \succ B$ do not entail $A' \wedge C \succ B$ when $A' \models A$. This fact is due to the extreme cautiousness of System P. It is contrasted in the following example with Rational Monotony.

Example 4 (Stone throwing). *An agent believes that a window shattered because a stone was thrown at it ($\text{Window} : \text{Stone} \Rightarrow_{\text{ca}} \text{Shatter}$), based on its beliefs that $\text{Window} \succ \neg \text{Shatter}$ and $\text{Stone} \wedge \text{Window} \succ \text{Shatter}$. Using the Cautious Monotony of System P, it is not possible to predict that the agent would make a similar ascription if a small stone had been thrown (SmallStone), or even if a white stone had been thrown (WhiteStone), or even if a big stone had been thrown (BigStone), although it holds that $\text{SmallStone} \models \text{Stone}$, $\text{WhiteStone} \models \text{Stone}$, and $\text{BigStone} \models \text{Stone}$. Adding Rational Monotony [19] to System P allows the ascriptions $\text{Window} : \text{BigStone} \Rightarrow_{\text{ca}} \text{Shatter}$ and $\text{Window} : \text{WhiteStone} \Rightarrow_{\text{ca}} \text{Shatter}$, but also $\text{Window} : \text{SmallStone} \Rightarrow_{\text{ca}} \text{Shatter}$. To block this last ascription, it would be necessary that the agent has specific knowledge about the harmlessness of small stones, such as $\text{Window} \wedge \text{Smallstone} \not\models \text{Shatter}$ or even $\text{Window} \wedge \text{Smallstone} \succ \neg \text{Shatter}$.*

4.5 Stability w.r.t. disjunction and conjunction

\Rightarrow_{ca} is stable with respect to disjunction, both on the right and on the left, and stable w.r.t. conjunction on the right.

Proposition 4. *The following properties hold:*

1. *If $C : A \Rightarrow_{\text{ca}} B$ and $C : A \Rightarrow_{\text{ca}} B'$, then $C : A \Rightarrow_{\text{ca}} B \vee B'$.*
2. *If $C : A \Rightarrow_{\text{ca}} B$ and $C : A' \Rightarrow_{\text{ca}} B$, then $C : A \vee A' \Rightarrow_{\text{ca}} B$.*
3. *If $C : A \Rightarrow_{\text{ca}} B$ and $C : A \Rightarrow_{\text{ca}} B'$, then $C : A \Rightarrow_{\text{ca}} B \wedge B'$.*

Proof. Applying AND to the first part of the definitions of $C : A \Rightarrow_{\text{ca}} B$ and $C : A \Rightarrow_{\text{ca}} B'$, i.e., $C \succ \neg B$ and $C \succ \neg B'$, yields $C \succ \neg B \wedge \neg B'$, and thus $C \succ \neg(B \vee B')$. Now, applying AND to the second part of the definitions of $C : A \Rightarrow_{\text{ca}} B$ and $C : A \Rightarrow_{\text{ca}} B'$, i.e., $A \wedge C \succ B$ and $A \wedge C \succ B'$, yields $A \wedge C \succ B \wedge B'$, which together with Right Weakening yields $A \wedge C \succ B \vee B'$. The definition of $C : A \Rightarrow_{\text{ca}} B \vee B'$ is thus satisfied. The proof of Fact 2 is obtained by applying OR to the second part of the definitions of $C : A \Rightarrow_{\text{ca}} B$ and $C : A \Rightarrow_{\text{ca}} B'$. Finally, applying AND to the first part of the definitions of $C : A \Rightarrow_{\text{ca}} B$ and $C : A \Rightarrow_{\text{ca}} B'$, i.e., $C \succ \neg B$ and $C \succ \neg B'$, yields $C \succ \neg B \wedge \neg B'$, which together with Right Weakening, yields

$C \vdash \neg B \vee \neg B'$, and thus $C \vdash \neg(B \wedge B')$. Now, applying AND to the second part of the definitions of $C : A \Rightarrow_{ca} B$ and $C : A \Rightarrow_{ca} B'$, i.e., $A \wedge C \vdash B$ and $A \wedge C \vdash B'$, yields $A \wedge C \vdash B \wedge B'$. The definition of $C : A \Rightarrow_{ca} B \wedge B'$ is thus satisfied. \square

\Rightarrow_{ca} is not stable w.r.t. conjunction on the left. If $C : A \Rightarrow_{ca} B$ and $C : A' \Rightarrow_{ca} B$, then it is not always the case that $C : A \wedge A' \Rightarrow_{ca} B$ (see example 5). This lack of stability is once again due to the cautiousness of System P; for $C : A \wedge A' \Rightarrow_{ca} B$ to hold, it is necessary that $C \wedge A \vdash A'$ or, alternatively, that $C \wedge A' \vdash A$. Then Cautious Monotony will yield $A \wedge A' \wedge C \vdash B$. Rational Monotony can soften this constraint and make it enough that $C \wedge A \not\vdash \neg A'$ or $C \wedge A' \not\vdash \neg A$.

Example 5 (Busy professors). Suppose that professors in your department seldom show up early at the office ($Prof \vdash \neg Early$). However, they generally do so when they have tons of student papers to mark ($Prof \wedge Mark \vdash Early$), and also when they have a grant proposal to write ($Prof \wedge Grant \vdash Early$). When learning that a professor had tons of papers to grade and that she came in early, you would judge that $Prof : Mark \Rightarrow_{ca} Early$. Likewise, when learning that a professor had a grant proposal to write and came in early, you would judge that $Prof : Grant \Rightarrow_{ca} Early$. But what if you learn that a professor had tons of papers to grade and a grant proposal to write and that she came in early? That would depend on whether it is an exceptional situation to have to deal with both tasks on the same day. If it is not exceptional ($Mark \not\vdash \neg Grant$), then you will judge that $Prof : Mark \wedge Grant \Rightarrow_{ca} Early$. If, on the contrary, $Mark \wedge Grant$ is an exceptional event, it does not hold anymore that $Mark \wedge Grant \vdash Early$, and it is thus impossible to feel sure about $Prof : Mark \wedge Grant \Rightarrow_{ca} Early$. For example, it might be the case that faced with such an exceptional workload, a professor will prefer working at home all day rather than coming to the office. In that case, her coming in early would be due to another factor, e.g., a meeting that could not be cancelled.

5 ASRIPTIONS OF JUSTIFICATION

Perceived causality as expressed in Def. 2 should be distinguished from the situation that we term ‘justification.’ We write that $C : A \Rightarrow_{ju} B$ when an agent judges that the occurrence of A in context C gave reason to expect the occurrence of B .

Definition 3 (Justification). An agent that learns in context C of the sequence $\neg B_t, A_t, B_{t+1}$ will judge that $C : A \Rightarrow_{ju} B$ if it believes that $C \not\vdash \neg B, C \not\vdash B$ and $A \wedge C \vdash B$.

Faced with facts $C, \neg B_t, A_t, B_{t+1}$, an agent believing that $C \not\vdash \neg B, C \not\vdash B$ and $A \wedge C \vdash B$ may doubt that the change from $\neg B_t$ to B_{t+1} is really due to A_t , although the latter is indeed the very reason for the lack of surprise at having B_{t+1} reported. Indeed, situation $\neg B_t$ at time t appears to the agent to be contingent, since it is neither a normal nor an abnormal course of things in context C . This clearly departs from the situation where $C \vdash \neg B$ and $A \wedge C \vdash B$, wherein the agent will judge that $C : A \Rightarrow_{ca} B$. In a nutshell, the case whereby $C \not\vdash \neg B, C \not\vdash B$ and $A \wedge C \vdash B$ cannot be interpreted as the recognition of a causal phenomenon by an agent: All that can be said is that reporting A caused the agent to start believing B , and that she should not be surprised of having B_{t+1} reported.

What we call justification is akin to the notion of explanation following Spohn [27]: Namely, ‘ A is a reason for B ’ when raising the epistemic rank for A raises the epistemic rank for B . Gärdenfors [11] captured this view to some extent, assuming that A is a reason for B if B is not retained in the contraction of A . Williams et al.

[29] could account for the Spohnian view in a more refined way using kappa-rankings and transmutations, distinguishing between weak and strong explanations. As our framework can easily be given a possibilistic semantics [4], it could properly account for this line of thought, although our distinction between perceived causation and epistemic justification is not the topic of the above works.

6 RELATED WORKS

Causality plays a central role in at least two problems studied in AI, diagnosis and the simulation of dynamical systems. Diagnosis problems are a matter of abduction: One takes advantage of the knowledge of some causal links to infer the most plausible causes of an observed event [23]. In this setting, causality relations are often modelled by conditional probabilities $P(\text{effect}|\text{cause})$.⁴ Dynamical systems are modelled in AI with respect, e.g., to qualitative physics [6], and in logics of action. The relation of nonmonotonic inference to causality has already been emphasized by authors dealing with reasoning about actions and the frame problem [13, 20, 28]. Material implication being inappropriate to represent a causal link, these approaches define a ‘causal rule’ as ‘there is a cause for effect B to be true if it is true that A has just been executed’, where ‘there is a cause for’ is modelled by a modal operator.

The problem discussed in this paper is not, however, one of classical diagnosis. Neither does it deal with the qualitative simulation of dynamical systems, nor with the problem of describing changes caused by the execution of actions, nor with what does not change when actions are performed. We are concerned here with a different question, namely the explanation of a sequence of reported events, in terms of pairs of events that can be considered as related by a causality relation. In that sense, our work is reminiscent of the ‘causal logic’ of Shafer [25], which provides a logical setting that aims at describing the possible relations of concomitance between events when an action takes place. However, Shafer’s logic does not leave room for abnormality. This notion is central in our approach, as it directly relates to the relations of qualitative independence explored in [7] – causality and independence being somewhat antagonistic notions.

Following [22], Halpern and Pearl [14, 15] have proposed a model that distinguishes real causes (‘cause in fact’) from potential causes, by using an a priori distinction between ‘endogenous’ variables (the possible values of which are governed by structural equations, for example physical laws), and ‘exogenous’ variables (determined by external factors). Exogenous variables cannot be deemed causal. Halpern and Pearl’s definition of causality formalizes the notion of an active causal process. More precisely, the fact A that a subset of endogenous variables has taken some definite values is the real cause of an event B if (i) A and B are true in the real world, (ii) this subset is minimal, (iii) another value assignment to this subset would make B false, the values of the other endogenous variables that do not directly participate to the occurrence of B being fixed in some manner, and (iv) A alone is enough for B to occur in this context. This approach, thanks to the richness of background knowledge when it is represented in structural equations, makes it possible to treat especially difficult examples. Our model is not to be construed as an alternative or a competitor to models based on structural equations. Indeed, we see our approach as either a ‘plan B’ or a complement to structural equation modeling. One might not have access to the accurate

⁴ Nevertheless, Bayesian networks [21] (that represent a joint probability distribution by means of a directed graph) do not necessarily reflect causal links between their nodes, for different graphical representations can be obtained depending on the ordering in which variables are considered [8].

information needed to build a structural equation model; in this case, our less demanding model might still be operable. Alternatively, a decision support system may be able to build a structural equation model of the situation, although its users only have access to qualitative knowledge. In that case, the system will be able to compare its own causality ascriptions to the conclusions of the qualitative model, and take appropriate explanatory steps, would those ascriptions be too different. Indeed, our model does not aim at identifying the true, objective cause of an event, but rather at predicting what causal ascription an agent would make based on the limited information it has at its disposal.

Models based on structural equations are often supplemented with the useful notion of *intervention*. In many situations, finding the cause of an event will be much easier if the agent can directly intervene in the manner of an experimenter. In future work, we intend to explore the possibility of supplementing our own model with a similar notion by means of a $\text{do}(\bullet)$ operator. An ascription of causality (resp., facilitation) would be made iff the requirements of Definition 2 (resp., 1) are met both for A, B, C and for $\text{do}(A), B, C$, where $\text{do}(A)$ means that the occurrence of A is forced by an intervention [22]. As for now, we only give a brief example of how such an operator can be used in our approach.

Example 6 (Yellow teeth). *An agent learns that someone took up smoking, that this person's teeth yellowed, and that this person developed lung cancer. The agent believes that generally speaking, it is abnormal to be a smoker, to have yellow teeth, and to develop lung cancer (resp., $(C \vdash \neg\text{Smoke}, C \vdash \neg\text{Yellow}, C \vdash \neg\text{Lung})$). The agent believes that it is normal for smokers to have yellow teeth ($C \wedge \text{Smoke} \vdash \text{Yellow}$) and to develop lung cancer ($C \wedge \text{Smoke} \vdash \text{Lung}$), and that it is not abnormal for someone who has yellow teeth to develop lung cancer ($C \wedge \text{Yellow} \not\vdash \neg\text{Lung}$). From these beliefs and observations, Definitions 1 and 2 would allow for various ascriptions, including the following one: Smoking caused the yellow teeth which in turn facilitated lung cancer. With the additional constraint based on the $\text{do}(\bullet)$ operator, only one set of ascriptions remains possible: Both the yellow teeth and the lung cancer were caused by smoking. Yellow teeth cannot be said anymore to facilitate lung cancer because, inasmuch as lung cancer is generally abnormal, it holds that $C \wedge \text{do}(\text{Yellow}) \vdash \neg\text{Lung}$: There is no reason to think that one will develop lung cancer after painting one's teeth yellow.*

7 CONCLUDING REMARKS

We have presented a simple qualitative model of the causal ascriptions an agent will make from its background default knowledge, when confronted with a series of events. In addition to supplementing this model with a $\text{do}(\bullet)$ operator, we intend to extend our present work in three main directions. First, we should be able to equip our framework with possibilistic qualitative counterparts to Bayesian networks [3], since System P augmented with Rational Monotony can be represented in possibilistic logic [4]. Second, we will derive postulates for causality from the independence postulates presented in [7]. Finally, in parallel to further theoretical elaboration, we will maintain a systematic experimental program that will test the psychological plausibility of our definitions, properties, and postulates.

Comparing sets of positive and negative arguments: Empirical assessment of seven qualitative rules

Jean-François Bonnefon¹ and Hélène Fargier²

Abstract. Many decisions can be represented as bipolar, qualitative sets of arguments: Arguments can be pros or cons, and ranked according to their importance, but not numerically evaluated. The problem is then to compare these qualitative, bipolar sets. In this paper (a collaboration between a computer scientist and a psychologist), seven procedures for such a comparison are empirically evaluated, by matching their predictions to choices made by 62 human participants on a selection of 33 situations. Results favor cardinality-based procedures, and in particular one that allows for the internal cancellation of positive and negative arguments within a decision.

1 Introduction

Would you rather go to Rome or Beijin next spring? There are many arguments for or against each choice, and some may be more compelling than others, although it will be difficult to scale them on a common metrics. Maybe you really want to see the Coliseum, as much as you want to spend a night at Beijin opera house. You are somewhat concerned that you cannot speak Chinese. Language will also be an issue in Rome, but arguably less of one. How to decide?

Comparing the two decisions amounts to comparing two sets of arguments. Putting aside arguments that are irrelevant to the decision at hand, arguments can be positive (pros – typically, the good consequences of the decision), or negative (cons – typically, the bad consequences of the decision). Some of these arguments will be stronger or more compelling than others; however, decisions often have to be made on the basis of an ordinal ranking of the strength of the arguments, rather than on a numerical evaluation: some decision processes are of a qualitative nature. What is needed is thus a qualitative, bipolar approach to the comparison of sets of arguments. Meeting these two requirements would improve the cognitive plausibility of the method, as psychologists have argued that human choice processes are likely to be qualitative [11] and bipolar [5, 6, 15].

Ordinal ranking procedures from bipolar information have received scarce attention so far. Amgoud et al. [1] compare decisions in terms of positive and negative arguments, using a complex scheme for evaluating the strength of arguments (which possess both a level of importance and a degree of certainty, and involve criteria whose satisfaction is a matter of degree). They then compare decisions using simple optimistic or pessimistic rules, independently of the polarity of the arguments. Benferhat and Kaci [12, 3] propose to merge all positive affects into a degree of satisfaction (using the max rule). If high, this degree does not play any role and the decision is based

on negative affects (using Wald's principle, see below). If low, it is understood as a negative affect and merged with the other ones. Finally, Dubois and Fargier [8] introduce a number of qualitative, bipolar rules for comparing sets of arguments; all these rule follow the prospective work of [17] on order of magnitude calculus and thus receive an interpretation in terms of order of magnitude probabilities.

This article, which is a collaboration between a computer scientist and a psychologist, will present an extensive empirical assessment of the descriptive validity of these rules. It will not, however, thoroughly describe all their properties or include their axiomatic characterization, for which the reader can refer to [8].

2 The rules

[8] consider the simple situation where each possible decision d is assessed by a finite subset of arguments $C(d) \subseteq X$. X is the set of all possible arguments. Comparing decisions then amounts to comparing sets of arguments, i.e. subsets A, B of 2^X . X can be divided in three disjoint subsets: X^+ is the set of positive arguments, X^- the set of negative arguments, X^0 the set of indifferent ones. Any $A \subseteq X$ can likewise be partitioned: let $A^+ = A \cap X^+$, $A^- = A \cap X^-$, $A^0 = A \cap X^0$ be respectively the positive, negative and indifferent arguments of A .

Arguments can be of varying importance. In a purely qualitative, ordinal approach, the importance of arguments can be described on a totally ordered scale of magnitude $L = [0_L, 1_L]$, for example by the following function π :

$$\pi : X \mapsto L = [0_L, 1_L]$$

$\pi(x) = 0_L$ means that the decision maker is indifferent to argument x : this argument will not affect the decision process. The order of magnitude 1_L (the highest level of importance) is attached to the most compelling arguments that the decision-maker can consider. Finally, the *order of magnitude* $OM(A)$ of a set A is defined as the highest of the order of magnitude of its elements:

$$\forall A \subseteq X, OM(A) = \max_{x \in A} \pi(x)$$

2.1 The qualitative Pareto comparison \geq^{Pareto}

This rule compares the two sets of arguments as a problem of bi-criteria decision. The first criterion compares negative arguments according to Wald's [16] rule: A is better than B on the negative side iff $OM(A^-) \leq OM(B^-)$. The second criterion compares positive arguments according to the optimistic counterpart of Wald's rule:

$$A \geq^{\text{Pareto}} B \iff \begin{aligned} OM(A^+) &\geq OM(B^+) \\ OM(A^-) &\leq OM(B^-) \end{aligned}$$

¹ LTC-CNRS, 5 allées Antonio Machado 31058 Toulouse Cedex 9, France.
 E-mail: bonnefon@univ-tlse2.fr

² IRIT-CNRS, 118 Route de Narbonne 31062 Toulouse Cedex, France. E-mail: fargier@irit.fr

\geq^{Pareto} is reflexive and transitive, but incomplete. A is strictly preferred to B in two cases: $\text{OM}(A^+) \geq \text{OM}(B^+)$ and $\text{OM}(A^-) < \text{OM}(B^-)$, or $\text{OM}(A^+) > \text{OM}(B^+)$ and $\text{OM}(A^-) \leq \text{OM}(B^-)$. A and B are indifferent when $\text{OM}(A^+) = \text{OM}(B^+)$ and $\text{OM}(A^-) = \text{OM}(B^-)$. In other cases, A is not comparable with B .

2.2 The implication rule \geq^{DPoss}

This rule focuses on the most important arguments in the situation. A is at least as good as B iff, at level $\text{OM}(A \cup B)$, the presence of arguments for B is cancelled by the existence of arguments for A , and the existence of arguments against A is cancelled by the existence of arguments against B . Formally:

$$A \geq^{\text{DPoss}} B \text{ iff :}$$

$$\begin{aligned} \text{OM}(A \cup B) = \text{OM}(B^+) \Rightarrow \text{OM}(A \cup B) = \text{OM}(A^+) \\ \text{and } \text{OM}(A \cup B) = \text{OM}(A^-) \Rightarrow \text{OM}(A \cup B) = \text{OM}(B^-) \end{aligned}$$

\geq^{DPoss} is reflexive, transitive and incomplete. E.g., a set with a positive and a negative argument in 1_L is incomparable to any other set.

2.3 The ordinal bipolar rule \geq^{Poss}

This rule is simpler but less decisive. It considers any argument against A as an argument for B ; any argument for A as an argument against B ; and reciprocally. Then, the decision supported by the strongest argument(s) is preferred:

$$A \geq^{\text{Poss}} B \text{ iff :}$$

$$\max(\text{OM}(A^+), \text{OM}(B^-)) \geq \max(\text{OM}(B^+), \text{OM}(A^-))$$

This rule is complete but quasi-transitive only. That is, \succ^{Poss} is transitive but the indifference relation is not necessarily transitive. For example, when $\text{OM}(B^+) = \text{OM}(B^-)$, it is possible that indifference obtains between A and B , and between B and C as well, but not however between A and C .

Notice that \succ^{Poss} is the rule identified in [17] as a principle for order of magnitude reasoning. It is less decisive than \geq^{DPoss} in the sense that \geq^{DPoss} is a refinement of \geq^{Poss} :

$$A \succ^{\text{Poss}} B \Rightarrow A \succ^{\text{DPoss}} B.$$

2.4 Discriminating arguments: \geq^{Discri} and \geq^{DDiscri}

\geq^{Poss} and (to a lower extent) \geq^{DPoss} and \geq^{Pareto} suffer from a severe drowning effect [2, 7, 9] that is often found in purely possibilistic frameworks. For example, when B is included in A , and even if all of the proper elements of A are positive, A is not necessarily strictly preferred to B .

This drowning problem is related to the fact that the three rules \geq^{Poss} , \geq^{DPoss} , and \geq^{Pareto} do not satisfy the condition of preferential independence, a very natural principle of decision making used when the criteria (or arguments) are non-interactive:

$$\forall A, B, C \text{ such that } (A \cup B) \cap C = \emptyset : A \geq B \iff A \cup C \geq B \cup C$$

\geq^{Discri} and \geq^{DDiscri} incorporate the principle of preferential independence, by cancelling elements that appear in both sets before applying \geq^{Poss} or \geq^{DPoss} .³

$$\begin{aligned} A \geq^{\text{Discri}} B &\iff A \setminus B \geq^{\text{Poss}} B \setminus A \\ A \geq^{\text{DDiscri}} B &\iff A \setminus B \geq^{\text{DPoss}} B \setminus A \end{aligned}$$

³ A similar variant of the Pareto rule might also be proposed ($A \geq^{\text{DiscriPareto}} B \iff A \setminus B \geq^{\text{Pareto}} A \setminus B$). We did not study any further the refinements of \geq^{Pareto} , since it rapidly appeared that the rule was counter intuitive.

\geq^{Discri} is complete (as is \geq^{Poss}) but not transitive, although its strict part \succ^{Discri} is. \geq^{DDiscri} is partial (as is \geq^{DPoss}) but not transitive, although \succ^{DDiscri} is.

2.5 Cardinality rules \geq^{Bilexi} and \geq^{Lexi}

These rules are based on a levelwise comparison by cardinality. The arguments in A and B are scanned top-down, until a level is reached such that there is a difference either in the number of arguments for A and B , or in the number of arguments against A and B . At this point, the set that presents the lower number of negative arguments and the greater number of positive ones is preferred. Formally: for any level $i \in L$, let

$$\begin{aligned} A_i &= \{x \in A, \pi(x) = i\} \\ A_i^+ &= A_i \cap X^+ \\ A_i^- &= A_i \cap X^- \end{aligned} .$$

Let δ be the highest value of i s.t. $A_\delta^+ \neq |B_\delta^+|$ or $|A_\delta^-| \neq |B_\delta^-|$. Then:

$$A \geq^{\text{Bilexi}} B \iff |A_\delta^+| \geq |B_\delta^+| \text{ and } |A_\delta^-| \leq |B_\delta^-|$$

\geq^{Bilexi} is reflexive, transitive, but not complete. Indeed, if (at the decisive level) one of the set wins on the positive side, and the other on the negative side, the rule concludes to incomparability. A more decisive variant of \geq^{Bilexi} loses information about this conflict. The idea behind \geq^{Lexi} is to simplify each set before the comparison, accepting that one positive and one negative argument of A can cancel each other. In other terms, at each level j , A is assigned the score $|A_j^+| - |A_j^-|$. A top-down comparison of the scores is then performed:

$$A \geq^{\text{Lexi}} B \iff \exists i \in L \text{ such that:}$$

$$\begin{aligned} \forall j > i, \quad |A_j^+| - |A_j^-| &= |B_j^+| - |B_j^-| \\ \text{and } |A_i^+| - |A_i^-| &> |B_i^+| - |B_i^-| \end{aligned} .$$

3 Empirical Tests

3.1 Methods

How well does each rule predict the actual choices made by lay persons? To answer this question, we elaborated 33 situations of choice between two options, each option being represented as a list of positive and negative features of varying importance (see Table 1; the set of situations was designed to maximize the differentiability of the different rules, as well as to check some basic hypotheses about the qualitative nature of the decisions). Participants were 62 adults (31 men, 31 women, mean age = 24). The decisions involved ‘Poldeevian’ stamps (a fictive nation). Stamp collection provided us with a clear-cut situation of qualitative comparison. Insofar as information about the monetary value of the stamps was unavailable, they were sorted in two broad groups: the rare, coveted stamps on the one hand and the common ones on the other. This was explicitly explained to participants:

"Poldeevian stamps come in two types, **rare** and **common**. Rare stamps are difficult to find, and they are treasured by collectors. Common stamps are much easier to find, and add much less value to a collection. Among the many Poldeevian stamps, we will only be interested today in four rare and four common stamps. The rare stamps are called ARBON, BANTA, CASSA, and DIDOR. The common stamps are called WIV, XYL, YER, and ZAM."

Table 1. The 33 situations, with choices yielded by the 7 rules. Option $a^{++}(xy)^-$ has one very positive feature a and two mildly negative features x and y . \emptyset is the null option. $>$, $<$, $=$, and \sim resp. read ‘prefer option 1’, ‘prefer option 2’, ‘indifferent’, ‘options are incomparable’.

	Option1	Option2	Pareto	DPoss	Poss	DDisci	Discri	BiLexi	Lexi

24	$(bd)^{--}$	$(ab)^{--}w^-$	\sim	\sim	$=$	\sim	\sim	$=$	$=$
25	$(bd)^{--}$	$a^{--}(wxyz)^-$	\sim	\sim	$=$	\sim	\sim	$=$	$=$
26	$(ab)^{++}(wxyz)^-$	a^{++}	\sim	\sim	$=$	\sim	\sim	$=$	$=$
27	$(bd)^{++}(wxyz)^-$	c^{++}	\sim	\sim	$=$	\sim	\sim	$=$	$=$
28	a^{--}	$(wxyz)^+(ac)^{--}$	\sim	\sim	$=$	\sim	\sim	$=$	$=$
29	c^{--}	$(wxyz)^+(bd)^{--}$	\sim	\sim	$=$	\sim	\sim	$=$	$=$
30	$d^{++}w^-$	d^{++}	\sim	\sim	$=$	\sim	\sim	$=$	$=$
31	$b^{++}w^-$	a^{++}	\sim	\sim	$=$	\sim	\sim	$=$	$=$
32	$c^{--}w^+$	c^{--}	\sim	\sim	$=$	\sim	\sim	$=$	$=$
33	$d^{--}w^+$	a^{--}	\sim	\sim	$=$	\sim	\sim	$=$	$=$

It is worth noting that using an abstract setting like this one, with little appeal to participant's world knowledge and little import to their personal life, is a routine procedure in experimental psychology. It allows to escape the idiosyncrasies of a given application domain (e.g., choice of an apartment, or a car), and to study a mental process under rigorously controlled conditions.

Participants' task consisted in a series of 33 choices between two options (in choices 1 to 5, the second option was the status quo). E.g., in Situation 15, participants were asked which of Club 1 or 2 they would join: Club 1 offered ARBON as a welcome gift, but required DIDOT and CASSA as a membership fee. Club 2, on the other hand, offered WIV, XYL, YER, and ZAM as a welcome gift, but required BANTA as a membership fee. Participants could choose one of four responses: (a) choose Club 1, (b) choose Club 2, (c) indifferent, one or the other, would agree to choose randomly, and (d) unable to make a decision, would not agree to choose randomly. While the third response suggests indifference between the two options, the fourth response indicates incomparability.

3.2 Results

3.2.1 Preliminaries

Choices made by participants in all 33 situations are reported in Table 2. Before we turn to the results proper, three general remarks are in order. First, a great majority of the sample (80 to 90%) used a pure qualitative ranking of the arguments, as we expected. It remains that some participants (10 to 20%) appear to go beyond a strictly qualitative evaluation of the arguments: Situations 16 and 21 (and possibly Situation 1) make it clear that these participants value four common stamps more than one rare stamp.

Second, some participants (28 to 34%) seem to re-scale negative arguments, giving them more weight than positive arguments: getting a rare stamp is less important than loosing a rare one. E.g., these 'qualitative pessimists' prefer the null option in Situation 3, or option 1 in Situation 11. Finally, some misunderstandings apparently could not be avoided, especially in the third tier of the task. E.g., a small number of participants (7 to 10%) manifest a strict preference for Option 2 in Situations 22, 23, 24, or for Option 1 in Situation 25. This rate nevertheless stays low (below 10% in any case).

3.2.2 Overall descriptive validity

As a first measure of overall descriptive validity, we computed the 'fit' of each procedure to the choices made by participants. The fit of a procedure is the *average percentage of answers it correctly predicts*, across participants. A good fit might not be a guarantee of cognitive plausibility, but a low fit is certainly an indicator of poor descriptive validity. A second measure of overall validity is what we call the 'restricted fit' of the procedure, i.e., the average percentage of answers it correctly predicts across participants, only taking into account the situations *for which it predicts a strict preference*. Table 3 reports the general and restricted fit of each rule. (We also tested the fit of the procedure suggested by Benferhat and Kaci [12, 3], which we mentioned in the Introduction – this fit was only 26%).

\geq^{DPoss} , \geq^{Pareto} and especially \geq^{Poss} fare badly in this first evaluation. The restricted fit of \geq^{Poss} may seem high, but it concerns 4 situations only (on the positive side, this shows that the principles of $>^{\text{Poss}}$ are considered as an obvious, minimal norm by the decision makers). On the contrary, \geq^{DPoss} and \geq^{Pareto} show some serious weakness with respect to restricted fit. Only \geq^{Bilexi} and \geq^{Lexi} achieve promising general

Table 2. Choices made by participants (in % of answers) in the 33 experimental Situations.

	Option1	Option2	>	<	=	~
1	$a^{++}(wxyz)^-$	0	79	21	–	–

31	$b^{++}w^-$	a^{++}	–	97	3	–
32	$c^{--}w^+$	c^{--}	90	–	3	7
33	$d^{--}w^+$	a^{--}	86	–	4	10

Table 3. Average % of answers predicted by each rule, overall or when restricted to situations when it predicts a strict preference

	Overall fit	Restricted fit
Poss	13	83
Dposs	23	57
Pareto	31	53
Discri	32	83
DDiscri	39	70
BiLexi	64	82
Lexi	77	79

fits of 64% and 77%. Although very decisive (\geq^{Lexi} is decisive in 32 of the 33 situations), these two rules also have a good restricted fit.

\geq^{Lexi} has the best fit with the choices made by any single one of the participants – it always provides the best description for all individual patterns of decisions. The second best fit is always \geq^{Bilexi} 's. The difference between \geq^{Lexi} 's and \geq^{Bilexi} 's fits is statistically reliable, as assessed by Student's $t(61) = 11.1$, $p < .001$: The probability of observing such a difference in our sample, were the fits actually similar in the general population, is less than one in a thousand. The same result holds when comparing the fit of \geq^{Bilexi} to the fits of all other procedures. From these initial considerations, only \geq^{Lexi} and \geq^{Bilexi} emerge as serious candidates for predicting participants' choices. We will now consider in more detail the case that can be made from our data in support of these two cardinality-based procedures.

3.2.3 Escaping the drowning effect by cancellation principles

Twelve situations (17–18, 22–23, 26–33) were designed so that they could elicit a drowning effect. Depending on the situation, 66 to 95% participants escape drowning. This strongly suggests that human decision-makers know their way out the classic drawback of purely possibilistic procedures like \geq^{Poss} , \geq^{DPoss} or \geq^{Pareto} .

\geq^{DDiscr} and \geq^{Discr} (on the one hand), and \geq^{Bilexi} and \geq^{Lexi} (on the other hand), represent two different ways to overcome the drowning effect. \geq^{DDiscr} and \geq^{Discr} do it by cancelling the arguments that appear in both options, thus realizing a refinement by inclusion of \geq^{DPoss} and \geq^{Poss} . The two rules \geq^{Bilexi} and \geq^{Lexi} lexi rules also allow the cancellation of positive (resp. negative) arguments of the same level, an additional refinement by cardinality (see [8] for more details).

The proportion of participants who refine by inclusion and not by cardinality is very low, less than 10 % in any case. To a couple of exceptions only, anytime a participant drowns on a situation that could be refined by cardinality, this participant had already failed to refine by inclusion on the corresponding version of the problem. Thus, in a very large majority of cases, refinement appears to operate through cardinality rather than simply inclusion.

Finally, evidence of *internal cancellation* (within a given option, a positive and a negative feature of the same level cancel each other) would count as an argument for favoring \geq^{Lexi} over \geq^{Bilexi} . In all relevant situations (3–5 and 10–15), the modal answer is *always* the one predicted by \geq^{Lexi} , and never the one predicted by \geq^{Bilexi} .

4 Conclusion

We proposed seven procedures for choosing among options represented as bipolar sets of ordinal-ranked arguments. We then asked the question of their descriptive value: How well does each of them predict the choices human decision-makers would make? For many of these procedures, the answer is: not very well, with the noticeable exception of the two cardinality rules that seem to predict human choices fairly well, and \geq^{Lexi} in particular has the highest empirical validity among our procedures.

An interesting parallel can be made in that regard between \geq^{Lexi} and the *Take the Best* decision heuristic that has been intensively studied by psychologists [4, 10, 13, 14]. When two options evaluated with respect to a series of strictly ordered criteria (in the sense that the criteria are supposed to be of very different order of magnitude so that they can be ranked lexicographically), Take the Best can be applied and amounts to choosing the option that is preferred by the most important of the criteria that makes a difference (going down

one level in case of a tie, and so forth). Applied on such a situation of lexicographically ranked criteria, the *discri* and *lexi* bipolar rules are formally equivalent to *Take the Best*. But they are able to account for other decision situations, e.g., several criteria can share the same degree of importance.

In this sense, \geq^{Lexi} is a natural extension of the widely popular (though controversial) rule advocated by psychologists.⁴ We believe that decision rules for artificial agents should be, whenever possible, as descriptively valid as they are formally sound – from the results we have reported, we see the present paper as a step towards showing that \geq^{Lexi} is blessed indeed with these two virtues.

⁴ While we will not push this comparison any further in the present paper, we do plan to give it due consideration in future work. In like vein, we plan to consider how other strategies identified in the psychological literature can relate to the rules we have already explored, or can be given a formal counterpart within our approach.

A Similarity and Fuzzy Logic-Based Approach to Cerebral Categorisation

Julien Erny^{1,2}, Josette Pastor¹ and Henri Prade²

Abstract. This work proposes a formal modelling of categorisation processes attempting at simulating the way information is categorised by neural populations in the human brain. The formalism mainly relies on a similarity-based approach to categorisation. It involves weighted rules that use inference and fusion techniques borrowed from fuzzy logic. The approach is illustrated by a simulation of the McGurk effect where the combination of contradictory auditory and visual stimuli creates an auditory perceptive illusion.

1 INTRODUCTION

The understanding and the prediction of the clinical outcomes of focal or degenerative cerebral lesions, as well as the assessment of rehabilitation procedures, necessitates knowing the cerebral substratum of cognitive or sensorimotor functions. This is addressed by functional neuroimaging studies. They have shown that sensorimotor or cognitive functions are the offspring of the activity of large-scale networks of anatomically connected cerebral regions [10]. However, no one-to-one correspondence between activated networks and functions can be found [11].

To understand the intricate relations between these networks and the cognitive functions, we need a model dealing explicitly with symbolic information while being strongly rooted in our knowledge of the neurobiological processes. Two complementary approaches address the problem. On the one hand, connexionist models focus on neural representation, at different scales. Biologically-plausible modelling deals with individual neurons, achieving a good level of accuracy but losing the symbolic aspect of information [26, 27]. On a coarser scale, simpler neuron models have revealed links between the neuronal substratum and simple cognitive functions [4, 13, 16, 17]. On the other hand, models from symbolic AI tend to reproduce cognitive processes without being interested in biological plausibility [3, 12, 20, 21, 24, 25]. However none of these approaches seems to answer the question of how the activation of large-scale networks follows the brain's information processing. This paper proposes an intermediary layer of interpretation, which echoes some other works [4, 6, 14]. However these works may lack a certain biological plausibility especially in the representation of categorisation processes, problem that will be addressed hereafter.

In the present paper, we first discuss the previous models and describe the requirements that a new model should address. Then we present a new approach that can fulfill some of these prerequisites. We then apply this model to phonemic discrimination. We conclude

with a discussion of the results and some perspectives.

2 EXISTING MODELLING APPROACHES

Representing information processing in large-scale cerebral networks necessitates departing from traditional connectionist methods, which tend to represent neural populations as neurons [2]. At this level, symbolic information processing is specific to the neuronal population that implements it and can be assumed to emerge from the numerical processing in the population's individual neurons. The causal connectivity approach [22] integrates this symbolic processing with more numerical aspects linked to the activation levels of cerebral regions in large-scale networks. This approach inspired probabilistic models [14] and has influenced our own work. In causal connectivity, the neuronal populations are seen as *information processors* while the axon bundles linking these populations are *information transmitters*. The information itself is represented as two-dimensioned data: i) a numeric component, called *magnitude*, stands for the overall activation of the neuronal population that processed this piece of information (thus allowing comparisons with neuroimaging data), and ii) a symbolic component, called *type*, that qualifies the pattern of the firing neurons in the population. Information is then spread in the network of populations using a dynamic Bayesian network formalism. The treatment taking place in a node can be seen as categorisation since the type of incoming information is compared to archetypes stored in the node. These archetypes represent the configuration of the synaptic weights inside the population and are modified dynamically every time information passes through, thus implementing an unsupervised, on-line learning mechanism.

However this model is lacking a primordial feature of cerebral categorisation: similarity [23]. It is known that close-by neurons will activate and fire for similar stimuli, suggesting a similarity code between stimuli based on the proximity between neurons responding to them. In the model mentioned above [14], there is no such a similarity and the archetypes are disconnected from each other. As a consequence, the model cannot interpolate between archetypes, losing the ability to compute a fine-tuned response to an ambiguous signal.

The information flowing through the brain is noisy and often uncertain. This is a major issue that has to be dealt with. Moreover, the proposed framework should have good potentials for learning on an unsupervised and online basis. Amidst classical categorisation systems in AI [19], none meets exactly these requirements. However, case-based reasoning [1, 8, 9], and fuzzy rules-based reasoning [9] provide ideas that can be a starting point for a specific formalism.

Our goal is to build a model dealing explicitly with cerebral information, while being as close as possible to neurophysiological reality, and flexible enough to incorporate new knowledge coming from

neurosciences. However, learning will not be addressed in this paper.

3 A MODEL OF A NODE IN A LARGE-SCALE CEREBRAL NETWORK

A node implements the information processing and propagation by a functionally coherent neuronal population. These mechanisms are based on a functional decomposition of this population.

3.1 Principle

3.1.1 Decomposition of a node

A node receives information through several inputs and emits one output. For each input, we consider a *receiving subpopulation* and, symmetrically, we consider another *emitting subpopulation*. Inside each subpopulation we consider patterns representing, i) in the case of the receiving populations, the neurons responding to a specific configuration of the input, and ii) in the case of the emitting population, the neurons firing to propagate the output. The output domain is discrete since the internal regions of the brain does not handle continuity (every continuous incoming signal, like audio waves for example, is “broken” into categories by primary sensory cortex). Receiving and emitting patterns are linked through inference rules using the following principle : an emitting pattern is linked to one receiving pattern in each receiving population. Hence, there is one inference rule per output category (i.e. emitting pattern). Although a given receiving pattern may be used in different rules, its contribution to the activation of the emitting pattern is rule-dependent. Therefore, what is referred to in the rule is not the receiving pattern *per se* (i.e. the neuron’s bodies) but a functional image of this pattern as it is used in the rule (i.e. the activated neurons : bodies *and* axons). From now on, “receiving pattern” will be used to designate those functional images (see Fig.1).

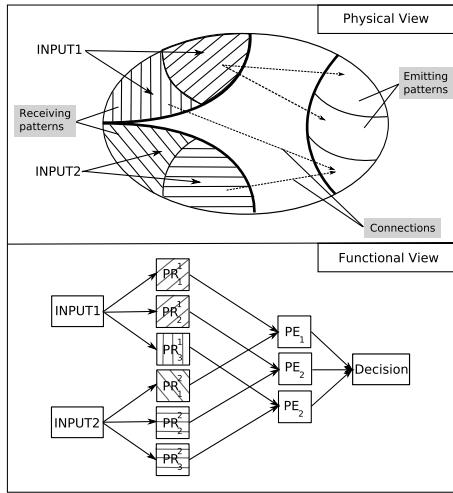

Figure 1: Physical view: the neuronal population is partitioned in two receiving subpopulations and an emitting one. Each receiving population contains two receiving patterns connected to the emitting patterns (some of the connections are not shown for readability’s sake). The functional view shows how two functional images of the same pattern can be used in two different rules.

3.1.2 Patterns

The patterns are formally fuzzy sets. In the case of emitting patterns, there exists one fuzzy set corresponding to each element of the output domain, that element being the core of the set. This element is called *referent* and characterizes the emitting pattern. The other members of the set will be referents of other emitting patterns and they belong to the set with a degree that reflects the similarity between these other patterns and the considered pattern. As for the receiving patterns, their cores contain the elements of the corresponding input domain that are perfectly recognised while the other members are the close-by and less recognised elements. The next section gives a formalism for these notions and presents the key equations describing it.

3.1.3 Inference Principle

Similarity of incoming information is computed against the receiving patterns. The more they are compatible, the more these patterns are activated. When the activity of a pattern exceeds a threshold, the pattern fires. When all the receiving patterns of an emitting pattern fire, this pattern is activated. Taking into account the similarity of the activated emitting patterns, a decision policy is then applied to decide which pattern fires the final output (see Fig. 2).

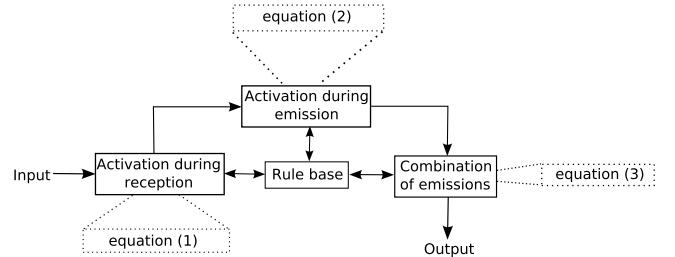

Figure 2: Inference principle

3.2 Formalism

Let X be a node with n inputs. Information is a couple (M, T) where M is the magnitude and T , the type. $M \in \mathbb{R}^+$ and T is a fuzzy set defined on \mathbb{D}_T , a discrete set. Let (M_i^{in}, T_i^{in}) be the incoming information on input i and (M_i^{out}, T_i^{out}) the output information. To keep the notations manageable, we call \mathbb{D}_i and \mathbb{D}_{out} the domains of T_i^{in} and T_i^{out} .

Let $\mathcal{BR} = \{R_i\}_{i \in [1, p]}$ be the inference rule base. We call PR_i^j the fuzzy set standing for the receiving pattern in input i for the rule R_j , and PE^j the fuzzy set standing for the emitting pattern corresponding to the conclusion of R_j . We call na_i^j (resp. sa_i^j) the level of activation (resp. the threshold of activation) of the receiving pattern PR_i^j . We call dec_i^j the firing level, i.e $\max(0, na_i^j - sa_i^j)$. Finally, we call dec^j the level of activation of the emitting pattern PE^j .

3.2.1 Activation during reception

For each time step, for each rule R_j and for each input i , the compatibility α_i^j of T_i^{in} with PR_i^j is computed as $\max_{C \in \mathbb{D}_i} \min(T_i^{in}(C), PR_i^j(C))$, which estimates the consistency

of the two fuzzy sets. Hence the activation level at time t is computed from the previous activation level by increasing it when α_i^j is sufficiently large and the pattern has not been already fired recently:

$$\begin{aligned} na_i^j(t) &= relax_X^{(1)}.na_i^j(t-1) + \\ &k.fact(\alpha_i^j, \tilde{M}_i(t)).f_{refract}(dec_i^j(t-1)) \end{aligned} \quad (1)$$

where,

- $fact$ is increasing from $[0, 1] \times [0, 1]$ on $[0, 1]$, and prevents information with a too low magnitude from passing through. \tilde{M} is a normalized magnitude ($\in [0, 1]$). $fact$ should be a threshold function, like a sigmoid for instance.
- $f_{refract}$ is decreasing from $[0, 1]$ on $[0, 1]$, with $f_{refrac}(0) = 1$ et $f_{refrac}(1) = 0$. It stands for the refractory period of the population, preventing it to activate again when it has been activated strongly before. A linear function ($f_{refrac}(dec) = 1 - dec$) or again a sigmoid can be used.
- $relax_X^{(1)} \in [0, 1]$ is called the relaxation parameter and characterises the temporal integration of the pattern. If it equals 0, there is no temporal integration.

3.2.2 Activation during emission

We have to update dec^j for each rule R_j . We assume that the combination of the emitting patterns obtained at the previous step is linear with respect to each component, hence,

$$dec^j(t) = relax_X^{(2)}.dec^j(t-1) + \sum_{i=1}^n p_i.dec_i^j(t-1) \quad (2)$$

where the p_i are parameters that have to be tuned in order to produce the more accurate simulation, and where $relax_X^{(2)}$ is the relaxation parameter for the emitting subpopulation, defined as above.

When the dec^j are known, we still have to combine and decide which pattern will fire. If there is only one emitting pattern activated ($dec^k \geq 0$), then the task is done and $T^{out} = PE^k$. However, when several rules R_{k_1}, \dots, R_{k_q} are triggered, there is a conflict that has to be solved. But first we will cumulate the activations, meaning that every time a pattern is mentioned as close to another, they will share their activations. If $rule(C)$ is the rule from which C is the referent, $dec^{rule(C)}$ is the total activation of the corresponding emitting pattern (i.e. direct activation summed with similarity activations):

$$dec^{rule(C)}(t) = \sum_{i \in \{k_1, \dots, k_q\}} PE^i(C).dec^i(t) \quad (3)$$

When all the activation levels are computed, we just choose the most activated pattern as the firing one.

3.2.3 Output magnitude

The magnitude representation is handled as causal connectivity as in [14], by a Bayesian-like propagation mechanism. The output magnitude depends on the one hand on the nature of the node (its function) and on the other hand on the level of compatibility of the incoming information. Formally,

$$M^{out}(t) = f_X^{(1)}(dec_{max}(t)).f_X^{(2)}(\overline{M^{in}(t-1)}, u) \quad (4)$$

where $\overline{M^{in}(t-1)}$ is the average over all the incoming magnitudes at $t-1$; u is a random variable standing for the noise, and dec_{max} is the activation of the firing emitting pattern. The function $f^{(1)}$ is increasing, defined from $[0, 1]$ on $[0, 1]$. Since its purpose is to generate a low output magnitude for something badly recognised, a threshold function would be a good choice. $f^{(2)}$ is a real function that may be non-linear.

3.2.4 Example

Let us consider a very simple example to make these equations somehow clearer. The focus will be on the inference mechanism letting aside the temporal aspect. To do so, we will describe the behaviour over one time step t_0 , in a completely relaxed node (there are no activation carried over from previous steps) and with all activation thresholds reduced to 0 (i.e. $\forall i, j, na_i^j(t_0-1) = dec_i^j(t_0-1) = 0$).

Consider a node with two attributes 1 and 2, with domains \mathbb{D}_1 and \mathbb{D}_2 , receiving respectively inputs T_1^{in} and T_2^{in} , with weights p_1 and p_2 . The magnitudes for each input are set to 1 and the parameter k is also set to 1. There are three “if...then” rules in the base :

$$(PR_1^1, p_1) \otimes (PR_2^1, p_2) \longrightarrow PE^1 \quad (5)$$

$$(PR_1^2, p_1) \otimes (PR_2^2, p_2) \longrightarrow PE^2 \quad (6)$$

$$(PR_1^3, p_1) \otimes (PR_2^3, p_2) \longrightarrow PE^3 \quad (7)$$

Where \otimes stands for conjunction. It then works in three steps :

- First, for each receiving pattern PR_i^j , reception activations na_i^j are computed. In this simplified case, it is just a matching rate between the pattern and the input (e.g. [9]), t_i^{in} being the input at t_0 :

$$na_i^j(t_0) = \max_{C \in \mathbb{D}_i} \min(T_i^{in}(C), PR_i^j(C)) \quad (8)$$

- Then, the direct activation dec^j of the emitting pattern PE^j is computed :

$$dec^j(t_0) = \sum_{i \in \{1, 2\}} p_i.na_i^j(t_0) \quad (9)$$

- Finally, the direct activations of the emitting patterns are combined using similarity and according to equation (3). Fuzzy sets PE^1 , PE^2 and PE^3 are shown in Fig.3. In the figure, c_1 belonging to PE^1 (whose referent is c_2) at a level h_1 means that the similarity between c_1 and c_2 is h_1 . It also means that the activation of the pattern whose referent is c_1 will contribute to the activation of PE^1 with h_1 as a discounting factor. The equation (3) gives us: $dec^{rule(c_1)}(t_0) = dec^2 + h_2 \cdot dec^1$; $dec^{rule(c_2)}(t_0) = dec^1 + h_2 \cdot dec^2 + h_1 \cdot dec^3$; $dec^{rule(c_3)}(t_0) = dec^3 + h_1 \cdot dec^1$, where $dec^{rule(c_i)}$ is the total activation of the pattern of referent c_i . The most activated pattern (i.e. for which $dec^{rule(c_i)}$ is maximum) is then chosen as the final output.

4 APPLICATION TO PHONEMIC DISCRIMINATION

As an illustration we have built with a unique node a very simple phonemic discriminator. This has permitted to reproduce an auditory illusion, the McGurck Effect.

4.1 Model

To define a phoneme, we use the articulatory theory of language that characterises a phoneme by the way we produce it. Table 1 represents

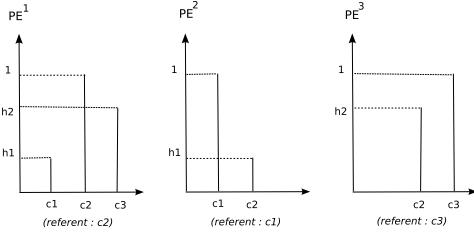

Figure 3: Emitting patterns

a simplified French phonologic system. The two described attributes (locus and mode of articulation) are our two inputs. The similarity follows what lines Table 1 suggest and we only focus on [b], [d] and [g] (i.e. [b] “is close” to [d] and “less close” to [g] and [d] “is close” to [g]).

Table 1: Consonants in the French phonologic system

locus \Rightarrow mode \Downarrow	labial	dental	velar
plosive voiceless	p	t	k
plosive	b	d	g
nasal	m	n	

The node is built with already learned categories. Assume there are four receiving patterns : $PR_{bil} = \{(bil, 1.0), (lab, 0.6)\}$, $PR_{dea} = \{(lab, 0.6), (dea, 1.0), (alv, 0.6)\}$, $PR_{vel} = \{(pal, 0.6), (vel, 1.0)\}$ and $PR_{plo} = \{(plo, 1.0), (plv, 0.6)\}$. There are three categories (i.e. emitting patterns) already implemented in the node : [b], [d], [g] and the corresponding rules are shown in expression (10). The parameters are : $k = 0.6$, and $relax^{(1)} = 0.98$ (for eq.1), and $relax^{(2)} = 0.15$ (for eq.2).

$$R_b : (PR_{bil}, 0.5) \otimes (PR_{plo}, 0.5) \rightarrow \{(b, 1.0), (d, 0.6)\} \quad (10)$$

$$R_d : (PR_{dea}, 0.5) \otimes (PR_{plo}, 0.5) \rightarrow \{(b, 0.6), (d, 1.0), (g, 0.6)\}$$

$$R_g : (PR_{vel}, 0.5) \otimes (PR_{plo}, 0.5) \rightarrow \{(d, 0.6), (g, 1.0)\}$$

Figure 4 shows the response of the node to a stimulus [b]. The stimulus is presented during 50 ms, every second, to allow neuronal processing to take place.

We see clearly that only the pattern [b] fires, the other two staying unactive all the time. Now what happens when we change the threshold?

4.2 McGurck Effect

Figure 5 shows the principle of this illusion discovered in 1976 by McGurck [18]. The visual [ga] is a person articulating a [ga] while the sound played is a [ba]. Using some recent insights about its neurophysiological nature, we implemented it using the same node but in a modulated way, i.e where the thresholds triggering the category [g] are lowered when a visual [g] is presented along with an auditory [b]. Thanks to the combination of activations in the emitting patterns, the response comes as a [d] (see Fig.6). Because of the lowering of the activation threshold, the emitting pattern [g] gets activated, and the pattern [b] is activated by the stimulus itself. If we look at Table 1, we see that between these two sounds, stands the [d]. Hence, the pattern [d] is close to the other two and gets activated when they are,

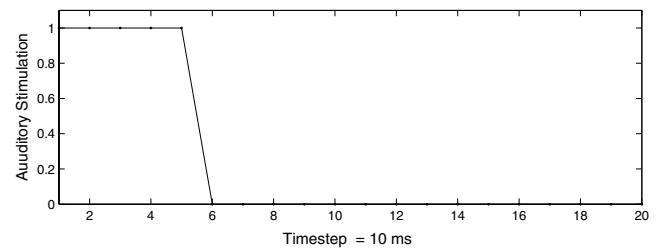

Figure 4: Activations of the emitting patterns, in response to an auditory stimulation of type [b]

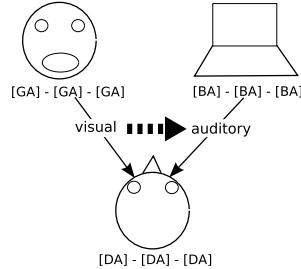

Figure 5: The simultaneous presentation of a ‘visual’ [ga] and of an ‘auditory’ [ba] leads to the auditory perception of a [da]

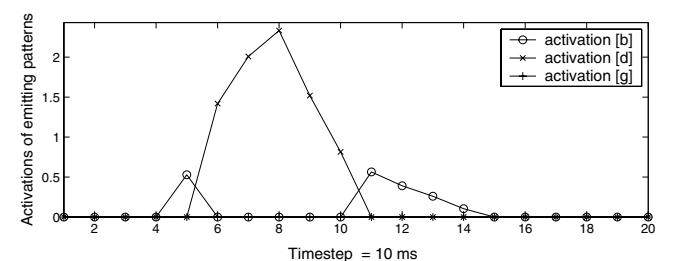

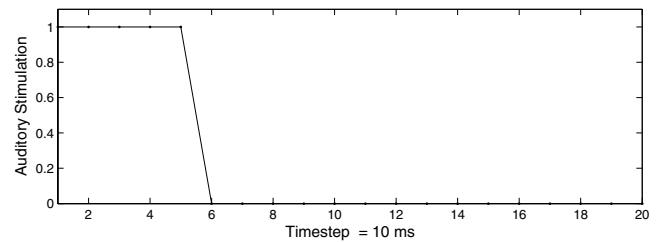

Figure 6: Activations of the emitting patterns in response to an auditory stimulation of type [b], modulated by a visual stimulation of type [g].

according to the principle of combination of activation 3.2.2. If [d] is close enough of the other two, it will exceed with this combination the activation of [b] or [g] alone and be the winner of the competition. That is what happens here.

In this simple experiment, we have shown that this model of a node can discriminate language sounds, and even reproduce an auditory illusion that was impossible to reproduce in a simple manner with previous models based on causal connectivity. However, we are not claiming that this experiment is an accurate description of how the real McGurck effect is produced by the brain. At least, it shows a demonstration of how we can use the model to simulate observable phenomena with a proper choice of parameters.

5 CONCLUSION AND FUTURE WORK

Cerebral modelling is particularly important in the medical field, to better understand the possible outcomes of a lesion or a degenerative disease. Causal connectivity [14], although promising, is still lacking a certain biological plausibility. In this work we tried to fill this gap a little, and we managed, doing that, to reproduce a phenomenon that was not modelled before by the other models of this family.

Our approach found its roots in empirical knowledge on neurophysiology and we scaled it on an “intermediary level”: the neuronal populations. This interpretation finds an interesting echo and a beginning of formal justification in the work of Balkenius and Gardenfors [5, 6], who proved that it was possible to produce non-monotonic logical inferences using activation patterns of neuronal networks. The inferences could then be encoded by weighted formulas as in possibilistic logic [7]. This calls for a comparison with the similarity-based inference mechanism as a future line of research.

Regarding the future work, dynamic learning mechanisms are being developed to build and tune the rules using only incoming information. In terms of machine learning, it is an *online* and *unsupervised* learning. We plan to test these learning abilities in two ways. They will be compared to other algorithms on machine-learning benchmarks. We will also design a simple categorisation experimental task and will compare results of the task performance by humans and by the model. Furthermore, using the work of Balkenius and Gardenfors as a starting point, we would like to formally prove that the neuronal substratum can support high level logic when one reasons in terms of patterns. This would contribute to fill the gap between connectionism and symbolic logic. Lastly, it has been shown in biology that the action of different neurotransmitters modulates the behaviour of neuronal populations (e.g. threshold lowering as in McGurck effect, see 4.2). By modelling specifically this action, we would be able to modulate our system in a systematic manner, while being even closer to biological reality [15].

Imitation of intentional behaviour

Bart Jansen¹

Abstract. In this paper a computational simulation of the imitation of intentional behaviour is presented. Important assumptions which make the problem computationally tractable are introduced and motivated. It is shown that horizontal, iterated learning, and vertical transmission schemes can be used to learn from imitation using the proposed framework.

1 Introduction

Robot imitation has been studied intensively over the past decade, as it yields the promise of extremely easily programmable robots: rather than completely specifying a task in a programming language, a task can be demonstrated to the robot. Simply by observing, the robot learns to perform the task himself. Depending on the precise application, different aspects of a behaviour must be imitated. In some cases, it is important that the demonstrated behaviour is replicated as reliably as possible (action level imitation) [11, 13, 3, 10, 5]. In goal level imitation [18, 1, 4, 7, 17], not the exact actions are copied, rather the intention of the demonstrator is deduced and a goal is achieved without reproducing the precise actions.

We propose a computational simulation of imitation of intentional behaviour. As a casestudy we investigate the imitation of spatial constraints on a blocks world and show that the proposed approach can be used in either horizontal, vertical and iterated learning schemes.

2 Case study

The experimental setup for this casestudy is depicted in figure 1². Every agent is equipped with a robot arm and can manipulate blocks on a board. With a camera system the agent can observe its own manipulations, but also the manipulations of the interacting agent. The agents can only perform very simple operations to the blocks world, like moving a block one cell to the right. A particular property of this experimental setup is that every agent acts on its own blocks world, containing the same objects. By consequence, the objects will be at different positions on each agent's blocks world, such that simple copying of actions will not result in successful imitation. Importantly, the assumption of individual environments is not essential for the presented results.

The goals the agent can learn in this blocks world express its desire to have the blocks world arranged such that it matches certain criteria. These criteria are expressed as relations over the blocks and can be combined. A possible goal is for instance $Above(A, B) \wedge LeftOf(B, C)$, supposing that the blocks world contains at least the blocks A , B and C and that the agent knows the relations $Above$

Figure 1. The agents each have a board on which configurations of blocks are demonstrated and imitated.

and $LeftOf$. This goal states that the agent pursues a configuration of the blocks world in which block A is above block B and block B is at the left of block C . Goals thus pose topological constraints on the blocks. Most often, such goals can not be reached within a single action, they thus require planning. When another agent observes such a sequence of actions, he has no unique mapping from actions to goals available. Complex processing is required to infer goals from observed sequence of actions. We propose perspective taking as a key mechanism, i.e. the imitator must be able to reason on the perceived action sequences as if he was the demonstrator.

3 Assumptions

A general strategy for deducing the intentions in others' actions can be based on the detection of structure or statistical regularities in the observed actions [6]. However, in general, the recognition of the goal of the other agent's actions is tremendously difficult. One of the reasons is that the mapping from goals to actions is very difficult to grasp. Two agents performing the same sequence of actions might pursue a different goal, while two agents performing different sequences might pursue the same goal [2]. So, the set of possible goals that an agent might pursue when performing a given sequence of actions is huge. In order to enable the agents to attribute goals to the actions they see other agents perform, this enormous search space must be constrained. This can be accomplished by taking external information into account, being for instance knowledge about human behavior in general, prior knowledge about the agent performing the actions and knowledge about the situation [2, 19, 21]. In order to restrict this search space and to allow for the efficient implementation of a goal detection method, several important assumptions are made. The first assumption poses constraints on the actions the agents can perform, the second one constrains the perceptual mechanisms and the third assumption forbids deception of the imitator by misleading actions. The fourth assumption states the existence of a memory of

learnt goals which is actively used for the recognition of goals. Every assumption is discussed in detail below.

3.1 Action constraints

Crucial in goal recognition is the ability to recognise the actions the other agents perform as actions one can perform himself. Therefore, it is tempting to assume that all the agents have the same set of actions they can use to manipulate their blocks world. The actions we suppose to be shared are actions which manipulate the blocks world and are possibly composed of many subparts. Such an action could for instance be “move block x one cell to the left”. In order to accomplish this, the correct block should be identified, the agent should verify whether the border of the blocks world is reached, reach for the object, grasp it, and so on. We do not suppose that all agents perform all these subtasks in exactly the same manner.

3.2 Perceptual and representational constraints

In order to be able to express spatial relations on a blocks world, agent must be capable to detect those spatial relations when they observe a changing configuration of blocks on the board. Therefore, each agent is endowed with a set of relational primitives. Primitives can differ among agents, but must have the same expressive power in order to be able to imitate successfully. In [14] it is investigated how differences in expressive power affect the agent’s performance in learning goal-directed behaviour from imitation.

3.3 Planning constraints

We assume that the agents do not fool or confuse each other by performing actions which are irrelevant for the pursued goal. This assumption is based on the principle of rational action, which assumes that actions function to realize goal-states by the most efficient means available [12].

We exploit this assumption to such a degree that we suppose that the planning algorithm inside each agent is optimal. So, if the goal can be reached by performing only x actions, no $x + 1$ actions are performed. This does however not mean that all agents come with the same planning algorithm, as long as it produces optimal plans; most goals can be obtained by different optimal sequences of actions. Using this strong assumption, the imitator knows that every action performed by the demonstrator is directly relevant for obtaining its goal. This knowledge is used to seriously reduce the set of possible goals for an observed sequence of actions.

3.4 Memory constraint

The approach we propose differs from some others in that we do not allow the agent to construct a goal for every sequence of actions it observes. We use a memory-based approach; agents store goals they have encountered (their *repertoire*) and try to categorize the observed sequence of actions as a goal from this repertoire. Only when categorization fails, a new goal is constructed. Together with the memory for goals, mechanisms are implemented for maintaining it: there is a novelty detector and a mechanism to add new goals and a mechanism to remove goals which have proven to be good ones. Initially, the agent’s repertoire is empty. During the imitative interactions, the agents build up their repertoires.

Generally, the learning of a repertoire of goals and imitation of goals are considered to be two different tasks. In our approach, the agents learn a repertoire of goals and imitate goals at the same time.

4 A computational model

The computational model we introduce here is based on *imitation games* which were used in study of the emergence of vowel systems [9] and in the study of action level imitation [16]. An imitation game is an interaction between two agents which are selected randomly from a population. One of them is assigned the role of *demonstrator*, the other one acts as an *imitator*. During the interaction, the imitator tries to imitate the demonstrated behaviour and learns from it by adapting the repertoire of known goals. The computational model will be explained assuming a single teacher with a fixed repertoire of goals and a single student, starting without any goals. By observing multiple demonstrations, the imitator should acquire all goals known by the demonstrator. Further in the document, it will be shown that the framework can be used for horizontal and iterated learning as well.

Every agent A_k learns and maintains a repertoire R of goals. Each goal in the repertoire has a usage counter and a success score associated, so $R = \{(g, u, s)_i\}$. A goal g itself consists of a conjunction of predicates $g = q_1 \wedge q_2 \wedge \dots \wedge q_n$ where all predicates $q_i \in P_k$.

The imitation game is defined as follows:

1. The demonstrator randomly selects a goal g from its repertoire, builds a plan p for it and executes the plan p .
2. The imitator observes this sequence of actions and finds the best matching goal g' from its own repertoire. If no suitable goal can be found in its repertoire, the game fails and a new goal is constructed.
3. The imitator builds a plan p' for reaching the goal g' in its own environment and executes the plan p' .
4. The demonstrator observes this sequence of actions and verifies whether its initial goal g holds in the blocks world arranged by the imitator. If that is the case, the game succeeds, in all other cases it fails.
5. The demonstrator informs the imitator about the success of the game. He sends a single bit of information to the imitator.
6. The imitator adapts its repertoire.

Below, several crucial components are each described in detail.

4.1 Planning

Given the configuration of the blocks in its environment and a goal, the agent has to build a plan for reaching the goal. A plan p consists of a sequence of actions $a_1 \dots a_n$ where $a_i \in A$ and A is fixed and known to all agents in the population. Rather than finding a sequence of actions which lead to a random state in which the goal holds, the agents search for a plan which requires as few actions as possible to obtain a state in which the goal holds. Since we suppose that all agents have a planner which satisfies this constraint and since we suppose that all agents know this, the exact sequence of observed actions contains useful information for constraining the search space when inferring the goal in a sequence of observed actions. Agents know that every single action in the sequence is strictly required for obtaining the goal. Technically, the plan is built using A*-search. If no plan can be found before a given depth is reached in the search tree, the search is aborted and the imitation game fails.

4.2 Learning

The imitator starts with an empty repertoire and learns its repertoire of goals by observing and imitating the demonstrator. The imitator

uses two sources of external information to learn from: firstly, by observing the sequence of actions performed by the demonstrator, he can infer a candidate goal for the demonstrator's actions, using its own repertoire and planner. How this complex task is accomplished, is explained in detail later in this paper. If the agent fails to infer a goal, it can construct a new candidate goal based on the observed sequence of actions. Secondly, the imitator is informed about the quality of its hypothesis, since the demonstrator sends feedback about the outcome of the game.

4.2.1 Maintaining a scoring mechanism

At the end of every game (step 6), the imitator can remove goals from its repertoire which have proven to be unsuccessful in the past. Therefore, a success score is associated with every goal. When goals are first added to the agents' repertoires, their success score is set to 0.5. Once the success score of a goal drops below the parameter value ϵ , the goal is removed from the repertoire of the agent.

Whenever imitation succeeds, the success score of the used goal is increased with δ , while the success scores of all other goals in the hypothesis set³ are decreased with the same amount (success scores are limited between 0 and 1). When the game fails, the opposite is done, meaning that the score of the used goal is decreased by δ , while the scores of all other goals in the hypothesis set are increased. This implements a kind of *inhibition* [20].

4.2.2 The construction of a new goal for a given sequence of observed actions.

When goal inference fails, agents can construct a new goal, based on the observed sequence of actions. This is not an easy task since the newly constructed goal should match the goal the demonstrator of the action sequence had in mind. Since telepathy is not allowed, only the observed actions can be used, together with the knowledge deducible from the four main assumptions outlined at the beginning of the paper. The construction of the new goal consists of two major steps: first a set of goals C which meet certain criteria is determined. Later, the most plausible goal from this large set is selected.

Due to the optimality constraint, it is not possible that a candidate goal already holds in the second last state, since the last action would be useless then. Thus, at least one of the predicates which hold in the last state, but do not hold in the second last state, must be part of the goal. Therefore, the imitator determines the sets P_n and P_{n-1} . P_n contains all predicates which hold in the last state s_n . The conjunction of any of the predicates in this set could be the goal intended by the demonstrator. The set P_{n-1} contains all relations which hold in the previous state s_{n-1} . Given both sets, the imitator can find relations which became valid when the demonstrator performed the last action. He defines $X = P_n \setminus P_{n-1}$ and $Y = P_n \setminus X$. Thus, the set P_n is partitioned into two parts: X and Y . Candidate goals $c \in C$ are generated by making the conjunction of at least one element x from X and zero or more elements y from Y . All goals c share the common property that they are valid in the last state s_n but not in the previous state s_{n-1} . The goal intended by the demonstrator is thus always a member of this set.

The imitator now has to estimate how well every candidate goal c is suited for explaining the observed sequence of actions performed

by the demonstrator. In order to assess that, the imitator can imagine what actions the demonstrator should have performed if its goal was indeed the candidate c . Therefore, the imitator builds a plan for reaching the goal c starting from the initial blocks configuration of the demonstrator s_0 . However, since both agents might have a different planning algorithm, this plan can not be compared directly to the observed sequence of actions. Nevertheless, the length of the plan imagined by the imitator provides information about the goal candidate c . Since it is assumed that the planner of every agent is optimal: the demonstrator reached its goal in as few steps as possible. Thus, if the plan built by the imitator for the candidate goal c requires less steps, the candidate goal c can not be the goal the demonstrator intended. Probably, the candidate goal is too general. On the other hand, if the plan built by the demonstrator requires more steps, the goal c is probably too specific, since more specific goals tend to require more actions before they are met than more general ones. Thus, the imitator removes all goals from its candidate set C which he can not reach in the demonstrators environment in the same number of steps as the demonstrator did.

From the remaining goals in the candidate set C , the shortest goal which is not already in its repertoire is selected as the goal the imitator constructs for the observed sequence of actions. By selecting the shortest one, there is a pressure on the imitator's repertoire to be as general as possible. Therefore, it might be that the goal of the demonstrator is more specific than the goal of the imitator, which might cause the game to fail. In later interactions, more specific goals might be created in such case.

4.3 Goal categorization

When the imitator observes the demonstrator performing a sequence of actions, he has to categorize the observed sequence as one of the goals in its repertoire. This is implemented by two filters operating on the repertoire of the imitator. Initially the set C of candidate goals contains all goals in the repertoire of the imitator. Firstly, the imitator verifies for every goal in C whether the goal holds in the last state s_n of the demonstrator's actions and does not hold in state s_{n-1} . Only goals matching this initial criterion are kept as candidate goals, others are removed from C . Secondly, the imitator builds a plan for every goal c in C starting from the initial state s_0 of the demonstrator's blocks world. Thus, here the *imitator* imagines a plan the *demonstrator* could have built for a given goal and a given state. Since planners are optimal, if the initial goal of the demonstrator was indeed c , the plan imagined by the imitator must have the same length as the action sequence performed by the demonstrator. If this is not the case, it is not possible that c was the original goal of the demonstrator. Therefore only goals c with the same length as the observed sequence of actions remain in C . The remaining set is called the *hypothesis set* and from this set the goal with highest score is selected.

In several cases, the goal categorization process can fail: the repertoire of the imitator can be empty. Also after the filter operations, the candidate set C might become empty. In all those cases the game fails.

5 Experiments

5.1 Experimental setting

The environment of the agents consists of a two dimensional five-by-five simulated blocks world, consisting of the blocks $BS = \{A, B, C\}$. Agents can manipulate those blocks; a block can be moved a single cell in any of the four directions:

³ The definition of the hypothesis set is given later. For now this set can be seen as containing all goals from the agent's repertoire which match the observed sequence of actions, but which have lower scores than the candidate goal.

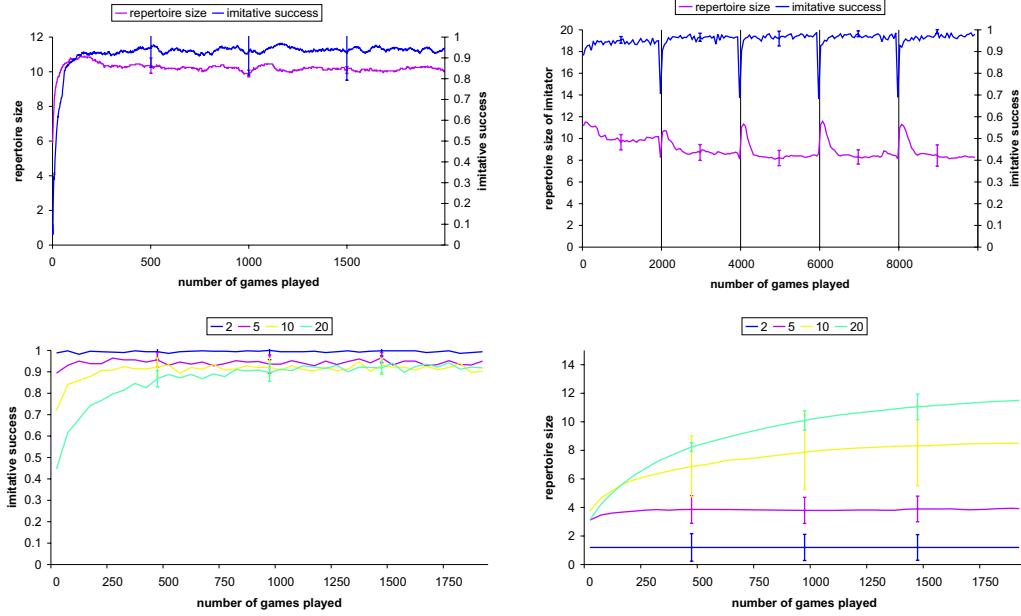

Figure 2. Top left: Results for a vertical transmission experiment. Top right: Results for an iterated learning experiment. Bottom: results for a horizontal transmission experiment.

$up(x)$, $down(x)$, $left(x)$, $right(x)$, where x denotes a block in BS . The plans built by the agents consist of several of those actions. In the experiments reported here the goals in the repertoires of the agents are represented as conjunctions of the predicates $Above?(x, y)$ and $LeftOf?(x, y)$. δ was set to 0.025, while ϵ was set to 0.1.

5.2 Measures

The performance of the agents is investigated by measuring the imitative success and the repertoire size. The imitative success is simply the fraction of games which resulted in successful imitation. A running average over a window of 100 games is calculated. Measures are explained in more detail in [15].

5.3 Vertical transmission of goals

In this first type of experiments, we consider a single demonstrator and a single imitator. The demonstrator starts with a repertoire of k different goals and tries to pass this repertoire as reliably as possible to the imitator. The goals in the repertoire of the demonstrator are generated randomly and consist of one or two predicates.

Using the parameter values stated above and $\delta = 0.025$, $\epsilon = 0.1$ and $k = 10$, imitative success is plotted in the left upper part of figure 2. Unless explicitly mentioned, all results presented in this paper are obtained by playing 2000 games and averaging over ten runs. 95% confidence intervals are plotted on the graphs whenever appropriate.

The results show that the repertoire of the demonstrator can indeed be transferred to the imitator: imitative success is stable and above ninety percent, throughout the 2000 games. The repertoire of the imitator also contains ten goals, almost from the beginning of the experiment. The goals which are learnt by the imitator are very similar to the demonstrated ones, but are not necessarily the same. Space

limitations prevent us from investigating the similarity between both repertoires in more detail. This and detailed parameter studies are presented in [14].

5.4 Iterated learning

In order to investigate the stability of the repertoire over transmission, it is useful to design an iterated learning [22] experiment. In such an experiment, an initial demonstrator is endowed with a repertoire consisting of k random goals. This repertoire is learnt by an imitator. After l interactions, the imitator becomes the demonstrator and a new imitator with an empty repertoire is created. In the top right part of figure 2 results of such an experiment are shown. The initial demonstrator starts with $k = 10$ random goals and every 2000 interactions, roles are changed. Even at the fifth generation, the repertoire of the imitator contains ten goals on average, while imitative success climbs to above 95% after an initial decline. The evolution of the repertoires over several generations is investigated in depth in [14].

5.5 Horizontal transmission of goals

In this experiment, we investigate whether a shared repertoire of goals can emerge in a population of agents, by repeatedly playing imitation games. A population consists of any number of agents, which now all start with empty repertoires and all can both take the roles of demonstrator and imitator. As all agents now start with empty repertoires, initially no games can be played, since the demonstrator also has no goals in its repertoire. Therefore, the game is slightly modified compared to the game used in the vertical transmission experiments: agents are now allowed to add a random goal to their repertoire whenever their repertoire is empty. This allows them to start the imitation games.

Results of experiments with populations of two, five, ten and twenty agents are given in the bottom part of figure 2. The graphs

indicate that stable repertoires of goals are learnt and that imitation is successful, independent of the population size.

6 Discussion

We have proposed a mechanism for the imitation of goals in a population of simulated agents. In this setup, goals are represented as spatial relations over the blocks in the agents' environments. With this approach, we deviate from the often made assumption that the goal of the agents' action is a certain configuration on the board; in our case not the configuration itself, but certain properties of the configuration are imitated.

The experimental setup was designed such that the mere copying of the actions performed by the demonstrator (*imitation of actions*) results in a failed interaction, because the agents operate on their own blocks world and thus all start with different configurations. Whether agents operate on a shared environment or each on their individual environment is not important for the model, the choice for separate environments is purely for illustrating this property.

Also the copying of the easily observable end configuration (which reduces it to *imitation of effects*) is not what is studied in the work proposed here. We and several others have argued that the endstate itself does not contain enough information for recovering the intent of the demonstrators' actions (e.g. [21, 2]). Therefore the imitator uses several sources of information for recovering the intent of the demonstrator (*imitation of goals*): the observable endstate as it was produced by the demonstrator, the sequence of actions performed by the demonstrator, context information, and a memory of previously learnt goals. Together, they allow the imitator to identify those spatial properties the demonstrator wanted to be fulfilled. The precise nature of the context information and the memory component were stated in four assumptions which were introduced and motivated.

In the approach used, the task of the imitator can not be summarized as *plan recognition*[8]. In plan recognition an agent observes a sequence of actions (a plan is operationalized) and compares this sequence of actions to every plan in its repertoire. In plan recognition, this repertoire of plans is predefined and not modified by a learning process. In this work, the agents do not store plans, but goals. Moreover, the repertoire of goals is learnt, rather than predefined.

In the vertical learning scheme, a single demonstrator starting with a predefined repertoire of goals interacts repeatedly with a single imitator, who's task is to learn the repertoire of the demonstrator. In the iterated learning scheme, the imitator can replace the teacher and the imitator is then replaced by a virgin imitator every N interactions. In the horizontal transmission scheme, a population of agents is considered. All agents start with empty repertoires and can interact with each other, both in the roles of demonstrator and imitator. Independent of the transition scheme and the precise parameter settings, we have shown both successful imitation and successful learning of repertoires of goals which are shared by all agents.

Dramatization Meets Narrative Presentations

Rossana Damiano^{†‡}, Vincenzo Lombardo^{†‡}, Antonio Pizzo^{*‡} and Fabrizio Nunnari^{†**} ¹

Abstract.

In recent times, information presentation has evolved towards sophisticated approaches that involve multi-modal aspects and character-based mediation.

This paper presents a novel methodology for creating information presentations based on a dramatization of the content exposition in two respects. On one side, the author plots a character's monologue that aims at achieving presentation goal and exhibits an engaging inner conflict; on the other side, the system architecture dynamically assembles the elementary units of the plot scripted by the author by implementing a tension between contrasting communicative functions.

The methodology has been applied in the implementation of a virtual guide to an historical site.

1 Introduction

A wide range of recent multimedia applications, from virtual assistants to video-games, exhibit sophisticated approaches to information presentation that involve multimodal aspects, narrative forms [13] and character-based mediation [29].

The use of artificial human-like characters improves the naturalness of the interaction with the user, making the system appear more responsive and cooperative. Much research has addressed the capability of engaging a natural face-to-face dialogue in the framework of Embodied Conversational Agents (ECA [7, 6]). The methodology for building ECAs ranges from synthesizing behavior from an abstract specification of the character to assembling pre-defined units [3, 25, 26]. In the latter case, the methodology usually involves a repository of elementary units in terms of synthetic speech, facial expressions, head movements, that are used to fill in pre-defined dialogue structures in response to user queries.

Most of the research in the field of embodied agents has focused on accounting for the emotional and expressive aspects in the multi-modal presentation of contents, while the organization of content in the exposition usually relies on simple templates derived from narrative theories like those by Propp [27] and Greimas [14]; the role of the author and the consequent production pipeline in the ECA-based system design remains unclear.

This paper focuses on methodological aspects of designing interactive information presentation systems based on artificial characters. The methodology we propose, called DramaTour, assumes that the generation of expressive behavior relies on the editing of audio-

visual elementary units in response to user input. In the DramaTour methodology, the interactional and communicative strategies of the artificial character are explicitly driven by the notion of *drama*: the presentation delivered to the user is characterized by the inner tension and the sense of direction that are typical of dramatic narrations. Information presentation becomes a dramatic monologue, in which the character exhibits an inner conflict in front of the audience, who reacts to the character's behavior. Dramatization applies to both the production of dramatic elementary units (from the writing of the script to its interpretation by the virtual character through animation) and the editing operated by the system in delivering the content to the user.

The idea of dramatizing the content, i.e. the fact that the information to be presented is encoded in a dramatic form has been recently explored, especially in the entertainment context, by the novel field of interactive storytelling. Posited at the junction of computer graphics and AI, interactive storytelling techniques aim at controlling both plot generation and real-time character behavior, mostly through planning systems [8]. Interactive storytelling involves the creation of an engaging story and its factorization into elementary units, the implementation of an AI system that reacts to the user's inputs in real time in order to assemble a dramatic performance from such elementary units, the organization of the story material within the framework provided by the AI system. These issues have been explored in some depth in the context of game design [19] and interactive drama for entertainment [22, 23].

In this paper, we apply interactive storytelling to information presentation. The working assumption is that a dramatic character, who acts in first person and shares the user's present time and space, yields a powerful effect of physical and emotional presence, especially when conveyed through an audiovisual display (cf. Esslin's notion of *dramatic media* [11]). This results in a greater effectiveness on content reception [20].

In order to create an effective system and test the practical effectiveness of the approach, the generation of the character behavior relies on pre-defined audiovisual behavior units that are assembled in real time. These units are categorized through meta-data, that serve the function of identifying their interactional and informational purposes. The applicative domain in which we are currently testing this methodology consists of guided tours in an historical site accompanied by a virtual character on mobile devices.

The structure of the paper is the following. First we describe how the notion of dramatization is put at work in this paper. Then, we present the methodology, both AI system architecture and content organization. Finally, we present the test application.

2 Dramatic issues put at work

In this section, we illustrate the aspects of the methodology that introduce the notion of dramatization in the design of a presentation

system of the type sketched above i.e. an interactive guided tour to be played by an artificial character on a mobile support in a museum, exhibition or historical site.

In line with the notion of drama formalized in [9], we see drama as the combination of two main features: the fact that drama displays action at present time and the fact that it enacts a relevant conflict related to an emotional-dramatic value concerning the characters. Drama moves toward the solution of this conflict, yielding the typical impression of movement, and does it through a sequence of elementary units, called beats [24]. Beats are pure actional units formed by a action-reaction pair.

The solution of the the conflict is called “direction”: it derives from the notion of “unity of action”, originally expressed by Aristotle [2] and clearly stated by Stanislavsky and Styan [28, 30].

2.1 Drama in Information Presentation

The principle of first-person, present-time action must be enforced by the authoring of the behavior units. The character’s behavior, in fact, is not synthesized from an abstract specification of the character, its personality, its will. So, the methodology poses some constraints on the form of data: the data encoded by the author must contain an explicit description of their informative content and of their interactional function, that the system can rely on to sequence the units according to a consistent communicative and interactional strategy.

The dialectics between different presentation modalities substantiates a dramatic conflict. The emergent behavior of the presentation system should resemble as much as possible to a carefully authored monologue, in which an internal conflict of the character is exposed to emotional response of the audience. For example, in the test application described below – a guide to a historical site – describing objects and narrating stories about the site may be put in a dialectical opposition, in which the descriptive task leaves the way, as the visit progresses, to the narration, thus realizing a shift of the character from “guide” to “storyteller”.

The advancement of drama performance, i.e., the realization of the drama direction, depends on a continuous exchange between the presentation carried out by the character and the response of the audience - intended here as the individual user - who manifests acceptance or rejection of the presentation through the input she/he provides to the system. Going back to the museum guide example, by moving to a different location, the user may implicitly communicate interest or lack of interest for the presentation, while pen-pointing on the interface controls, she/he may signal the desire to direct the presentation focus on a different object.

By applying the overall schema described above, the engagement of the audience/user is achieved by the emotional involvement in the satisfaction of the character’s goals. The characterization of emotions which the methodology implicitly refers to is the cognitive model of emotions by Ortony, Clore and Collins, in which the activation of emotions directly relates to the motivations of a rational agent [1]. The character on the virtual stage clearly wants to please the audience: as long as this goal is achieved, the character feels more and more satisfied, concretizing its initial feeling of hope into increasing self-gratification. However, this change cannot be accomplished without the passive or active intervention of the user: this fact projects the user/system interaction schema into a *meta-theatrical level*, in which the user is, at the same time, the ultimate object and an instrument of the performance.

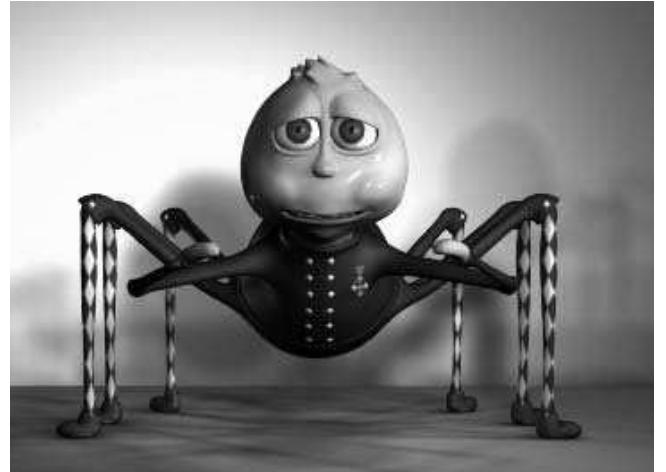

Figure 1. Carletto the spider.

2.2 An Example of Information Presentation

The test application of the methodology presented here is currently being tested in the historical location of a former residence of the Savoy family. The application consists of an interactive guided tour on a mobile device enacted by a teenage spider, which we will refer to as “Carletto”, whose family has inhabited the palace from ages. Carletto not only knows the history of the palace in detail, but knows a lot of funny anecdotes about the people who have lived there through the centuries, and is striving to tell them to the visitors.

The conflict between the role of an “audioguide”, who exposes facts orderly and plainly according to the topology of the location, and the desire to recount all the trivia and the anecdotes he knows from an historical perspective - most of which see him or his family personally involved - meet the methodology guideline of centering the presentation on an internal conflict of the character to gain the attentional and the emotional engagement of the users. Following the author guideline according to which the character itself must be carefully dramatized in the behavior units, Carletto engages in a continuous fight with the janitors, who would like to kick him out of the place.

The application is run on a mobile device. The user input consist of pen pointing on the graphical interface and localization through the use of wireless infrastructure. Abstracting from aspects of social interaction and visiting protocol, we give a short sketch of how the presentation is delivered to the user by Carletto. The visit is structured along a topological dimension, that models the palace as a set of rooms. At the beginning, Carletto follows a topological order, based on the current localization of the user. Each time the user enters a room, Carletto starts (or resumes) the presentation of the objects (furniture, artworks) in the room. When a certain amount of the room subtopics have been illustrated, Carletto happily switches to an anecdotic presentation style for a while, then gently starts inviting the user to a new room. If the user does not move, Carletto activates a “phatic function”, by playing funny games and gazing to the user from time to time.

3 The DramaTour methodology

The DramaTour methodology addresses the three issues sketched in the Introduction (story factorization, interactive story composition, drama-based and narrative-based content organization). In particular, it defines a system design that on one side provides a framework for conceptually organizing the behavior units of the system, and on the other side provides an architecture that reacts to user's inputs and assembles the units in real time. Consequently, it requires the author to create the presentation by thinking of a factorization in elementary units that the system will subsequently shape into a coherent drama direction along the interaction with the user.

The system architecture has a modular structure (see Section 3.1): the handling of the interaction with the user is mapped onto the *interaction manager*; the content organization is mapped onto the *presentation manager*; the ultimate delivery to the user in a well-edited, audiovisual continuum is handled by the *delivery manager*.

The author categorizes the units (that are scripted, interpreted and visualized) according to an ontological representation of the presentation topics and the communicative functions that contribute to the dramatization of the content delivery. The specification of the form of data (detailed in Section 3.2) concerns the set of meta data which describe the informational content conveyed by the behavior units, the interactional functions they realize and the audiovisual properties that characterize them.

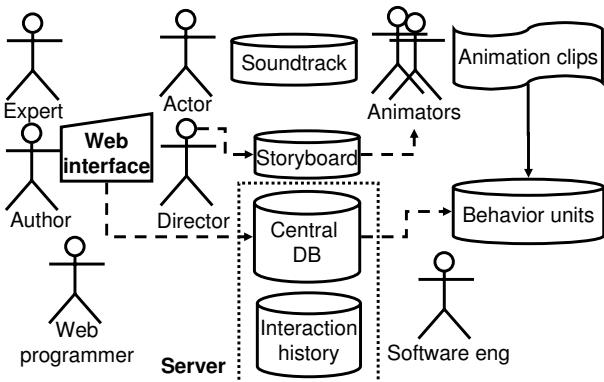

Figure 2. The production pipeline.

3.1 System architecture

The system architecture is inspired by the BDI agent model [5]: the system first selects a high-level communicative goal, then, given its library of actions, forms the intention to achieve the appropriate action; finally, it brings about the intention it is committed to by performing the action. However, the DramaTour methodology does not incorporate a full-fledged BDI model. The system does not represent goals and intentions explicitly, and does not monitor the effects of actions, as the properties of intentionality would prescribe: in fact, the context of information presentation requires only a simplified, limited interaction.

The input to the system is given by the interaction history and the user input. The system is reactive, i.e., it responds to the user input by displaying an appropriate social and communicative behavior. The system executes a *decision-execution-sensing* loop. Decision

addresses the selection of the next behavior unit; execution concerns the delivery of the unit; sensing concerns the processing of the user input.

The system views all the presentation as the realization of some communicative function [18]: in line with Grice's principle of cooperation [15], together with the presentational (informative) issues, the character must address interactional and social aspects. All of the communicative functions are hierarchically organized and, given the interaction history, some interactional functions have priority over informative functions (e.g. the character must introduce itself before providing any information).

The *informative* function is the primary task of the system, i.e., the task of providing the user with useful and relevant information during the visit. The execution of this function is assigned to the presentation manager, which handles the selection and the organization of the conveyed content through a sequence of behavior units. This module is responsible for realizing different presentation styles, according to a criterium of alternation of the presentation styles that enforces the principle of dramatization at the level of the character behavior (see next section).

The interactional functions are divided into *social interaction*, *directive* and *phatic*. Since the virtual character should qualify itself as a social agent, in order to gain believability and improve the user engagement, the system must perform some basic *social* behaviors. The *directive* function includes all the actions that the character performs in the attempt to force the user behavior in some way, like signalling conditions that may require the user to perform some action (for example, executing maintenance actions on the device on which the presentation is run, when prescribed by the visiting protocol in which the guided tour is embedded). In general, the directive function has no priority over basic social aspects (in order to enforce the notion of personification and autonomy of the virtual character) but has priority over the informative function. A relevant exception is given by the actions that, according to the visit protocol, should be executed only at the end of the presentation. The *phatic* function is activated when all other functions are applicable. Its purpose consists of signalling to the user that the character is active and willing to receive input. For example, it may be activated when the character has requested the user to perform an action of any kind - necessary for the prosecution of the interaction for maintenance reasons, and has not received any input after a given time interval.

3.2 Content organization

The behavior units, that factorize the behavior of the virtual character, constitute the knowledge base of the system. They contain multimedia content (an audiovisual clip with 3D animation and sound) and are tagged with the information that the system uses to generate the interactional and presentational behavior of the character.

The meta-data according to which the units are tagged are divided into three sets: *topic*, i.e. the description of the informative content of the unit, *communicative*, i.e. the communicative function accomplished by the unit, *editing*, i.e. the information needed for assembling the audiovisual clip with the adjacent ones. Figure 3 represents how meta-data are used by the modules of the architecture.

The *topic* section of the meta-data contains the description of the informative content of the units. The informative content is classified with respect to an ontological representation of the domain that is the object of the presentation. Topic description is necessary for the presentation manager to shape a coherent selection and exposition of the content of the presentation.

The presentation manager relies on the ontological representation of the domain information to select the content to be conveyed to the user and to structure it in a coherent way. This module follows a general strategy inspired by the focussing rules stated by Grosz and Sidner [16]. Since Grosz and Sidner's focussing heuristics have been elaborated for task-related discourse, in this methodology they have been adapted to the presentation of a set of domain facts. Task decomposition relations are mapped onto sub-topic relations, yielding the following preferences for discourse focussing:

1. Maintain focus on current topic. For example, by describing the domain according to mereological ontology, the current focus may be a piece of furniture - located somewhere in an historical location. Following a biographic description of the domain, the current focus may be an artist whose works are exhibited in a museum.
2. Move focus to a sub-topic of the current topic. With reference to the previous example, move to a subpart, a detail of the piece of furniture, or move to a certain period of the life of the artist.
3. Move focus to a the following sub-topic of the current topic. Again, the new focus may be a different detail of the previously focused detail of the piece of furniture, or a later period of the artist's life

Following sub-topic relations in an ontology according to the focussing heuristics corresponds to structuring the presentation along a certain dimension of meaning. Since the ontology is hierarchical, the focussing heuristics determine a depth-first visit of the ontology.

In principle, several meaning dimensions may be proposed to structure the same domain, corresponding to different presentation modalities. For example, the facts about an historical site may be "described" according to a topological dimension or "narrated" following a chronological dimension. In order to enforce the dramatization principle incorporated in the system design, the methodology requires the author to encode domain knowledge according to at least two different ontologies. This requirement serves the function of establishing a dialectic conflict between presentation modalities. The methodology postulates the presence of this conflict in the way the character accomplishes its presentation task, and aims at making it emerge along the interaction as a means to achieve the emotional engagement of the user.

The methodology assumes that the interaction with the user regulates the dialectic alternation between presentation modalities. So,

the methodology specifies a meta-theatrical schema according to which, as described in Section 2, user input along the interaction is interpreted as a positive or negative clue of user engagement (depending on the type user input allowed for by the specific application) and determines the presentational behavior of the character. If the user shows to dislike the current presentation modality, the character is disappointed and consequently switches to a new presentation modality. On the contrary, if the user likes the current presentation modality, the character maintains it until the related ontology has been completely explored (or explored to a sufficient degree), then switch to a different ontology.

In order to avoid abrupt transitions from presentation modalities, the domain ontologies to which the presentation refers should not be completely unrelated. For this reason, the topic of a behavior unit is expressed by encoding its position on all the available ontologies: the topic is a tuple of ontology-value pairs, where the first element of a pair refers to one of the ontologies encoded by the author, and the second element refers to a concept in that ontology.²

The system design exploits the topic description to enforce the focussing heuristics illustrated above on the set of all available ontologies: at each moment, one ontology (the reference ontology) drives the presentation, determining the active presentation modality. Each time a set of presentational units match the current topic on the reference ontology, they are ordered according to how they satisfy the focusing heuristics on the remaining ontologies, according to an author-defined preference order. In this way, when a presentation modality must be abandoned (according to the meta-theatrical schema described above, the the reference ontology changes), the transition to the new one (the secondary one) will be smooth in most cases.

The other two sets for unit categorization are the *communicative* function accomplished and the *editing* features involved.

Each behavior unit accomplishes a primitive communicative function belonging to one of the four communicative functions described above (informative, social interaction, directional phatic). It is up to the author to make sure that at least one unit matches each of the communicative functions acknowledged by the system. Moreover, each unit realizes only one communicative function. Clearly, the coordination between the system designer and the procedural author who develops the data of an application is the key to consistent scriptwriting with the system design. Moreover, it is up to the author to individuate and dramatize the character through the use of scriptwriting techniques in the authoring of behavior units.

Editing features connect some unit with another unit by interposing an audiovisual segment (called a *Transition Unit*) between them, with the aim of obtaining visual fluency [4]. The system incorporates a set of editing rules, that implement a number of editing techniques, e.g., graphic qualities (including framing, mise-en-scene, etc.) and spatial continuity. Transition units, like behavior units, are selected by the delivery manager from a repository according to the editing rules, and performs limited audiovisual adaptation if needed.

In order to assist the authoring task, a web-based authoring interface has been created to enter the application data (behavior units and transition units) and to define the meta-data according to which data are classified by the system (topics, communicative functions and editing features).

The system assumes that behavior units are self-contained, i.e. that

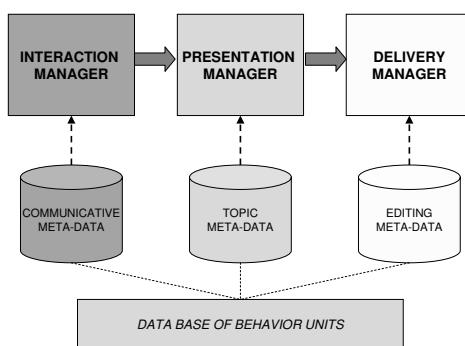

Figure 3. The system architecture according to the DramaTour methodology

² If the topic of a behavior unit is not present in one of the domain ontologies, the value element for that ontology will refer to the root of the ontology, meaning that it may equivalently subsume any specific topic in that ontology.

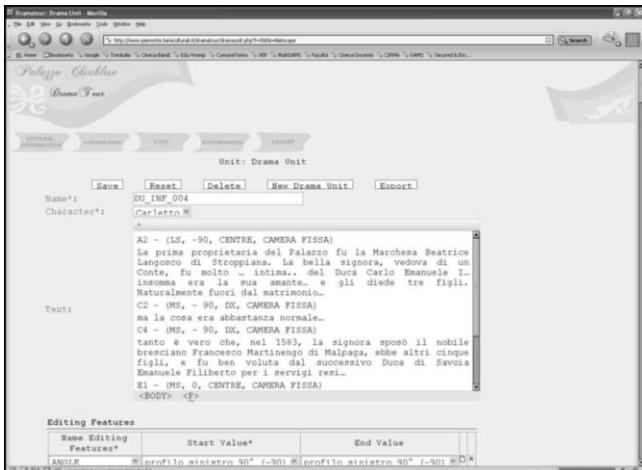

Figure 4. Authoring web-based interface

each of them accomplishes the execution of some specific communicative function, or, if its function is tagged as presentational, that it conveys a unit of meaning according the ontological representation.

3.3 Implementation details

The current implementation is based on common hardware available on the consumer market and mostly on open-source software. The visit server, that follows the specifications described in Section 3.1, is implemented in Java (<http://java.sun.com>), while the data base system is mySQL (<http://www.mysql.com/>). The web-based authoring interface has been developed in PHP (<http://www.php.net/>).

The client is written in Java and runs on an ASUS A636 PDA (PocketPC series). The video clips implementing the behavior units are encoded in Macromedia Shockwave Flash (<http://www.macromedia.com>). The client pilots the media player by sending text-based commands to localhost. The PDA also supports a localization client, that provides the user's current location, i.e., it identifies the room in which the user is currently situated.

Since the DramaTour methodology is media-independent, beside the PDA-based version of the virtual tour, a web-based guided virtual tour of the same location has been developed by using the same visit server. The web interface simulates the tour in the virtual space, by proposing to the user a PMVR (QuickTime VR) representation of each room, accompanied by the sequence of clips in which Carletto provides information about the room.

4 Conclusions

The DramaTour methodology presented in this paper is modeled on the typical workflow required by the production of a semi-automatic character-based presentation. Such a simplification of the process of system design and on-the-fly multimedia generation poses some expressiveness limitations to the author. However, we believe that the task assignment devised by the methodology between the system designer and the author represents a reasonable trade-off. Author's scripting is guided by a set of well-defined constraints on data content and form which are functional to the needs of the system. System design guidelines, in turn, enforce the key notions of character, storytelling and dramatization in an explicit way, by posing the method-

ology half-way between fully intelligent, experimental systems and off-the-shelf scripted systems for practical applications.

MAMA: An architecture for interactive musical agents

David Murray-Rust¹ and Alan Smaill² and Michael Edwards³

Abstract. In this paper, we present MAMA — an architecture for interactive musical agents. This system uses a theory of Musical Acts, based on Speech Act Theory to support the agents interaction. We discuss the basics of a representation language which these agents can use to represent and reason about music. We present a case study system based on these ideas, and discuss its ability to support distributed execution of a minimalist score.⁴

1 INTRODUCTION

Agent based music offers an exiting range of possibilities for the composition and performance of music. The distributable and mobile nature of agents suggests possibilities for remote collaborations and truly global music; the potential intelligence of agents allows for complex responses, understanding of high level inputs and a combination of flexibility and organisation; and the “human-like” properties of agents give us a way to explore models of human interaction through groups of musical peers working with dynamic material.

The “Live Algorithms for Music” group⁵ defines some characteristics that a software system needs in order to be considered a live algorithm, which are designed to coincide with it being an interesting musical partner. A Live Algorithm must be able to interact musically without any human intervention; it must make creative contributions to the music which is being produced; it should avoid rule based approaches which give a simplistic mapping between input and output. [4, 5] give an example of a particular group of live algorithms — the use of a swarm to create musical output. These systems tend to avoid traditional AI approaches of reasoning and planning, and concentrate on a lower level engagement with the musical surface. Another example of a live algorithm is the Continuator [15], which uses hidden Markov models to learn a player’s style, and respond with more music in the same vein.

Recently, there have been many projects aimed at creating “net” music - music which allows realtime collaboration over some form of network, whether a local area network, or the internet⁶. These projects have been categorised in [18] into four distinct approaches:

Server A server is used to send musical data to disconnected participants, but no interconnection or communication takes place between players

⁴ Audio recordings of the system are available at <http://homepages.inf.ed.ac.uk/s0239182/MAMA>

⁵<http://www.livealgorithms.org>

⁶For a more exhaustive survey, see [1].

Bridge The network is used to create a bridge to facilitate traditional interaction as if distanced players were in the same place

Shaper A central system generates musical material, which the participants collaboratively shape

Construction Kit Creates a multi-user composition environment, where participants can manipulate and shape each other’s music

Two systems are of particular interest here. Firstly the CODES system [12], which enables participants to cooperate in the construction of a “musical prototype” of a piece of music. “Lines” are made by choosing one of a set of patterns at each stage, with users able to create and modify patterns. The use of patterns allows untrained musicians to join in with the prototyping.

Secondly, the PIWeCS system [19] is a marriage of intelligent agents, electroacoustic processing and network music. A variety of traditional Maori instruments were played, and loaded into MAX/MSP (a graphical dataflow language, with extensions for sound processing). Users can then control parameters of these samples via a web interface, to create an arrangement. To allow for users with a low skill level, agents would listen to the output of the users, and supply additional material, or enter into dialogue as appropriate.

1.1 Background

This work is influenced by the characterisation of different forms of interaction between agents based on the notion of *communicative act*, which in turn draws upon the notion of *speech act* from linguistic pragmatics. The motivation behind the use of communicative acts to structure agent interaction is that the different communicative acts, such as “agree”, “cancel”, “call for proposal”, call for different forms of interaction; agreement on a set of such acts enables the reuse of composite communicative acts, and a platform for reasoning about such interactions, as well as supporting interoperability (see for example [7, 20]). This approach also naturally invokes the notion of the *intentionality* of the agents, and the opportunity for agents to reason about the intentions of other agents in the course of communication [9].

We exploit the analogy between this notion of intention, and that of musical intentionality present when musicians improvise and perform together; such musical interaction is often described in terms of “conversation” or “discussion” between the musicians, suggesting further the relevance of work on dialogue in the natural language case. The musical case differs in some respects, however.

First, musicians typically perform at the same time as other musicians, rather than taking turns as in natural language dialogues; the architecture below reflects this, in that the outputting of musical statements cannot be taken as an atomic step, but takes place in real time while monitoring simultaneous musical activity of other agents. Second, it is important to model more than interaction between two

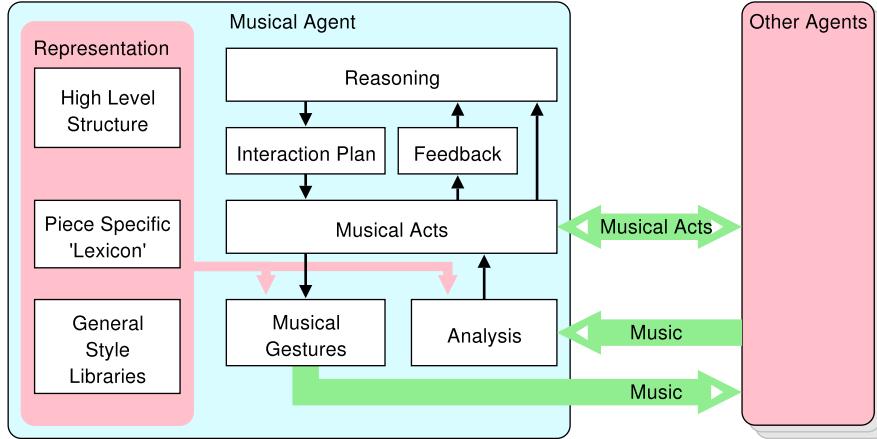

Figure 1. Musical Agent System Architecture

agents, which is the case usually treated in dialogue, with some exceptions ([2, 17]). Finally, we make no use of the notion of “literal meaning” of a musical statement that might correspond to the literal meaning of a natural language statement.

There have also been a few more direct approaches to the use of multi-agent systems in music. Dixon [6] uses a set of agents to track beats in audio streams. [21] details the construction of a musical multi-agent system where a group of agents adjust and play patterns in realtime, with themselves and human musicians. [16] describes an open architecture for Musical Agents, based on Java.

1.2 Paper Structure

In this paper we present our work on the MAMA (Musical Acts - Musical Agents) architecture. We describe the architecture, and give an overview of musical acts. We then discuss some issues of representing music for agents, and conclude by describing a current case study.

The overall aim of our work is to create a society of agents which can improvise music with each other, and interact with humans (either musically or through a higher level interface). These agents will use theory of Musical Acts, analogous to Speech Acts, to inform their music making (building on work in [13]. This is different to current approaches for a number of reasons:

- We focus on the logical aspects of computational music making, rather than the expressive and reactive aspects.
- We focus on the interaction between agents, rather than the generative capabilities of any particular agent.

2 Musical Agents Architecture

By creating a system of musical agents, we aim for a point between computationally assisted composition and interactive musical systems. The agents use high level representations of a piece of music to both inform their interaction with other agents and generate musical output. This is aimed at a range of situations where individual performers have some degree of autonomy, but they are working within a structure. Benson [3, 26-30] gives a series of increasingly “free” types of improvisation on a score. We are looking primarily at:

- I₁ The players fill in certain details which are not specified by the score
- I₂ The players add notes to the score, in a manner expected by the composer (e.g. trills)
- I_{3,5} The players add whole measures, sections etc. to the score; if this is in a manner approved or expected by the conductor, it is (I₃), otherwise, it is (I₅).
- I_{7,8} The score is changed considerably, reharmonisation, melodic alteration etc. The difference between I₇ and I₈ is that of recognisability - in the former, there is some obvious connection between the score and the rendition, but in the latter there is not.

The musical agent system is intended as a layer of “Musical Middleware” for composers and musicians (Figure 1); to create a piece, the composer:

- specifies some aspects of the high level structure
- provides a lexicon - a set of fragments and constraints on their usage - to the system.
- provides a set of general style libraries for the particular style(s) of music being created.

The agent system will maintain a high level representation based on this score. By reasoning about the current state of the score, the actions of other agents, and its own internal state, the agent will be able to construct an interaction plan, to guide interaction with other agents. This may suggest to the agent different general roles to take (such as soloing or keeping a groove), and it may result in specific courses of action - such as playing a response in a call and response section.

From the interaction plan, the agent constructs a specific set of musical acts to execute. These acts (see next section) cover the introduction, assessment and development of different musical ideas, and provide the substrate on which interaction is based.

A musical act may well only define a small section of the musical surface, and there may well be times when an agent is not executing any acts at all - for example, when supporting a soloist, one’s playing would be relatively free of new ideas in order that the soloist’s voice is more clearly heard (much as one is silent in conversation to allow another party to speak). This means that musical acts are a supplement to the generation process, and the bulk of the musical

surface may have to be generated from other sources. We hence use a combination of the high level representation with both style- and piece-specific information.

As the agent generates output, it also listens to the output of others. This output is analysed according to whatever features the particular agent knows about. From this analysis, and from the musical surface itself, the agent extracts the musical acts which other agents have performed. The activities of the other agents are used in the reasoning process, and also to determine feedback about the agent's actions.

It can be seen from Figure 1 that each agent has two communication channels to the rest of the world. Firstly, there is the musical channel, where musical information, in some form, is transferred between agents. Secondly, there is a formal channel, which allows the direct communication of Musical Acts. This could be used to transmit representations of the hand signals used in samba drumming, a nod to indicate that one agent likes another's contribution, or other traditional extra-musical gestures. It also provides the possibility for a higher level interaction with the agents - a user interface could deal directly in Musical Acts, giving a way to organise the playing of ensembles, without having to define low level detail, and while keeping the autonomy of the individual agents intact. Finally this channel provides a means of injecting, after suitable processing, data from other modalities, such as the sensor data in an interactive installation.

In order for an agent to reason effectively, it must receive feedback about the quality of its actions. We have three types of feedback that an agent is interested in:

- Satisfaction of internal goals: these may be given by the composer, or arise during the performance of a piece.
- Direct feedback from other participants; the equivalent of a smile or nod from another band member could be given by a human participant directly through some interface.
- Interaction feedback; when someone takes up an idea that an agent suggests, this results in positive feedback, even more so if they develop the idea, or enter into dialogue about it.

2.1 Interactions

To support a rich level of interactions, we will use a system of Musical Acts [13], which are analogous to Speech Acts as used in common agent communication languages (e.g. FIPA-ACL [8]). This is built on a set of modal operators as follows:

$BM_i p$ (BelMusic) “Agent i believes p to be a part of the shared representation of all agents”.

$UM_i p$ (UndefinedMusic) means “Agent i does not believe there is a commonly accepted value for the part of the representation covered by p ”.

$IM_i p$ (IntendsMusic) means “Agent i intends p to become part of the shared representation”.

$PM_i p$ (PersonalMusic) means “Agent i has p as part of its private representation”.

There is also the idea of musical “compatibility”. A musical proposition ψ is compatible with ϕ ($Comp(\psi, \phi)$) if ψ is in some way an extension of ϕ . The exact details of compatibility may be defined differently for different features, but examples would be extending or ornamenting a melody (compatible), adding degrees to a chord (compatible), changing one of the degrees in a chord (incompatible).

By combining the possible states of the world, and the values of the modal operators, the following set of musical acts may be obtained (also shown in Table 1):

Inform If an agent is expressing a facet of the musical structure which it believes has not been explored - it has no value in its public representation - then it simply INFORMS the other agents of it's desire that the representation be modified thus.

Confirm If agent A INFORMS of some facet for which agent B has no value, and B is content with the value A has suggested, then B can CONFIRM As suggestion

Disconfirm As above, except B is not happy with A's value, and DISCONFIRMs it. This could take the form of B playing something which is not compatible with A's exposition

Extend If A has a value in its public representation which it wishes to alter in a manner which is compatible with the current value, it can EXTEND the current value.

Alter If A has a value in its public representation which it wishes to alter in a manner which is *not* compatible with the current value, it can ALTER the current value.

Preconditions			Act
Agent i	$B_{i,j}$	Other	
$UM_i \phi \wedge IM_i \phi$	*	-	Inform-Music
$IM_i \phi$	$IM_j \phi$	-	Confirm-Music
$\neg IM_i \phi$	$IM_j \phi$	-	Disconfirm-Music
$BM_i \phi \wedge IM_i \psi$	*	$Comp(\phi, \psi)$	Extend-Music
$BM_i \phi \wedge IM_i \psi$	*	$\neg Comp(\phi, \psi)$	Alter-Music

Table 1. Musical Acts and their preconditions

2.2 Music Representation for Agents

We had several design goals when creating the music representation language. In particular:

- It would be human readable, to allow composers to understand their own and others' scores.
- It would not be tied to traditional Western music, and potentially represent as many types of music as possible
- It would support pieces with dynamic structures; sections of music could be re-ordered, extended and omitted at run-time.

We took several inspirations for our representation; in particular, this is a development of work carried out in [14]. We are working towards a target set of pieces which can be represented. To get a well balanced set of features, we are looking at:

Latin The “Latin Real” fake books provide a high level representation of Latin pieces; they specify structure and some musical features, with the players left to fill in the details using their own understanding of the style of music

Minimalist By looking at In C we examine a piece where the notes are given, but the structure is dynamic, determined by the decisions of the agents.

By creating a system which can represent these musics we ensure sure that it can be extended to deal with a wide range of music.

2.2.1 Structure

The hierarchical decomposition of music is not new, and has been widely used in many computational representations of music - [10] is a recent implementation of Lerdhal and Jackendoff's Generative Theory of Tonal Music [11].

In our system, a piece of music is divided up into a hierarchical tree of “Sections”. The leaf sections are used to define aspects of

the music to be played, while non-leaf sections are used to order the leaves. Attributes are inherited down the hierarchy, making it easy for a composer to create many similar sections, and specific relations may also be given.

Sections have several controls over their ordering. By default, sections would be played out in the order they are given. It is possible to specify different orderings, so that a section may use a decision rule to choose which of its subordinates is played next.

In order to exchange information about music, the agents need to have a way to refer to sections of the music. We use path like structures here, so that the exact place a section is used can be specified. This allows for agents to tell each other what section they are currently playing, and propose changes to certain sections of the piece.

Many scores supplement their notation with a set of playing directions. For certain styles of music, it is essential that we can represent these directions such that agents can use them - in some minimalist and contemporary works⁷ the directions define a large part of the structure of the piece.

We represent these directives as behaviours which an agent may enact, and specify them as a combination of a condition and an action; the agent is responsible for maintaining certain variables, to do with the musical surface and its own internal state, which can then be used in an expression which is the condition of a directive. The action of a directive can have a structural effect, such as choosing to move from one section to the next; it can trigger the use of certain musical material, such as playing the response to a call; it can shape output which has already been generated, such as adjusting dynamics to create a crescendo.

2.3 System Infrastructure

In order to avoid having to deal with realtime issues at many levels, while maintaining realtime output, we have made the following decisions and simplifications:

- There is a central “Conductor” in the agent system, who is responsible for gathering the output of all the agents and translating it into MIDI or audio data.
- A piece occurs at a certain tempo, determined by the conductor. Individual agent produce their output at times specified in beats.
- An agent creates output in a buffer, which is then periodically sent to the conductor for output. The conductor will ask for a section of output covering a given time span.

This means that an agent’s only temporal responsibility is to ensure that the playahead buffer is filled, and to return a requested chunk of it in a timely fashion when asked.

The information available to an agent about the playing of other agents is always one time span behind. There is hence a tradeoff between reactivity of the agent system, and the latency of the network (and message passing overhead).

The agents are situated within a virtual space, and can be moved around by means of a graphical interface. Their positions within the space affects where their sound appears in the stereo field, and can be used to alter how much attention is paid to the output of other agents.

3 CASE STUDY: In C

We chose “In C”, by Terry Riley both due to its impact at the beginning of the Minimalist movement, and because of its suitability

to agent based techniques. The score consists of a series of short fragments of music, ranging from half a beat to several bars. Each performer plays the fragments of music in turn, repeating each indefinitely before moving on to the next. Directions are given such as:

- performers should stay within 2 or 3 patterns of each other
- performers must listen carefully, and should occasionally drop out and listen
- a pattern may be played in unison or canonically in any alignment with itself
- the group should aim to merge into a unison at least once or twice during the performance

To implement this, in our agent system, we provided the following components:

Representation We created a score which details the notes provided in each section. We then added a tacet section which agents can jump to to take a break, and special section for the end - once all players have arrived on the final section, the group crescendos and diminuendos a few times, with players dropping out on each diminuendo.

Musical Acts When an agent begins a new section, it sends a message to all the other agents to inform them of the section it is starting. This is done through the formal channel (see Figure 1)

Reasoning In order to follow the direction that players should stay within about 3 sections of each other, each agent tracks the progress of the others through the piece. The relative position in the score of the other agents is perceptually weighted (scaled by the inverse square distance and the volume) and summed to give a total weighting for the relative progress of the group. We then use a sigmoid function to turn this into a probability, with control over both the base probability of moving from section to section, and how much spread the agents are comfortable with.

Analysis Some low level features such as dynamics are analysed, and some more complex features such as syncopation and unity are planned. This will feed into the analysis section, and allow agents to make changes in their output to increase or decrease syncopation, for example.

4 RESULTS

We had a variety of aims in implementing this piece. Firstly, we were testing whether the system infrastructure could deal with a reasonable number of musical agents playing together, without dropout. Secondly, we wanted to test that by using a set of simple directions, we could create a result which was musically pleasing, and demonstrated some behaviours we would expect from a human ensemble.

We found that the system could support a useful number of simple agents - so far In C has been played by 20 musicians on a standard PC, using the internal synthesis engine provided by Java. We found that the system is quite sensitive to other applications running on the computer, although CPU usage remains reasonably low. Use of an external synthesiser is expected to improve timing and quality of sounds produced.

We have not performed a serious experiment concerning the musicality of the current system, as we do not feel it is warranted at this stage. The fact that its musical output is generally pleasing is a function of the piece in question as well as the agent system itself.

⁷e.g. Stimmung (Stockhausen), In C (Riley), Canto Ostinato (ten Holt)

5 DISCUSSION AND FUTURE WORK

In this paper we have presented an architecture for interactive musical agents, and discussed a prototype system which implements some of this architecture. This is useful for a proof of concept, but there are many possibilities for further extension.

There are several comparable systems at present, but they all address slightly different concerns: Pachet's Continuator [15] is capable of high quality interaction with human musicians, but lacks higher level descriptions of music; the Andante project [16] gives an architecture for mobile musical agents, but focuses on the low level aspects of this area; and Wulfhorst's system [21] lacks high level structure.

It is clear that the use of a formal set of musical acts allows some very precise communication between the agents, and it is certainly less computationally intensive than having every agent analyse the output of every other agent. This makes the prospect of hybrid human/machine interaction an interesting area, as humans cannot easily give this privileged view onto their mental states. It should be possible to analyse human playing, and pick out musical acts, which could then be distributed to the agents; it may also prove interesting to supplement a traditional instrument with some means of generating metadata about one's playing - e.g. the capture of physical gestures, or a specific physical interface.

Often with agent systems, there is a question of autonomy, about how different this approach is to standard object oriented techniques, or even distributed OOP. This has a sister question in musical circles, concerning the autonomy of a player within a musical ensemble. In certain styles of music, the musicians are given highly precise descriptions of what to play, whereas in others the players have a lot of creative control over what they play. In terms of Benson's levels of improvisation, the current prototype is working with I₃ - the players are adjusting the structure in a manner sanctioned by the composer. This is very much a starting point - we intend to work towards I₇ and I₈ to allow use of the system as a truly interactive tool.

As more of the architecture is filled in, we gain the capability to experiment with more diverse situations. We envisage use of the system as a compositional tool, to create new works with a complexity and interdependence which would not be possible with human performers. We also intend the creation of interactive installations, which allow non-musical participants to become engaged in the creation of dynamic musical works.

Bayesian modelling of colour's usage impact to web credibility

Eleftherios Papachristos¹ and Nikolaos Tselios² and Nikolaos Avouris³

Abstract. Colour plays an important role in web site design. The selection of effective chromatic combinations and the relation of colour to the perceived aesthetic and emotional value of a web site is the focus of this paper. The subject of the reported research has been to define a model through which to be able to associate colour combinations with specific desirable emotional and aesthetic values. The presented approach involves application of machine learning techniques on a rich data set collected during a number of empirical studies. The data obtained were used to train a Bayesian Belief Network which associated a simple chromatic model to perceived aesthetic and emotional dimensions. A set of tools that have been build in the process to support the methodological framework and ensure its reusability with minimal effort, are also described.

1. INTRODUCTION

The web has increased in complexity over the years and has gradually transformed from an online publication medium to a platform for carrying out complex tasks, such as shopping, learning, communication, and collaboration. Due to this transformation, additional research is required to support design of effective web sites. Various issues influence the effectiveness of a web site, such as structure, content hierarchy, styles, text format and navigational support. One of the most important design factors that influence the effectiveness of a web site is colour. Research and application of traditional human computer interaction methods and practices led to a significant improvement of web design quality. Yet, there is an open discussion about the specific elements that should be incorporated in a "well designed" web site. This question has particular significance during the development of web applications, considering the complexity of such a task [1].

Recent work [2], [3], has shown that the design space of a web site is affected by both engineering and aesthetic issues. Other work, suggests that the visual aesthetics of computer interfaces are a strong determinant of users' satisfaction and pleasure [4]. An effective web site design has to communicate well not only the content and the overall information architecture, but also wider values such as sense of professionalism, skilfulness and credibility. Furthermore, often the web site values are influenced by cultural beliefs, traditions, as well as goals and usage expectations [6]. The aforementioned criteria determine the *Perceived Value* of the site. Recent web based studies [5], showed a clear link between effective page design and credibility. Websites which seemed to have a more suitable visual appearance for the scope of the site were rated by the subjects as more credible. This reinforces the theory, established by social psychology research, that physically attractive sources have been perceived to be credible [7].

However, in general, there are not well established guidelines that affect the emotional aspects of interaction which, in turn,

influence a web site's perceived credibility. As a result, various interaction values are implemented via ad hoc procedures and trial and error implementations. So, there is a need for a systematic development of models that can guide the design practice in this area. Most modelling approaches supporting human interaction with web sites have focused primarily on the cognitive aspects of interaction [8],[9]. However, the importance of aesthetics on websites is well accepted and models of their impact on credibility have been proposed [10]. In general, however, little is known about the influence of aesthetics and the role of the colour. The most prominent designer's tool to use colour in websites is that of guidelines. However, existing colour guidelines are often awkward, easy to misinterpret and of limited value. According to Schwier and Misanchuk [11], experiential advice tends to be non-representative, contradictory or even obsolete. This is due to the outdated equipment used in the experiments, the fact that some guidelines may be only applicable on display media other than CRTs, and the tasks are so different and unique from common situations, that their generalization may be impossible. Even assuming that relevant guidelines exist, they are of little value to novice designers with little experience with colour theory and art. Many issues remain untackled by existing guidelines, such as the relationship between colours, the optimal number of colours for each case etc. Following this, it is desirable to obtain a methodology, which is capable of proposing specific directives about colour usage in any web design problem.

In this paper, we use Artificial Intelligence techniques to define a model to aid us select the most appropriate colour combination for a web site of a given purpose. The goal is to identify methodologically the colour combinations which communicate effectively desired emotional values. For example, a news web site should effectively communicate values such as consistency, reliability, objectivity, etc. Due to the fact that a direct evaluation of each colour is heavily subjective, the methodology tackles this problem by indirectly evaluating the credibility influence of selected colour combinations, and then breaking down the underlying influence of each factor using a Bayesian Belief Network. The developed Emotional Colour Model has been used in a tool to suggest appropriate chromatic schemes according to the desired perceived web site values.

2. EMOTIONAL COLOUR MODEL DEFINITION

The proposed model is partially inspired from a similar research by Guerin et al. [12]. This experiment examined colour usage, in the frame of interior space design. The subjects of the experiment had to evaluate computer generated interior environments against a list of 21 words, selected for this purpose on a scale from 1 to 5 (1 when a characteristic described by a specific word was rarely present, 5 when its presence was very strong). A variation of this experiment has been used to recognize differences in colour

¹ University of Patras, Greece, email: epap@ee.upatras.gr

² University of Patras, Greece, email: nitse@ee.upatras.gr

³ University of Patras, Greece, email: avouris@ee.upatras.gr

preferences between the two sexes [13]. The methodology proposed in this study is built upon the same idea, but is applied on web pages instead of interior environments. Our ultimate research aim is to determine relations between colour characteristics and descriptors of the web site's perceived value. The benefit of such an approach is the elicitation of a formal methodological process to select the appropriate colour combination. Furthermore, the process could be applied reversely: For a web site of a given scope we can elicit the appropriate colour characteristics.

A Colour Model has been defined first, combining physical, aesthetic and artistic dimensions. This includes aspects such as dominant and secondary colour, number of colours, dominant colour and secondary colour attributes such as degree of saturation and brightness (see Table 1). This model contains attributes related to the physical properties of the primary and secondary colour (e.g. colour hue, degree of saturation and brightness), as well as psychological properties (e.g. perceived warmth of the primary colour, colour scheme). Any web page colour scheme can be described according to this. The model cannot be conceived as too restrictive or exhaustively prescriptive, in terms of explicitly describing the very exact nature of each colour, which a web site's layout contains. This is compatible with our scope: The purpose of the proposed methodology is to guide the designer selecting appropriate colour schemes, not to suggest the exact attributes of each colour contained in the layout to be designed.

Table 1. Colour Model attributes with typical values

Attribute	Description	Values
Dom_colour	Hue of the dominant colour	Blue, Red, Grey, Green, Purple
Sec_colour	Hue of the secondary colour	Blue, Red, Grey, Green, Purple,
Dom_atr_dark	Brightness of the dominant colour	Dark, neutral, bright
Sec_atr_dark	Brightness of the secondary colour	Dark, neutral, bright
Dom_at_muted	Saturation level of the primary colour	Low, Neutral, High saturation
Sec_at_muted:	Saturation of the secondary colour	Low, Neutral, High saturation
Dom_atr_warm	Dominant colour's warmth	cold, neutral, warm
Sec_atr_warm	Secondary colour's warmth	cold, neutral, warm
Contrast_Values	Shows if contrast between brightness levels of main colours are high or low	high, neutral, low
Contrast_colours	Shows if contrast between hues of the main colours are high or low	high, neutral, low
Colour_sheme	Shows the type of chromatic combination used	Analogous, complementary, split-complementary, monochromatic
Numb_col	Total number of colours	(integer)

The Model is correlated to a number of descriptors, describing the perceived value of a web site. According to our methodology, typical users of the web site are requested to provide their subjective feeling about different colour schemes applied on representative web page layouts. A questionnaire has been designed for this purpose. By simply asking the participants for their preferences in colours, their answers would have been highly subjective, thus leading to non meaningful or contradictory conclusions. For example, in the case of a sports news web page, a person's preferences is heavily biased by social and geographic

influences (colour of local team, national team etc.). Therefore, we constructed an indirect approach to gather the perceived value of the site.

The Perceived web site value dimensions are based on a model used by Guerin, et al. [12], to describe the characteristics of interior environments. To reduce the ambiguity due to similarity between a number of the terms, the 12 most distinctive were chosen: *Pleasant, Formal, Fresh, Modern, Friendly, Aggressive, Professional, Attractive, Calming, Dynamic, Reliable and Sophisticated*. These values are compatible with the thirteen emotional dimensions that have been used by Kim et al. [14] to describe the emotional value of web site design, which were derived through a systematic process. The only dimensions missing from the model used in this study are those related to the web site structure and form (e.g. concise, simple) that are not related to the colour of a web page.

The product of the method described above is the *Emotional Colour Model*, a knowledge body that can be interrogated, in order to extract useful recommendations on colour usage. We do not expect generalized conclusions from this Model, at least unless a very large number of representative users are engaged. However, specialized strategies for colour usage in certain layouts may be obtained. For every new web site of a given scope and with recognized typical users in terms of characteristics like age, sex, educative level and familiarity with the internet, the methodology attempts to propose the most suitable colours to be used.

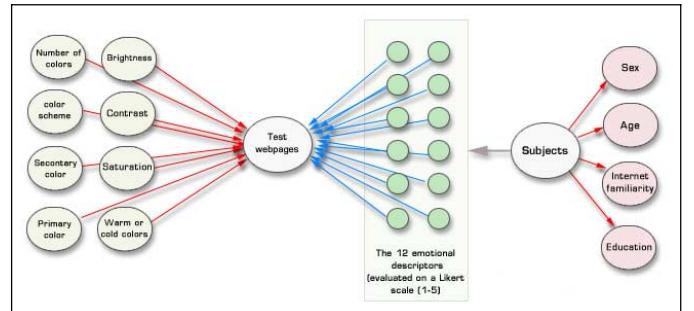

Figure 1. Overview of the proposed methodology

The data collected train a bayesian belief network. The variables of the network are not the layouts themselves, but their colour combination structural components. Thus, we can infer against most probable colour selections given specific credibility attributes which constitute the desired credibility for the designing web site to be designed. Reversely, given some colour scheme selections, we can predict the perceived credibility for given users.

Bayesian Belief Networks (BBN) are a significant knowledge representation and reasoning tool, under conditions of uncertainty. Given a set of variables $D = \langle X_1, X_2 \dots X_N \rangle$, where each variable X_i could take values from a set $Val(X_i)$, a BBN describes the probability distribution over this set of variables. We use capital letters as X, Y to denote variables and lower case letters as x, y to denote values taken by these variables. Formally, a BBN is an annotated directed acyclic graph (DAG) that encodes a joint probability distribution. We denote a network B as a pair $B = \langle G, \Theta \rangle$, (Pearl, 1988) where G is a DAG whose nodes symbolize the variables of D , and Θ refers to the set of parameters that quantifies the network. G embeds the following conditional independence assumption:

Each variable X_i is independent of its non-descendants given its parents.

Θ includes information about the probability distribution of a value x_i of a variable X_i , given the values of its immediate predecessors. The unique joint probability distribution over $\langle X_1, X_2 \dots X_N \rangle$ that a network B describes can be computed using (1):

$$P_B(X_1 \dots X_N) = \prod_{i=1}^N P(x_i | \text{parents}(X_i)) \quad (1)$$

In order to construct a BBN from the training data provided, two processes should be unified: learning the graphical structure and learning the parameters Θ for that structure. In order to seek out the optimal parameters for a given corpus of complete data, we directly use the empirical conditional frequencies, extracted from the data [15]. The probability that the model gives to the data can be extracted using the following formula proposed by Glymour and Cooper [16]. Then, we follow greedy search with one modification: instead of comparing all candidate networks, we consider investigating the set that resembles the current best model most. As we shall discuss in the conclusions section, BBN are a significant tool for knowledge representation, visualizing the relationships between features and subsets of them. This fact has a significant result on identifying which features actually affect the class variable, thus reducing training data size without any significant impact in the performance.

The proposed model building process is supported by a tool aimed at facilitating data collection. The collected data are stored first in a relational database, together with the attributes of the Colour Model for each evaluated layout. A second tool realized, to allow the designer choosing which perceived value descriptor has to be present and at what degree on the web site to be designed. According to the designer's preferences, the system proposes a list of colour characteristics, by using the BBN obtained. Further explanations on the results, such as information for colour theory elements, are also provided. The outlined methodology and use of the derived model and tool is further discussed in a validation case study in the next section.

3. CASE STUDY

Two empirical studies were conducted, to identify the quantitative relations between emotional dimensions and colour usage in a specific layout. In the first study, we tested the methodology with 46 participants in a highly controlled experiment. Our goal was twofold. Firstly, to examine the soundness of the proposed methodology. Secondly, to proof the validity of the used emotional descriptors. It was also a good opportunity to evaluate the tools developed to support the proposed methodology, as well as to improve them. The conclusions of this preliminary experiment found to be very encouraging. The tool developed to make use of the data collected could be a very helpful addition in the web designer's toolbox [17]. However, to claim direct facilitation of the designer's task to pick the most appropriate colours, evaluation of a wider range of layouts and colour schemes by a larger sample of subjects should take place. That is, because the data are hardly sufficient to derive results of general value. In the second study, we conducted another experiment in which the objective was to overcome the weaknesses unveiled in the first one. The first problem was to recruit a respectable amount of participants for the goals of this study. To tackle this problem, we converted the tool with which the participants were called to identify the quantitative relations between the emotional descriptors and colour characteristics to operate online (Figure 2). By doing so, we were

able to recruit more participants to carry out the evaluation but had also to deal with problems derived by a less controlled experiment. The tool developed for the experiment is a web application, which presents the layouts and the emotional dimensions on a Likert scale in the same window of a common web browser. The participants had to evaluate 10 out of 30 test layouts, in order to complete the experiment which is a sufficient number taking into consideration the user's weariness. Consequently, the application had to generate the layouts in a random order. Also the order of the descriptors appearance had to change from user to user, in order to avoid position related bias. Furthermore, the application has to provide sufficient documentation and techniques to avoid errors during the evaluation. Finally, it had to adapt to the users screen resolution and depict the appropriate layout.

Figure 2. Tool to acquire users' subjective evaluations

In order to represent in our study a larger area of colours, colour schemes and their derivatives, we had to increase the number of test layouts considerably. We considered that 30 different layouts comprised of six dominant colours with five variations in brightness, saturation, colour scheme etc. managed to balance a representative sample. By taking user weariness in consideration we decided that each participant should evaluate no more than 10 test layouts.

Table 2. Most friendly dominant colour

	First experiment	Second Experiment
1	Green	43.79 %
2	Blue	35.77 %
3	Grey	17.23 %
4	Purple	1.61 %
5	Red	1.60 %
6		Orange

Overall, 214 users (64 male, 150 female) participated in the experiment, evaluating a total of 10 randomly selected layouts from the 30 available, which totals an average of 70 evaluations for each layout. The median age was 18 years old. Most of the participants were undergraduate students from the department of Educational Sciences and Early Childhood Education Department as well as from the department of Electrical and Computer Engineering at the University of Patras. The majority of the participants had average (65,45%) or frequent experience (27,44%) with the Web.

Table 3. Most friendly brightness of the dominant colour

	First experiment	Second Experiment
1	Dark	4.31 %
2	Neutral	27.03 %
3	Bright	68.66 %

By comparing the data of the two experiments some findings seemed to be aligned. For example, the findings found to be similar both for the most “friendly” dominant colour, as shown in Table 2, and the attribute brightness of the dominant colour as shown in Table 3.

The network obtained showed no significant differentiation in preferences between the two genders in both experiments. In the first one, no connection was found between the node user’s gender and the other network, which lead us to believe that either our sample was inadequate or there is no difference in preference. In the second experiment the gender node found its way into the network but as shown in Table 4 there is only a slight difference between male and female preferences. This is mainly due to the unilateral sample of the participants.

Table 4. Differences between genders in dominant colour preferences

Men		Women	
Green	17.38 %	Green	17.43 %
Yellow	17.19 %	Yellow	17.30 %
Purple	16.59 %	Blue	16.50 %
Blue	16.36 %	Orange	16.32 %
Orange	16.27 %	Red	16.27 %
Red	16.21 %	Purple	16.18 %

By examining the structure of the tree, one may notice that the perceived values, the colour attributes and the demographical data were clustered into three large groups. The group of the perceived values has been placed at the bottom and the colour attributes at the top left of the tree of Figure 4. The only connection between the two sections of the model is made through the nodes “modern” and “saturation level of secondary colour”. According to BBN’s theory, if they’re no direct connections between two nodes then there is no direct relationship between them. However, a relationship may exist if they are connected indirectly, via other nodes, but the former case is an indication of a stronger relationship. Therefore, conclusions can be carried out, based on the position of every node and their “distance” from the Perceived Value descriptor nodes.

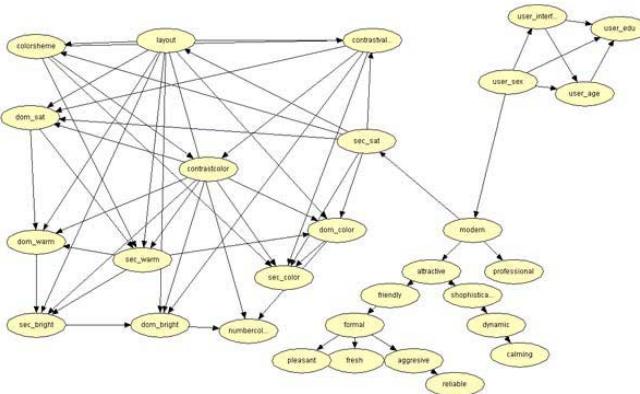

Figure 3. BBN obtained from user’s evaluations.

So, according to the tree structure the *saturation* of the secondary colour has a stronger effect on the site’s Perceived Value than its *hue*. Further analysis of the model structure, led to a categorization of influence of colour factors into 3 levels of importance: The ranking of the importance of the colour model aspects that influence the values perceived by the user seems to be

the following:

- First, the *saturation* of the secondary colour.
- Secondly, the *Hue* of the dominant and secondary colour, *saturation of the dominant colour*, the *colour scheme* and the *contrast levels of brightness*
- Finally, the saturation of the dominant colour, brightness of the dominant colour and the type of the dominant and secondary colour (warm or cold).

By comparing the trees generated by the two experiments we found slight changes in the nodes positions and dependencies. In the first experiment, the top node in the perceived value section was the node *friendly* and for the colour attributes the node *brightness of dominant colour*. This is due to the different physical layouts used. These users were more sensitive to these values for this particular layouts. This ascertainment stress the need to include a variety of test layouts in order to have results of generalizable value

Table 5. A web site’s colour model with respect to the emotional dimension ‘professional’

Attribute	“Professional” web page	Less “Professional”
Dominant colour	Green	Purple
Brightness of dominant colour	Bright	Dark
Saturation of dominant colour	High	Neutral
Secondary colour	Blue	Yellow
Brightness of secondary colour	Neutral	Dark
Saturation of secondary colour	Saturated	Neutral
Contrast of brightness between colours	Low	High
Contrast between Hues	High	Low
Number of colours	3	4
Colour Scheme	Complementary	Monochromatic

Besides observations based on the structure of the network, or performing sensitivity studies on various nodes, other interesting conclusions have been derived. It is possible to get information for every emotional dimension and for combinations of them from the model. For example, a colour scheme comprising no more than 3 colours seems to be the most appropriate to use, and the best chromatic combinations are complementary and analogical. In addition, it seems to be suitable to use low contrast levels between colours. Warm colours are preferable for dominant colours and cold for secondary. Furthermore, if we choose to adopt a monochromatic colour scheme it is preferable to have neutral contrast in brightness. Finally, regarding saturation, it was deduced that the best combination is high-saturated dominant colour with low saturated secondary colour. In order to demonstrate the use of the derived model, the proposed ideal colour factors for a web page required to communicate a sense of ‘professionalism’ is presented in Table 5. Additionally to this, the differentiation of those colour factors is presented, in case where the complete opposite emotional descriptor is required to be communicated.

The aforementioned analysis results do not comprise the only approach to take advantage of the knowledge embedded in the network. A great analysis tool is the observation of the quantitative dependencies between the nodes of the network. For example, by choosing a combination of emotional dimensions if we desire the presence of the descriptor “attractive” to a high extent, and the presence of the descriptor “professional” to a medium level, the network suggests ‘purple’ to be selected as a dominant colour with a probability of 17,43%. Setting dominant colour’s attribute value

to ‘purple’ the network led us to recommendations related to the other attributes. It suggested using bright warm and highly saturated purple, combined with a bright low saturated blue for secondary colour. It also posited usage of a complementary colour scheme but with no more than 3 colours of low contrast. Therefore, the solution space for the designer is significantly reduced to a certain amount of layouts complying with the requirements set in the described example.

4. CONCLUSIONS

In this paper, we proposed an innovative approach to define a model of a web site’s colour characteristics associated to desired perceived values. The proposed methodology involves a machine learning approach to create a belief network correlating the colour model of a web site with the values that are attributed to it by its users. We argue that the selection of appropriate colour schemes can lead to effective communication of the desired values for the web site users, thus enhancing the perceived credibility of the web site to be designed. In addition, we consider the proposed model-based approach to have significant advantages compared to the most common approaches, i.e. applying guidelines for colour usage.

The objective of the framework is to extract conclusions related to the specific colour selections and their emotional impact. To evaluate the proposed method we conducted two experiments: one preliminary with a small number of participants and a second one with a considerably large amount of subjects. However, the results reported in this paper, cannot be claimed to be of general value, since neither the number of subjects, nor the number of the test web pages was sufficient to justify general conclusions from the conducted studies. Despite that, it should be stated that many of the findings reported here, confirm earlier empirical rules related to colour’s usage and current tendencies in web design, which is an encouraging indication of the validity of the proposed methodological approach.

As for future research, we intend to extend the nature of the forthcoming experiments by altering the physical layout of the used template by differentiating parameters such as different layouts, font sizes, white space used etc. in order to examine the effect of those parameters to the results obtained. Additionally, we intend to use the proposed methodology on actual web sites. Subsequently, to perform other experiments in which to make use of the developed models for the design of specific kinds of web sites, like e-learning applications. With regard to the colour model used, several attributes seem to have more practical usefulness than others, while using the methodology reversely, since the proposed colour model might be considered insufficient by many practitioners involved in web design.

Finally, as an extension to the reported study, one may view the issue of appropriate chromatic combination to a broader context and examine its impact to the perceived information gain in particular environmental conditions in dynamic Internet ecology [18]. We argue that various models of typical web user behaviour, like information foraging [19], based on cognitive models combined with AI techniques, should be extended to take into account colour issues.

ACKNOWLEDGEMENTS

This research was funded by EPEAEK 2: ‘Pithagoras 2: Models of information foraging on the web’. Substantial appreciation should be paid to Dr. Manolis Maragoudakis for his valuable insights in Bayesian Belief Networks application on our problem.

Evaluating Perception of Interaction Initiation in Virtual Environments using Humanoid Agents

Christopher Peters¹

Abstract. We evaluated user perception of certain attention behaviours, eye head and body orientation in particular, of humanoid agents in a virtual environment for the purposes of interaction initiation. Users were shown a number of scenarios involving agents making gaze, gesture and locomotion behaviours and were asked to report their impressions of how attentive the agents were and their perceived likely-hood to engage in interaction. These evaluation studies are critical for furthering our understanding of the early phases of human-computer interaction where distance may be involved and there is uncertainty as to the intention of the other to interact. Amongst other results, we establish here that the human perception of interest, interaction seeking and openness from a humanoid agent is based, in part, on the time-varying behaviour of its eyes, head, body and locomotion directions. Application domains include social robotics and embodied conversational agents.

1 INTRODUCTION

In this paper, we describe an experiment to determine the extent to which agents in virtual environments give a human user the impression that they are attentive or interested in them, in particular, by orienting their gaze, body orientation and locomotion with respect to the user. We furthermore evaluate how, in the absence of other modalities of communication (e.g. verbal or facial expression), such behaviours may be interpreted by the human as a sign by the agent that it is open to or wishes to become involved in a more in-depth interaction with the user e.g. start a conversation with them.

The start of interaction is an important phase in human-computer interaction, *HCI*, and one that has thus far been largely neglected in the literature. Many ‘start of interaction’ scenarios in *HCI* consist of an inflexible stage occurring at short-distance, where either of the participants have already been identified as having the goal of interacting with each other, or in other cases, one participant has the task of fulfilling a number of inflexible constraints and overt cues in order to open with the other. For example, a human may have to stand in a predefined position in front of the computer, press a button or make an utterance in order to activate it. This approach avoids many complex issues but, unfortunately, also disregards the grace, naturalness and subtleness with which real human interactions tend to begin. Our work represents a first attempt to allow for a more natural start to the process of interaction opening. The design of such a system will no doubt involve a wide range of concepts in fields that are still developing, including computational modelling of visual attention and theory of mind.

In this paper, we evaluate some fundamental aspects of how humans *perceive* attention and related behaviours from humanoid

agents in both static and dynamic scenarios. Research concerning this domain is a veritable jigsaw of varying interrelated topics spanning a number of fields over a wide time-line, from sociology to evolutionary psychology to neuroscience; holistic, macro-level research that is of use in the construction of practical *HCI* systems is still lacking. In this respect, we provide a first practical evaluation towards the construction of such a system. Our particular application domain is to support the cognitive modelling and animation of certain autonomous agent behaviours, such as gaze (see for example [11] and [6]).

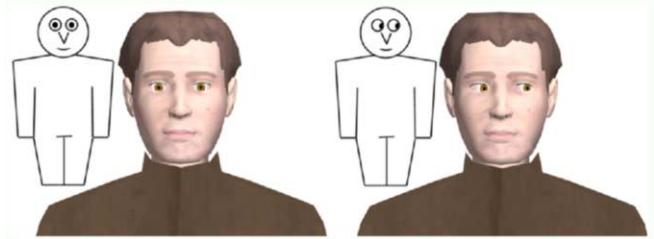

Figure 1. A close-up of the humanoid agent used in the evaluation studies. Beside each agent is an illustration of the eye, head and body directions.

2 RELATED WORK

A number of studies have established some fundamentals regarding the human perception of humanoid agents and avatars for up-close interaction. Colburn et al. looked at how eye-gaze animations affected the perception of humanoid agents and found that a natural gaze model elicited changes in a human viewers’ eye gaze patterns [2]. Garau et al. studied the impact of the graphical realism level of an avatar and how it affected the quality of communication [4]. They found that an informed-gaze avatar significantly outperformed a random gaze avatar and also that alignment of behavioural and visual realism was important for creating effective avatars.

Turk et al. manipulated the gaze of avatars in order to change user’s perception of attention in immersive virtual environments and found large gender differences in presenter awareness, persuasion and memory between different gaze conditions [13]. Vertegaal et al. [14] considered the significance of gaze and eye contact in the design of GAZE-2, a video conferencing system that ensures parallax-free transmission of eye-contact during multiparty mediated conversation. More recently, and of great interest to our studies, Sidner et al. [12] have studied rules of looking behaviour in order to allow robots to maintain engagement with humans in a collaborative environment. They found that users engaged in mutual gaze with the

¹ LINC Laboratory, University of Paris 8, email: c.peters@iut.univ-paris8.fr

robots, directed their gaze to them during turns in conversation and responded to changes in head and gaze direction by changing their own gaze or head direction.

3 BACKGROUND

Our work pays homage to the role of the eyes, gaze and attention in the start of interaction. There are numerous reasons as to why vision is important for the early detection and signalling of willingness to interact. For example, in the social sciences, Kendon [7] analysed human greetings, describing a sequence of opening cues for meeting interaction and noting interaction fundamentals, such as the requirements for participants to first sight each other and identify the other as someone they wish to greet. Goffman further noted [5] that we generally seek to avoid the social embarrassment of engaging in interaction with an unwilling participant: thus, even if we have identified the other as one we wish to interact with, if we are to limit the possibility of social embarrassment (suffered, for example, if the other were to completely ignore us), it is a wise strategy to first establish with some degree of confidence that they will reciprocate in the interaction before we become too explicit in our actions. Gaze negotiation may be one such method of establishing such confidence in a subtle manner, while at the same time having the benefit of orienting the senses towards the object of communication. In the field of evolutionary psychology, the special importance of the eyes and perception of visual attention has been noted in theory of mind research [1]. This work has been supported by neurophysiological evidence [9] and it is particularly in this area where we wish to evaluate social gaze research [3] using computational models [10] in a practical scenario.

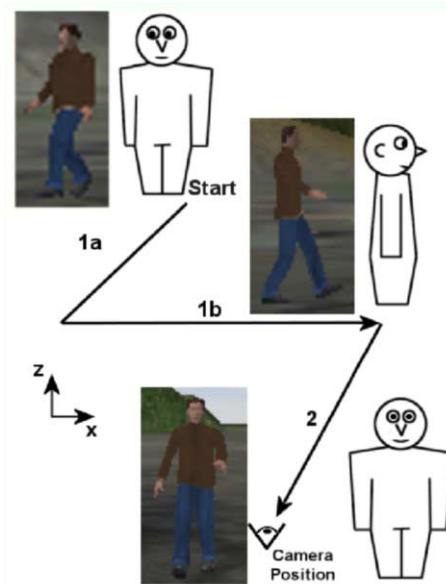

Figure 2. Path taken by the agent in the virtual environment. The path was divided into two main segments (1 and 2). During each DES trial, the agent followed a number of these segments, in order 1a, 1b, 2. While walking along segment 1a, the agent was at an oblique angle to the camera. In contrast, when walking along segment 2, the agent directly faced the camera.

4 EXPERIMENTAL DESIGN

A total of 21 participants engaged in a two-stage evaluation process. The first evaluation, which we will refer to as the static evaluation study, or *SES*, consisted of participants being shown a sequence of 25 static images featuring a humanoid agent standing in an upright posture. In each trial, body segments of the humanoid agent were oriented in varying positions with respect to the viewer: in some images, only certain body segments were visible. After viewing the image, participants were asked to select, using a slider, the amount of attention that they felt the agent was paying to them (“Attention which is being paid to me”), from a range of *NONE* to *A LOT*. The default position of the slider was a center point of the scale. Participants were then required to click a button in order to proceed to the next trial image. The ordering of the trials in the sequence was randomised for each participant.

In the second evaluation, referred to here as the dynamic evaluation study, or *DES*, participants were shown a sequence of 10 animations featuring a humanoid agent moving around in a virtual environment and making a range of behaviours. The behaviours of the agent ranged from ignoring the user, to looking at them, walking towards them and waving. After each trial, the participants had to adjust a number of sliders indicating how they interpreted the actions of the agent in terms of e.g. the amount of interest it had shown towards them and whether they thought the agent had seen them (see Table 1 for full listing). Participants then clicked a button to proceed to the next trial. Prior to the *DES*, participants were shown a test animation demonstrating the capabilities of the agent and what they were about to witness. We distinguished between two cases of an agent that was perceived to ‘want to talk’ to the participant (Table 1: *T*) and one that was thought ‘would respond’ (Table 1: *R*) to a talk request if made by the participant. The first case is suggestive of an agent that was perceived to be proactive in seeking interaction, while the second was a measure of the openness of the agent to interaction, but in a more passive sense.

Table 1. Evaluation sliders to be set after each trial of the DES.

	Text (The agent ...)	Type / Scale
(L)	looked at me	Yes / No
(K)	knows that I am here	Yes / No
(I)	is interested in me	Not at all ↔ Completely
(T)	would like to talk to me	Not at all ↔ Completely
(R)	respond to my request to talk	Not at all ↔ Completely
(F)	intention towards me is	Bad / Harm ↔ Good / Help

4.1 Goals and Hypotheses

This experiment had a number purposes. The most fundamental of these was to verify that human viewers could in fact infer attention and interest from an artificial humanoid character when viewed in a virtual environment. When a humanoid character looks at one, does one have the sense that they are the object of some form of attention? There were also more precise goals for each study. First of all, from the *SES*, to test the notion that the amount of attention that users perceive from an agent in a virtual environment is related to the manner in which three main body segments (the eyes, the head and the body) are oriented with respect to the viewer. This is inspired by research from ethology [3] suggesting that a similar situation may exist in nature, whereby the eyes, head, body and locomotion direction all

influence the perception of the amount of attention that one has in the self. Our initial hypothesis for SES was that the attention perceived by the user would increase as the orientation of agent subparts were directed more towards to user, with the eyes as the biggest indicator of attention, followed by the head and finally the body. Secondly, from the DES, we aimed to test human perception of the intention of an agent to start interaction based only on their direction of gaze and locomotion. Our hypothesis was that increased directed gaze, locomotion and gesture behaviour would result in an increased perception of an agent that was interested in the viewer and open to or seeking interaction.

4.2 Population

All participants were French computer science undergraduate students, between the ages of 19 and 25 and all therefore had a technical background. One sequence of results was disqualified from the SES due to all entries having a zero value and three were disqualified from the DES due to participants following the evaluation guidelines incorrectly. Of the 21 participants, 3 were female.

4.3 Apparatus

The study was conducted in two separate labs. Software was installed on six standard desktop PC's and tests were run in parallel, with six participants involved in the study at any one time independently of each other. All machines were similar in capability, with 3 GHz Intel CPUs running with 1GB of RAM and using Windows 2000 OS with a video resolution of 1280 x 1024 in 32 bit colour. In terms of viewing equipment, four of the machines had identical 19" *Belinea 10 19 20* flat-screen monitors with viewing areas of approximately 15" x 12", the other two monitors had viewing areas of approximately 14.5" x 11" and 13" x 10" respectively. Participants were seated between 40cm and 70cm from their screens. For the SES, the participants had as long as they needed to view the images and select a response. For the DES, participants only viewed an animation once before being presented with the questionnaire screen.

4.4 Software

The Torque engine (<http://www.garagegames.com>) was used to provide the three dimensional virtual environment and other graphics capabilities and to collect evaluation information from participants. The demonstration and collection process was fully automated, although a regulator was on hand to observe correct following of experimental protocol and to answer questions. Participants were initially presented with an in-engine screen providing instructions in French, their native language. From this screen, the participants were then guided through the entire evaluation process via menus, which also prompted for results. For the DES in the virtual environment, since the visibility of the agent's behaviours might be difficult for the viewer when the agent was far away due to the nature of the display equipment, we placed a magnified view of the agent in the top right corner of the display.

4.5 Virtual Agent and Environment

For the DES, participants' avatars were placed in a predetermined position in the virtual environment. They could not alter this position or move around in the environment, but could rotate their viewpoint through the use of the mouse. We used a single male agent model

in all of the cases (see Figure 1). In each trial, the agent started in a set start position (see Figure 2) and walked along a predefined path. The first sub-segment of path (1a) was directed so that the agent would move closer to the viewer without walking directly towards them. The second sub-segment (1b) was positioned so that the agent would walk perpendicular to the viewer. The second segment of path (2) was positioned so that the agent would have a locomotion direction directly towards the viewer. During trials, the agent would either walk along the first segment of path (1), or else both segments of path (1 and 2). A variety of gaze, locomotion and gesture behaviours were made during the trials: thus, trials differed in gaze (gaze at / not gaze at), gesture (wave / no wave) and locomotion direction (oblique / perpendicular / towards) with respect to the viewer.

5 RESULTS

Separate results were obtained for the two evaluation studies, SES and DES, as follows.

5.1 Static Evaluation Study

The averaged results of the static evaluation study for all 21 participants are summarised in descending order according to the amount of attention as perceived from static images of the humanoid agent (see Table 2). Values have a range of 0.0 to 1.0. Participants were asked to adjust a slider that indicated the amount of attention they thought the agent was paying to them in each instance: the slider ranged from *NONE* to *A LOT*. *NONE* has been mapped onto 0 and *A LOT* onto the value of 1.

Table 2. Results for the Static Evaluation Study (SES) in descending order according to the mean amount of attention that participants reported as perceived from the static images of the humanoid agent. The agent was segmented into three main parts: eyes, head and body. Direction was encoded as facing forwards towards the viewer (F), midway (M) and to the side (S).

	Eyes	Head	Body	Av. Rating	Std. Dev.
(a)	F	M	S	0.758	0.186
(b)	F	M	F	0.744	0.169
(c)	F	F	S	0.727	0.293
(d)	F	M	M	0.710	0.163
(e)	F	F	M	0.589	0.233
(f)	F	F	F	0.507	0.322
(g)	M	M	M	0.466	0.302
(h)	M	M	F	0.372	0.322
(i)	S	F	F	0.277	0.269
(j)	S	S	F	0.221	0.240
(k)	S	S	S	0.192	0.278

5.2 Dynamic Evaluation Study

The results for seven of the DES tests are shown in Figure 3. Each test shows, on the left, the path (corresponding to Figure 2) taken by the agent as well as icons indicating the timing of behaviours made along the path. On the right is a graph of the mean values over the 21 participants for each of the queries (Table 1: *I*, *T*, *R*, *F*). Values have a range of 0.0 to 1.0, where 0 is mapped onto *NOT AT ALL* for *I*, *T*, *R* and *BAD / HARM* for *F*. A summary of the results, in descending order for each category, is provided in Table 3.

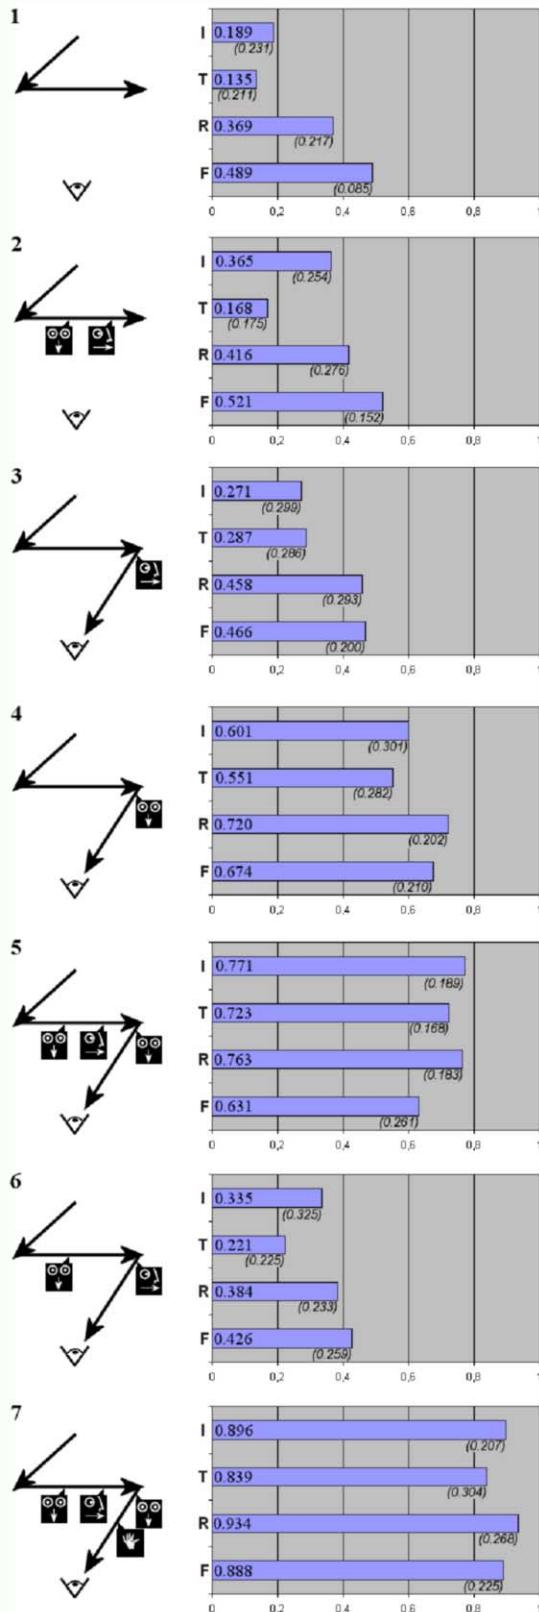

Figure 3. DES results for 7 cases. For each case, a top-down view of the path is presented on the left side, tagged with behaviour icons corresponding to look at viewer, look away from camera and wave gesture respectively and marked at the time at which they occurred. On the right are mean values for perceived *interest* (I), *want to talk* (T), *would respond* (R) and *intention* (F) accompanied, in brackets, by the standard deviation for each data set.

Table 3. Averaged perceived values from DES in descending order as reported by participants. Columns correspond to rows (I), (T) and (R) in Table 1. Cases and values correspond to those illustrated in Figure 3.

Interest (I)		Want Talk (T)		Would Respond (R)	
Case	Value	Case	Value	Case	Value
7	0.89	7	0.83	7	0.93
5	0.77	5	0.72	5	0.76
4	0.60	4	0.55	4	0.72

6 DISCUSSION

At a fundamental level, it is evident from our studies that virtual humanoids have the ability to give users the impression of being paid attention to through gaze, body orientation, gesture and locomotion behaviours. In addition, participants tended to report higher perceptions of interest, interaction seeking and openness overall from the agent when these behaviours were directed towards the user: In the SES, the case rated lowest in terms of the amount of attention perceived to be paid by the agent is that where all body segments are oriented away from the camera. Similarly, in the DES, the case rated lowest in all categories related to interest and interaction was case 1 (Figure 3; see also Table 3). It was in this case that the agent did not look at, walk towards or gesture towards the camera at all.

6.1 Static Evaluation Study

In general, from Table 2, it can be seen that participants' perception of attention from the humanoid agent was highly correlated with the agents eye direction: that is, when the agent was looking forward into the camera (giving the impression of looking at the user), participants rated it highly in terms of paying attention. Head direction correlated less strongly than eye direction, whereas the correlation between perceived attention and body direction was very low. Generally, these results adhere to the hierarchy put forward in [3] and used in [10], which is of the form eyes > head > body.

The most surprising result of this study was the relatively low ranking of 0.507 for case (f) (Table 2), the case where all of the body segments of the agent faced the user (Eyes: front, Head: front, Body: front). One would have expected this to be one of the highest ranked situations. A closer inspection of the results for this case revealed that participants were divided into two distinct categories: of the 21 participants, 9 provided a rating between 0.0 and 0.336 while 8 rated it between 0.654 and 1.0. Considering that, overall, higher ratings were awarded when the eyes were forward and the head/body were not, it is possible that these cases made an 'attentive signal' more apparent due to the contrast of the head/body directions with that of the eye direction. Thus, the lower rating group in case (f) may have perceived less of a signal from the agent e.g. interpreted it as a blank stare, due to lower contrast between segment directions and thus a less obvious signifier of attention in static images.

6.2 Dynamic Evaluation Study

Comparing cases 1 and 2 (Figure 3), where the only difference is a brief glance at the user, participants recorded an increased perceived level of interest from the agent (Interest: 0.189 → 0.365). In case

2, where the agent did not change locomotion direction after glancing at the camera, participants had the impression that the agent was somewhat interested in them (Interest: 0.365), would be responsive to conversation (Would Respond: 0.416), but not that the agent was actively trying to start an interaction (Want Talk: 0.16). Cases 3 and 4 provide a similar situation in terms of interest (0.271 → 0.601) and would respond to an interaction request (0.458 → 0.720). Unlike the previous situation, there was also an increase in the perception that the agent wants to talk (0.287 → 0.551). These results seem to suggest that, although perceived openness is closely linked to the perceived interest through gaze, the coupling between the perception of interest and perception that the agent wants to actively start an interaction requires more overt cues signalling this intention: in this case, a change of locomotion direction towards the camera. This is again supported in a comparison of cases 2 and 5: the agent glances at the user in both cases, but in case 5, it then changes locomotion direction towards them. This locomotion change results in a large increase in all reports (Interest: 0.365 → 0.771, Want Talk: 0.168 → 0.723, Would Respond: 0.416 → 0.763), particularly the impression that the agent actively wants to talk. Without the presence of any gesture behaviours, case 5 was rated highest. Ethologically too, this would seem to be one of the most natural behaviours preceding the start of an interaction: from the user's perspective, the agent walks perpendicular to them without initially being aware of them. It glances over, becomes aware of them, makes a decision to engage them and so, changes direction, walks towards them into interaction range and starts a conversation. The presence of a waving gesture seems to further concretise the perception of attention and reaffirm the intention of the other to engage in interaction (case 7).

In terms of the intention of the other, gaze and locomotion behaviour alone were able to influence participants' perception of the valence of the agent's intention towards them. Comparing cases 4 and 5, where the agent looks towards the participant as it approaches them, with cases 3 and 6, where the agent looks away, reveals a difference of 0.208 between cases 3 and 4 and 0.206 between cases 5 and 6. In each set, the only difference in behaviour was whether the agent looked towards the participant as it moved towards them. In both cases, when the agent moved towards the participant without looking at them, its intention was judged nearer the BAD / HARM end of the scale. In addition to looking towards the user while moving towards them, and despite the absence of facial expression in our studies, unsurprisingly, the agent was perceived as having the best intentions when a waving gesture was present (Figure 3, case 7). Despite the fact that participants reported the agent as not having looked at them, in many cases, they nonetheless reported that they thought the agent was aware of their presence. This may indicate that people attribute similar visual perception capabilities, such as field-of-view, to humanoid characters as to real humans (see case 3).

7 CONCLUSIONS AND FUTURE WORK

We have established a number of factors in this study which have not been the subject of previous research. First of all, virtual humanoids have the ability to give human users the impression that they are being paid attention to through their gaze, body orientation, gesture and locomotion behaviours. Secondly, the human perception of interest, interaction seeking and openness from the agent is based on the direction of eyes, head, body and locomotion of the agent and its dynamic behaviours. The studies here show that a perception of attention metric concerning different body segments, e.g. [10], needs to place a very high emphasis on the eyes of the agent. Beyond this,

more research is needed to establish the exact contributions of the head and body segments to the perception of attention. Our work could also be improved by using a better participant population: in particular, most of the participants in this experiment were male, and it is likely that there are important gender differences when interpreting the behaviour of others [8]. This work may also provide some illumination in areas of human-robot interaction initiation [12], although we are careful to stress the likely-hood of differences between the three cases of users perceiving from the real-world, perceiving a virtual environment using a flat-screen monitor, and perceiving while fully immersed in a virtual reality environment.

Cognitive situated agents learn to name actions

Julien Poudade and Lionel Landwerlin and Patrick Paroubek¹

Abstract. We present experiments in which a population of situated autonomous cognitive agents learns by means of “language games” a common lexicon of symbols that designates basic motions (translation, rotation) in a 2D world. We study the quality of the lexicon learnt when we give our agents a cognitive functionality akin to working memory, and we explain how they are able to agree on a set of common names for basic actions, if their world representation is built using sensorimotor contingencies informations.

1 Introduction

Up to now, all the attempts that have been made for giving a machine the ability to understand a language have consisted in providing it with the corresponding interpretation function. This means that if the machine is expected to interpret a message about its environment, it must then be given what is generally called “common sense” information. Since coding the world has revealed to be a hopeless task, except for a few extremely limited cases, we propose here the first fundaments of an approach where a machine could develop a language from sensorimotor categories it has discovered by itself while interacting with its environment, including machines like itself (unsupervised situated autonomous learning). Our initial aim is to identify the conditions required for the emergence of a language under this hypothesis. We decided to use variation of the naming game developed by L. Steels [14] as communication protocol to test our ideas. With these games, we studied how a population of autonomous agents develops a common lexicon, first to designate static objects then in a second set of experiments, to designate basic motions (rotation, translation) in a 2D world (Figure 1).

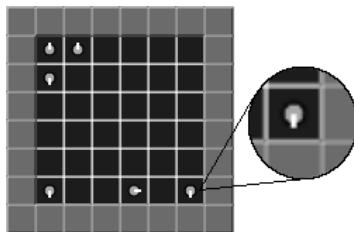

Figure 1. View of the simulation game board: circles are agents, (the light dash give their direction) darkened squares are free locations to which agents can move to, and light squares are obstacles which delimit the game area.

In addition to shedding some light on the fundamental principles required to validate our approach, we look in our experiments at the influence that a cognitive structure akin to “working memory” has on

the learning process. In this paper, we explain first how we think it is possible to perform meaning grounding through interaction with the environment, and describe the effects that such grounding has on the representations built by the agents. On this occasion, we make a short recall on affordances [5] and sensorimotor contingencies [10], two notions coming from precursory works which are essential to our enterprise. Then we describe the architecture of our agents and the different naming game protocols that we have used. The discussion of our experimental results for both the experiment on static object naming and basic action naming precedes the conclusion in which we recall the three results we have obtained so far.

2 Naming Games and Working Memory

Language game models [8] are assimilable to models of communication between agents of a population discoursing about their environment. Our interaction protocol, was inspired by the “naming game” [14]. In this game, agents communicate with each other by pointing objects to other agents and by enunciating words built from a common finite set of syllables. An environment is made of a set of objects and a population of agents². The lexicon is a set of pairs of word-object association, considered at the level of an agent or globally over the whole population. Each agent has an associative memory accessed by content, holding a representation of its lexicon, initially empty. This representation records the credit that the agent gives to each word-object association. As credit function we use the ratio of the number of times the association has successfully been used in a game over the total number of time it has been selected to take part in a game. The notion of working memory in humans has been introduced by [6] then redefined by [2] as being a multiple-component master-slave system. He showed throughout various experiments that the working memory influences everyday cognition activities, like reading apprenticeship, language understanding and vocabulary acquisition. We have completed the model of agent described above by adding a working memory (or short term memory) of fixed size. It contains the elements of the long term memory made salient by the current situation or the result of a cognitive computation.

In [12], we measured the effect that the working memory size has on the ambiguity factor of the lexicon built by our cognitive agents [4] in the course of a series of language games for learning to name objects. Even in an unambiguous closed world, i.e. a world where objects are uniquely distinguished from one another and the number of object is finite and enumerable, the event combinatorics of the language interactions generates ambiguous representations (homonymy, synonymy). It has been shown that in some cases up to 8 words can be used to reference the same object [12]. In these past experiment about the designation of static objects, it has been proved that the ambiguity factor is directly linked to the size of the working memory

¹ LIMSI-CNRS, Orsay, France, email: {poudade,landwerlin,pap}@limsi.fr

² Both sets are finite in our experiments.

of an agent. By increasing a little the size of the working memory, we drastically decrease the size of the lexicon, while the number of objects named remains constant. It is the number of word-object associations for the same object that diminishes.

Consequently, it has been shown that the size of working memory has a strong decreasing effect on the ambiguity factor of lexicon shared by the whole population of agents. Although the model of language game that was used was rather simplistic, the results obtained led us to think that the cognitive structures play an essential role in the acquisition of the symbols of a language. Now convinced of the role played by cognitive structures and of the necessity to define meanings through interaction with the environment, we can address the problem of perceptive categorization raised by [7]. To this end, we will now have a look at affordance, contingencies and semantic representations.

3 Affordances, Contingencies and Meaning

The notion of affordance or action grounding is initially borrowed from "the Gestalt" and can claim its origin in the ecologic psychology of [5]. The central idea behind the notion of affordance is that we perceive directly the functional value of objects, their practical meaning : what is appropriate to do, the risks and obstacles. Affordances are characterized by first, the facts that any object is meaningful (meaning being linked to perceptual experience, in particular linked to traces left by previous experiences), and second by their practical value, objects are immediately associated to a meaning for action. For instance, according to [3], experts almost never plan, they use their skills, action rules, which require an ability to distinguish perceptual clues. One can almost talk of "situated" routines which rely heavily on what is on hand. In that case, instead of reasoning about the world, one accesses it directly by perception and manipulation. But this notion needs to be extended since the work of [11] has shown that the separation between perception and manipulation (action) is artificial and that our access to the world is more likely done directly by means of an association between a perception and an action through a law that ensures the conformity of this association with the state of the world.

The theory of sensorimotor contingencies has been introduced by [10]. It re-integrates action and physical stimulus into the heart of perception, by postulating that sensations are explained by properties of the sensorimotor dependencies (relationship between motor commands and sensorial feedback) rather than sensorial input only. Following this theory, [11] has shown that with a simplified model of the world, it is possible for an entity to experience alone a sensorimotor law which implies unknown sensorial codes and motor commands, and to extract from this law a set of properties which are independent of the codes and commands, provided it receives enough information about its environment. This properties thus reflect an "objective" property of the environment, like for instance the dimensionality of the physical space. The resulting perception is embodied, since it depends on the sensorimotor experience, but it is independent from any specific motor command or sensorial apparatus.

In computational linguistics [9] as well as in models of language evolution [7], semantic representations are strictly descriptive. All the models deal only with the input of the system they consider. They are passive models of knowledge representation which cannot faithfully convey the intrinsic quality of meaning, since the signification that something has for an entity necessarily entails a part of manipulation. Even if some systems like OPENCYC encode the physical laws of the world in their definitions, a machine using such definition will

never have enough information for all the situation it could face in the real world. For instance if we look at the definition of the verb "to walk", there is no information in the definition about the physical reality of the action in situ. To solve this problem, we propose to integrate the notion of sensorimotor contingencies into semantic representations of the world. In this tripartite model, the sensorimotor contingencies bring the knowledge of the laws regulating the world and the entity, the perception part carries perceptive categories and the action part holds functional categories (objects uses). Contingencies are the mean we propose to use for grounding an entity in its world.

4 Learning to name Actions

With the new types of games we introduce here, we are entering the realm of Distributed Situated and Cognitive Artificial Intelligence. In this sort of game, a population of situated agents moves around in a closed world. When not involved in game playing, agents use their contingency function to constantly update their world representation according to the perception they have of their environment when performing random actions. When agents meet, they try to transmit a piece of their knowledge, by means of a symbol, which can be assimilated by analogy with humans to a verb in imperative form. The knowledge which is the subject of the interaction corresponds to the representation that an agent can build in response to spatiotemporal modifications of its environment following a motion (rotation or translation) of himself or of another agent present in its perceptive field [13]. Of course, to play this game, at least two agents need to have their perceptive field intersected. One agent plays the role of locutor; he randomly selects a word from his memory and enunciates it while computing a prediction of what should be his next perception. If his memory is empty, he invents a new word by combining randomly a fixed number of syllables. The other agent uploads into his working memory all the actions that he find associated in world representation with the word perceived and performs the action that he thinks to be the most appropriate for the current context, thus playing the role of actor. The locutor then gives the result of the game by enunciating the word that corresponds to the action he just perceived. The game is a success if the actor has performed the action expected by the locutor, i.e. the modification of locutor's perception corresponds to the one he expected. In that case, the locutor enunciates twice the same word during the game. Otherwise the locutor, using the same process for action selection as the actor (which involves the working memory) enunciates the word he thinks to be associated with the action he just perceived. Both agents update their world representation according to the game result before restarting their exploration.

In our protocol, a series of games is divided into epochs during which each agent must play at least a given number of times the role of locutor in order to ensure that their knowledge is propagated enough throughout the population. For this game to be possible, we propose the following four hypothesis:

1. All the agent have the same motor and cognitive functionality.
2. The sensorimotor categories corresponding to the different classes of actions (here 2 rotations and 1 translation) must exist BEFORE the learning of their designation. An agent cannot talk about something he has not experienced himself before.
3. As a consequence of the previous hypothesis, the agents must have a categorization function that give them the means to organize the content of their long-term memory and their cognitive operations.

This categorization function must take into account the intrinsic characteristics of the agents and the laws of the world, i.e. the sensorimotor contingencies.

4. In order to validate a game, the locutor must be able to somehow “simulate” the behavior of the actor and his perception if he were performing the action in place of the actor [1].

To be able to verify the third hypothesis, our action designation experiments should have been preceded by an experiment of autonomous learning of sensorimotor contingencies, but since this concerns a rather young field of research, no appropriate software is readily available. Because we know the laws that rule our artificial 2D world, we decided to equip our agents with a priori hand-coded sensorimotor contingencies function. Our aim is not to conduct research in situated perception but to study the emergence of meaning (the only results about sensorimotor contingencies that exist in the domain of situated perception concern the perception of the spatial dimensions and of colors, and they concern a unique agent in a noise-free environment[11]). This little liberty taken with respect to our initial line of conduct, namely to have everything emerge from the autonomous behavior of the agent, does not invalidate our main hypothesis on meaning emergence, since if such meaning does emerge in the population, it would still have been built only from sensorimotor contingencies. But even if our agents have been given the laws that govern the spatial and temporal aspects of their world, they still need to learn their environment, in particular because of its topology, of the objects it could contain, or of the other agents present in it. So when not involved in a designation game, our agents will use their sensorimotor contingencies function to structure the representation of the world they maintain in their long term memory. They do so by choosing an action at random, computing the expected perception, performing the action and comparing the actual perception to the one expected. The recording of the result of an interaction is done according to a similarity function which induces a classification over the event stored in the long term memory, and those categories or subcategories are called “concepts”. Such event record the current action, the current perception and the expected perception in addition to a credit function. Let us note that our model, although quite simple, can generalize easily to any kind of representation of the associations between action and perceptions. We will now look at the experimental results we have obtained with our action designation experiments.

5 Action Naming Experiments

We first present a study of the convergence of a population of agents toward the use of a common set of symbols to name basic actions, then we detail what influence the presence of a working memory in the cognitive structure of the agents has on the lexicon building process. Finally, we show the pertinence of using sensorimotor contingencies in the agent representations for elaborating a common lexicon of action names. In the following series of experiments, we consider a population of 6 agents functioning in a 2D world made of a game board of 8×8 square locations (see figure 1).

In figure 2 we can observe a rapid increase of games successes for the three curves, i.e. independently of the working memory size, but two points are remarkable:

- convergence is not monotonous,
- convergence speed depends on the working memory size.

The first point is explained by the embodiment of the agents, our agents are situated so they are more likely to interact with agents

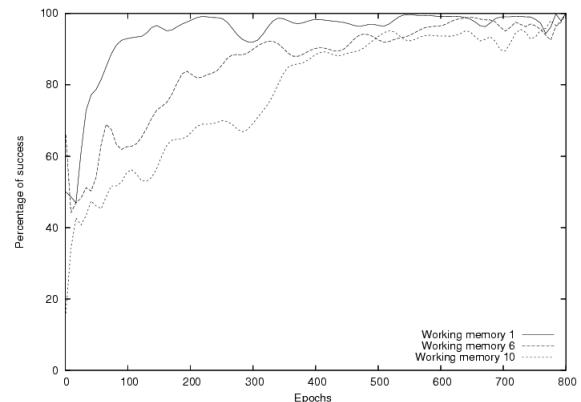

Figure 2. Success rate at action designation in function of time (number of epochs played, up to 800) for 3 different sizes of the working memory (1, 6, and 10).

located in their neighborhood, as a consequence the information flow throughout the population is not evenly distributed but depends on the motion of the agents. The second point stems from an interaction between the working memory size and the reinforcement learning process. Let have a more detailed look at these two phenomena.

5.1 Agent's Embodiment

Because of the situated character of the simulation, there is no certainty that each agent could systematically communicate with all other agents, as opposed to what happens in the more “classical” implementation of our object naming game with disembodied agents. Nevertheless, figure 2 shows convergent systems. Geographically determined subpopulations that share a local lexicon do exist, but most importantly there is also a set of common symbols that is shared by the whole population, as table 1 shows. It contains the number of words shared between all pairs of agents at epoch 800, with agents equipped with a working memory of size 6. All the agents have 14 words in common, but there are some agents with more words in common, a consequence of the locality induced by having embodied agents.

Mixing of information between the subpopulations induced by locality appears in the convergence curves as oscillations in the game success rate. When two subpopulation merge the disagreements between the two lexicons generates failure at the naming game.

agents	1	2	3	4	5	6
1	27	20	23	29	21	
2		25	26	33	25	
3			24	24	19	
4				28	20	
5					26	
6						26

Table 1. This table shows for each pair of agents the number of words they share at epoch 800.

5.2 Working Memory

As we have already said in section 2, to equip the agents with a working memory has the effect of reducing the ambiguity in the lexicon. If we look at figure 2, we observe a very strong levelling of the curve slopes as soon as the working memory is greater than 1. The most striking example is for a working memory of size 1, where we see a sharp progression up to the 200th epoch after which convergence increase diminished drastically.

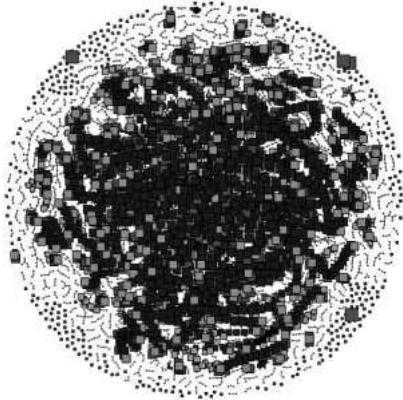

Figure 3. Graph representation of the long term memory of an agent after convergence for a working memory of size 1. Nodes represent concepts (sensorimotor categories) and edges represent inclusion relationships between concepts.

To find an explanation for this fact, we need to look at the internal representation built by the agents, examples of which are shown in graphs³ in figures 3 and 4.

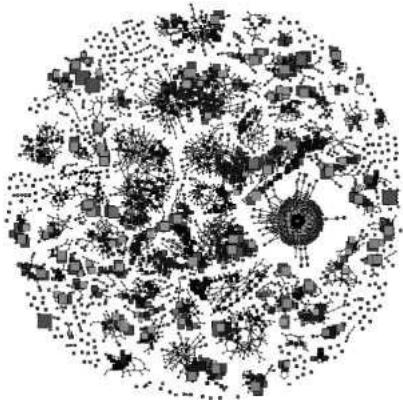

Figure 4. Graph representation of the long term memory of an agent after convergence for a working memory of size 10.

Edge density is linked to working memory size. The smaller the working memory is, the denser the graph is. Density is function of the number of nodes in the graph and so of the number of concepts (categories and subcategories) present in the internal representation of the agents. The working memory is involved in the valida-

tion/validation process of concepts since it contains the most salient concepts in the long term memory of the agent depending on the current situation. A working memory of size 1 does not always permit the selection of all the concepts pertinent for the situation, as a result new concepts will be created while there may exist in the long term memory of the agent concepts that were pertinent but could not be selected because the working memory was already full or because their credit was too low to permit their selection. On the other hand, a working memory of size 10 will select a larger number of concepts at each game and thus entail a reduction of the credit of all the concepts selected if the game is a failure. The greater the working memory size is, the wider the spreading of the penalty will be over the concepts in case of failure. The credit associated to a concept being the ratio between the number of times a concept has been successfully used over the number of times it has been selected (loaded in the working memory), this last number tends to grow along with the working memory size, since selection chances increase with the working memory size. Since penalty is more widespread among the concepts when the working memory is bigger, the saliency of concepts is decreased accordingly and as a consequence also the success rate of the game, because local dialects are preserved longer. In the end, this results corroborates what we have already found in the context of the object naming game described in section 2, the larger the working memory is, the better context disambiguation will be. But contrary to what was observed in the object naming game, here a better disambiguation (larger working memory) slows down convergence toward a common lexicon since it tends to spread penalty over all concepts, including the potentially pertinent concepts.

5.3 Sensorimotor Contingencies

Still with the same action naming game protocol, we will now show the pertinence of using a perception-action-contingency triplets to build and access the world representation stored in the agent's long term memory. We will proceed systematically and consider a population of situated agents which uses different types of information to build their world representation:

- only perceptions,
- only actions,
- perception and actions,
- and finally perception-action-contingency triplets.

Non converging games (perception only or action only): Figure 5 shows non convergence for a system which takes into account only perceptions. Since a key factor in the action naming game is the ability to predict the expected state of the environment following an action (expectation), a system that considers only perception cannot associate together all the perceptions generated by a given action. The agents cannot link causes to effects. The system is then “crushed” by perceptive combinatoric explosion and cannot anymore build sensorimotor categories. The required hypothesis of preexistence of the sensorimotor categories of section 2 for the action naming game to be convergent is not verified anymore. Nevertheless, the curve of figure 5 shows a certain amount of success, but it is only due to the random selection process for action given a perception, once in a while the agent selects by chance the correct action among all the possible ones.

Similarly, if we consider only action as access key for the agent's representation we face a paradox: all the games are successes but the population does not converge toward a common lexicon! This is

³ The graph were created with the Tulip visualizer of LABRI.

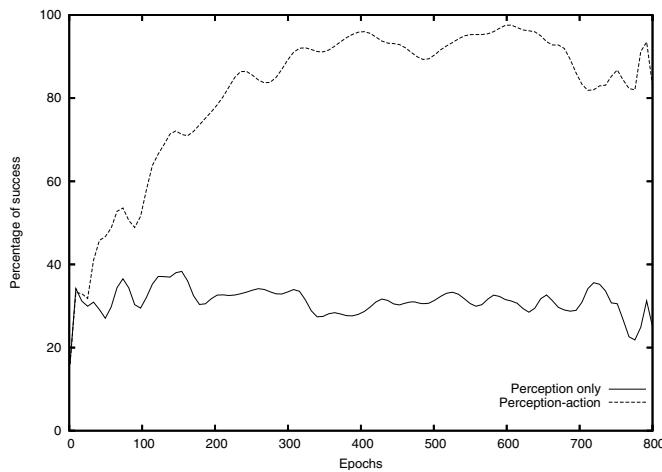

Figure 5. Success rate curve in function of time at naming action game for a population of agents which consider only perceptions and perception-action pairs for its representation (working memory of size 6, 800 epochs).

entirely due to the protocol, since the validation of a game is based on the comparison between an effective perception and an expected perception. If we do not take into account perceptions, all games are successes, necessarily. This degenerated case is of no interest for our purpose.

Converging games (perception-action and contingencies): If now we consider the pair perception-action as access key for the agent's representation (we will call it the PA case), we now obtain the expected convergence, as is shown in figure 5. Similarly, if we consider the triplet perception-action-contingency as access key (PAC case) we get exactly the same kind of convergence as for the perception-action case. So what is the interest of adding contingency information if both approaches result in the same convergence? The difference lies in the quality of the lexicon which improves drastically if we use sensorimotor contingency information. Let us consider, for instance, an agent that tries to perform a forward translation when facing a wall. In the PA case, “consistency” of the phenomena will not be checked and whatever the perceptive outcome of an action, it will serve as a base for building a sensorimotor category, which eventually will fall under the translation category (a particular sub-category of). But in the PAC case, the same situation will end up with the creation of a category different from translation (which we could call “no-action”) since the expected perception (change of location) predicted by the sensorimotor contingencies is not validated for an the agent trying to move into a wall. So adding the sensorimotor contingencies is equivalent to introducing consistency checking in the representation of the agent to ensure it reflects the effective laws of its environment by detecting “anomalies”. The addition of contingency information will result in more sensorimotor categories being created and in larger lexicons. Indeed, we measured experimentally for the size of the lexicon holding the associations between names and sensorimotor categories, an average lexicon size of 4 in the PA case and an average size of 14 in the PAC case.

6 Conclusions

These experiments of unsupervised learning action designation with situated cognitive agents in a 2D environment provided us with a first experimental validation of the possibility for a population of agents to converge toward a common lexicon of basic action names, while relying only on the representation built from sensorimotor contingencies recording and categorization, done when the agent interacts with its environment and other agents. Further, it enabled us to exhibit a necessary condition for the game to converge, namely the ability for an agent to project itself “mentally” in place of another agent in order to predict its perception. Note that in the case of simpler forms of the naming games, involving only static objects and disembodied agents, this condition does not hold. We have also shown that:

1. the situated character of agents generates the emergence of local lexicons (dialects) which tend to hinder global convergence toward a common lexicon
2. also the augmentation of the size of the working memory tends to reduce the ambiguity in the shared lexicon, it has the negative effect of preserving the existence of local dialects, and thus of slowing convergence.

Adding the sensorimotor contingencies to the agent's world representation is equivalent to introducing consistency checking in the representations to ensure that it reflects the effective laws of the environment. The addition of contingency information will result in larger lexicons, since the agents are then able to make finer grain distinction over the consequences of their actions in the environment.

Tracking the Lexical *Zeitgeist* with WordNet and Wikipedia

Tony Veale¹

Abstract. Most new words, or neologisms, bubble beneath the surface of widespread usage for some time, perhaps even years, before gaining acceptance in conventional print dictionaries [1]. A shorter, yet still significant, delay is also evident in the life-cycle of NLP-oriented lexical resources like WordNet [2]. A more topical lexical resource is Wikipedia [3], an open-source community-maintained encyclopedia whose headwords reflect the many new words that gain recognition in a particular linguistic sub-culture. In this paper we describe the principles behind *Zeitgeist*, a system for dynamic lexicon growth that harvests and semantically analyses new lexical forms from Wikipedia, to automatically enrich WordNet as these new word forms are minted. *Zeitgeist* demonstrates good results for composite words that exhibit a complex morphemic structure, such as portmanteau words and formal blends [4, 5].

1 INTRODUCTION

Language is a dynamic landscape in which words are not fixed landmarks, but unstable signposts that switch directions as archaic senses are lost and new, more topical senses, are gained. Frequently, entirely new lexical signposts are added as newly minted word-forms enter the language. Some of these new forms are cut from whole cloth and have their origins in creative writing, movies or games. But many are patchwork creations whose origins can be traced to a blend of existing word forms [1]. This latter form of neologism is of particular interest to the computational lexicographer, since such words possess an obviously compositional structure from which one can begin to infer meaning. In this paper, we demonstrate that, if given enough semantic context, an automated system can assign a sufficiently rich semantic structure to these words to allow them to be automatically added to an electronic database like WordNet [2]. When tied to a system for harvesting new word forms from the internet, this capability allows for a dynamic WordNet that grows itself in response to a changing language and cultural context.

Most neologisms bubble beneath the surface of widespread usage before they gain entry to a conventional dictionary. This is to be expected, since the internet is awash with idiosyncratic neologisms that lack both charm and staying power. Nonetheless, to experience the variety and inventiveness of the most creative new words in English, one need look no further than Wikipedia [3], an open-source electronic encyclopedia that is continuously updated by a on-line community of volunteers. If such words are likely to be encountered in any text to which NLP technologies are applied, from deep text understanding to shallow spell-checking, we should expect our lexical databases to possess a basic interpretation capability.

In this paper, we describe an automated system, called *Zeitgeist*, that harvests neologisms from Wikipedia and uses the semantic context provided by Wikipedias topology of cross-references to add corresponding semantic entries to WordNet. In section two we briefly describe WordNet and Wikipedia, and outline the properties of each that are central to *Zeitgeist*'s operation. Our goal is to exploit only the topology of cross-references, rather than the raw text of the corresponding Wikipedia articles (which would necessitate heavy-duty parsing and analysis methods). Since some topological contexts are more opaque than others, *Zeitgeist* employs a multi-pass approach to acquiring new word forms. In the first pass, only clear-cut cases are harvested; these exemplars are then generalized to underpin schemata that, in a second pass, allow less obvious neologisms to be recognized and semantically analyzed. Both passes are described in sections three and four. In section five, an empirical evaluation and discussion of *Zeitgeist*'s results is presented, while concluding thoughts are offered in section six.

2 LINKING WORDNET AND WIKIPEDIA

WordNet and Wikipedia each blur the traditional semiotic distinction between dictionaries and encyclopedias - which views the former as a source of *word* knowledge and the latter as a source of *world* knowledge - in different ways. WordNet is primarily an electronic dictionary/thesaurus whose structure is informed by psycholinguistic research (e.g., it uses different representations for nouns, verbs, adjectives and adverbs), but in eschewing alphabetic indexing for a semantic organization, it imposes an encyclopedia-like topic organization on its contents. Its coverage is broad, containing entries on topics such as historical events, places and personages more typically found in an encyclopedia. Unsurprisingly, it tends to be used in NLP applications not just as a lexicon, but as a lightweight knowledge-base for reasoning about entities and events.

For its part, Wikipedia's topic articles are surprisingly word-oriented. One finds many more headwords than in a conventional encyclopedia, and a richer level of interconnectedness. In many cases, composite headwords (such as "feminazi") are explicitly linked to the entries for their component parts, while detailed articles on lexical phenomena such as blended (or portmanteau) word-forms [4, 5] and political epithets provide links to numerous topical examples. Additionally, a sister project, Wiktionary [6], aims to exploit the Wikipedia model for an open-source dictionary.

The advantages accruing from an integration of such complementary resources are obvious. To Wikipedia, WordNet can give its explicit semantic backbone, as found in the *isa*-taxonomy used to structure its noun senses. To WordNet, Wikipedia can give its rich, open-textured topology of cross-references [7], as well as its larger and

¹ School of Computer Science and Informatics, University College Dublin, Ireland, email: {Tony.Veale}@UCD.ie

constantly growing set of topical headwords. To achieve this integration, the headwords of Wikipedia must be sense-disambiguated, though [8] report positive results for this task. In this paper, we explore the extent to which the semantic head of a neologism (that part which contributes the suffix, partially or completely, such as “pub” in “Gastropub” and “economics” in “Enconomics”) can be disambiguated by the priming effects of other links emanating from the same Wikipedia article. General purpose WSD techniques (e.g., [9,10]), applied to the text rather than the links of an article, can then be used to resolve those ambiguous heads that are not primed in this way.

Toward this end, we introduce two connectives for relating Wikipedia headwords to WordNet lexical entries. The first is written $x \text{ } isa \text{ } y$, and states that a new synset $\{x\}$ is to be added to WordNet as a hyponym of the appropriate sense of y . Thus, *superhero* *isa* *hero* assumes that WSD is used to identify the intended sense of “hero” in the “superhero” context. The second is $x \text{ } hedges \text{ } y$, as in *spintronics* *hedges* *electronics*. As described in Lakoff [11], a hedge is a category-building relationship that allows one to reason as if a concept belonged to a given category, in spite of strict knowledge to the contrary (e.g., most people know that whales are not fish, but reason about them as if they were). In WordNet terms, hedge relationships will ultimately be instantiated via taxonomic coordination: $\{\text{spintronics}\}$ will not be added as a hyponym of $\{\text{electronics}\}$, rather both will share the common hypernym $\{\text{physics}\}$. Hedges allow us to sidestep the awkward issues of hyperbolae and metaphor that frequently mark new coinages. Though “affluenza” (“affluence + influenza”) is not, strictly speaking, a kind of “influenza”, the hedge allows an NLP system to reason as if it were a real virus; this is apt, since the blend is used to depict affluence as a contagious affliction.

3 PASS I: LEARNING FROM EASY CASES

We employ a string-matching approach to recognizing and analyzing Wikipedia neologisms, in which specific schemata relate the form of a headword to the form of the words that are cross-referenced in the corresponding article. Let $\alpha\beta$ represent the general form of a Wikipedia term, where α and β denote arbitrary prefix and suffix strings that may, or may not, turn out to be actual morphemes. In addition, we use $\alpha \rightarrow \beta$ to denote a reference to headword β from the Wikipedia article of α , and use $\alpha \rightarrow \beta ; \gamma$ to denote a contiguous pair of references to β and γ from article α .

As noted earlier, *Zeitgeist* seeks out neologisms that are a formal blend of two different lexical inputs [4, 5]. The first input contributes a prefix element, while the second contributes a suffix element that is taken to indicate the semantic head of the neologism as a whole. The first schema below illustrates the most common arrangement of lexical inputs (as we shall see in section 5):

Schema I: Explicit Extension

$$\frac{\alpha\beta \rightarrow \beta \wedge \alpha\beta \rightarrow \alpha\gamma}{\alpha\beta \text{ } isa \text{ } \beta}$$

This schema recognizes blended word forms like “gastropub” and “feminazi” in which the suffix β is a complete word in itself (e.g., “pub” and “Nazi”), and in which the prefix α is a fragment of a contextually linked term (like “gastronomy” or “feminist”). The suffix β provides the semantic head of the expansion, allowing the new term to be indexed in WordNet under the appropriate synset (e.g., {Nazi} or {pub, public_house}). The textual gloss given to this new entry

will be a simple unpacking of the blended word: “ $\alpha\gamma\beta$ ” (e.g., “gastro~~onomy~~ pub” and “feminist Nazi”). To avoid degenerate cases, α and β must meet a minimum size requirement (at least 3 characters apiece), though in some exceptional contexts (to be described later), this threshold may be lowered.

Many neologisms are simple variations on existing terminology. Thus, “fangirl” is a male variation on “fanboy”, while “supervillain” is a criminal variation on “superhero”. When an explicit Wikipedia reference exists between these alternating suffixes, the new composite word can be identified as follows:

Schema II: Suffix Alternation

$$\frac{\alpha\beta \rightarrow \alpha\gamma \wedge \beta \rightarrow \gamma}{\alpha\beta \text{ } hedges \text{ } \alpha\gamma}$$

This schema identifies a range of alternating suffix pairs in Wikipedia, from *man* \leftrightarrow *boy* to *woman* \leftrightarrow *girl* to *genus* \leftrightarrow *genera*, *bit* \leftrightarrow *byte* and *bacteria* \leftrightarrow *toxin*.

We can now begin to consider portmanteau words in which the suffix term is only partially present. Words like “Rubbergate” are understood as variations on other terms (e.g., “Watergate”) if the prefix term (here, “rubber”) is explicitly linked. In effect, a partial suffix like “gate” becomes evocative of the whole, as follows:

Schema III: Partial Suffix

$$\frac{\alpha\beta \rightarrow \gamma\beta \wedge (\alpha\beta \rightarrow \alpha \vee \alpha\beta \rightarrow \gamma \rightarrow \alpha)}{\alpha\beta \text{ } hedges \text{ } \gamma\beta}$$

This schema additionally covers situations where the prefix is only indirectly accessible from the neologism, as in the case of “metrosexual” (where “metro” is accessible via a link to “metropolitan”), and “pomosexual” (where “pomo” is only accessible via a mediating link to “postmodernism”). We note that this schema ignores the obvious role of rhyme in the coinage of these neologisms.

This indirection means that, in words like “metrosexual”, both the prefix and the suffix may be partially projected to form a true portmanteau word. In Wikipedia, the lexical inputs to a portmanteau word are often stated as contiguous references in the corresponding article. For instance, Wikipedia describes “sharpedo” as a “shark torpedo”, while “Spanglish” is explicitly unpacked in the corresponding article as “Spanish English”. We can exploit this finding in the following schema:

Schema IV: Consecutive Blends

$$\frac{\alpha\beta \rightarrow \alpha\gamma ; \gamma\beta}{\alpha\beta \text{ } hedges \text{ } \gamma\beta}$$

Indeed, portmanteau terms are so striking that the corresponding Wikipedia articles often explicitly reference the headword “portmanteau”, or vice versa. In such cases, where $\alpha\beta \rightarrow \text{portmanteau}$, we can safely reduce the minimum size requirements on α and β to two characters apiece. This allows *Zeitgeist* to analyze words like “spork” (spoon + fork) and “spongery” (spam + forgery).

4 PASS II: RESOLVING OPAQUE CASES

The foregoing schemata anchor themselves to the local topological context of a headword to curb the wild over-generation that would arise from string decomposition alone. But even when this

topological context is uninformative, or absent entirely (since some Wikipedia articles make no reference to other articles), a system may be able to reason by example from other, more clear-cut cases. For instance, there will be many exemplars arising from schemas III and IV to suggest that a word ending in “ware” is a kind of software and that a word ending in “lish” or “glish” is a kind of English. If E is the set of headwords analyzed using schema III and IV, and S is the corresponding set of partial suffixes, we can exploit these exemplars thus:

Schema V: Suffix Completion

$$\frac{\alpha\beta \rightarrow \gamma\beta \wedge \gamma\beta \in E \wedge \beta \in S}{\alpha\beta \text{ hedges } \gamma\beta}$$

Since the Wikipedia entries for “crippleware”, “donationware” and “malware” - but not “stemware” or “drinkware” - make reference to “software”, the above schema allows us to infer that the former are kinds of software and the latter dishware. Suffix completion reflects the way neologisms are often coined as reactions to other neologisms; for example, once “metrosexual” is recognized using schema III (partial suffix), it provides a basis for later recognizing “retrosexual” using schema V, since “sexual” will now suggest “metrosexual” as a completion. Similarly, “Reaganomics” serves as an exemplar for later analysing “Enronomics”. If P denotes the set of prefix morphemes that are identified via the application of schemas I, II and III, we can also formulate the following generalization:

Schema VI: Separable Suffix

$$\frac{\alpha\beta \rightarrow \beta \wedge \alpha \in P}{\alpha\beta \text{ isa } \beta}$$

This is simply a weakened version of schema I, where α is recognized as a valid prefix but is not anchored to any term in the topological context of the headword.

Though the entry “logicnazi” makes no reference to other headwords in Wikipedia, one can immediately recognize it as similar to “feminazi” (a “feminist Nazi” as resolved by schema I). Conceptually, “Nazi” appears an allowable epithet for an extreme believer of any ideology, and in part, this intuition can be captured by noting that the “Nazi” suffix overwrites the “ism” / “ist” suffix of its modifier. If T is a set of tuples, such as $\langle \text{ism}, \text{Nazi} \rangle$, derived from the use of schema I, we have:

Schema VII: Prefix Completion

$$\frac{\alpha\gamma \rightarrow \alpha \wedge \langle \gamma, \delta\beta \rangle \in T}{\alpha\beta \text{ isa } \beta}$$

Zeitgeist recognizes “logicnazi” as a kind of “Nazi”, in the vein of “feminazi”, since, from “logic” it can reach an “ism” or belief system “logicism” for this Nazi to extol. Likewise, it recognizes “Zionazi” as an extreme Zionist (allowing for a shared “n”), and “Islamonazi” as an extreme Islamist (allowing for an added “o” connective).

Finally, the collected prefixes and suffixes of pass one can now be used to recognize portmanteau words that are not explicitly tagged (as in schema V) or whose lexical inputs are not contiguously referenced (as in schema IV):

Schema VIII: Recombination

$$\frac{\alpha\beta \rightarrow \alpha\gamma \wedge \alpha\beta \rightarrow \delta\beta \wedge \alpha \in P \wedge \beta \in S}{\alpha\beta \text{ hedges } \delta\beta}$$

Thus, a “geonym” can be analyzed as a combination of “geography” and “toponym”.

5 EVALUATION AND DISCUSSION

To evaluate these schemata, each was applied to the set of 152,060 single-term headwords and their inter-article connections in Wikipedia (as downloaded as a SQL loader file in June, 2005). Version 1.6 of WordNet was used to separate known headwords from possible neologisms. In all, 4677 headwords are decomposed by one or more of the given schemata; of these: 1385 (30%) are ignored because the headword already exists in WordNet, 884 (19%) are ignored because the hypernym or hedge determined by the analysis does not itself denote a WordNet term. Thus, though “bioprospecting” is correctly analyzed as “biology prospecting”, “prospecting” is not a lexical entry in WN1.6 and so this term must be ignored. The remaining 2408 (51%) of cases² are analyzed according to the breakdown of Table I:

Table 1. Breakdown of performance by individual schema.

Schema	# Headwords	# Errors	Precision
I	710	29%	.985
II	144	5%	1.0
III	330	13%	.985
IV	82	3%	.975
V	161	6%	1.0
VI	321	13%	.95
VII	340	14%	.90
VIII	320	13%	.965

Each *Zeitgeist* analysis was manually checked to find errors of decomposition and provide the precision scores of Table I. Two schemas (II in pass one, which e.g., derives Rubbergate from Watergate, and V in pass two, which e.g., derives retrosexual from metrosexual) produce no errors, while the most productive schema (explicit extension, schema I) has an error rate of just 1.5%. In contrast, schema VII (prefix completion in pass two, which derives logicnazi via the exemplar feminist/feminazi) is cause for concern with an error rate of 10%. High-risk schemata like this should thus be used in a controlled manner: they should not update the lexicon without user approval, but may be used to hypothesize interpretations in contexts that are more ephemeral and where more information may be available (e.g., a spellchecking or thesaurus application invoked within a particular document).

Some obvious factors contribute to an overall error rate of 4%. Company names (like Lucasfilm) comprise 12% of the erroneous

² Interestingly, the distribution for WN2.1 is much the same: 1570 analysed headwords (33%) are ignored because the headword is already in WN2.1, while 789 headwords (17%) must be ignored because their semantic heads are *not* in WN2.1. This leaves 2319 valid neologisms (49%) to be added to WN2.1, as opposed to 2408 for WN1.6. The number of neologisms remains relatively stable across WN versions because greater lexical coverage presents a greater opportunity to recognize neologisms that cannot be integrated into lesser versions. For instance, the “cyberpunk” entry in WN2.1 means that while this word is not treated as a neologism for this version (as it is for WN1.6), its presence allows “steampunk” and “clockpunk” to be recognized as neologisms.

cases, organization names (like Greenpeace and Aerosmith) 6%, place names (like Darfur) 11% and product names (like Winamp) 2%. Another 5% are names from fantasy literature (like Saruman and Octopussy). In all then, 35% of errors might be filtered in advance via the use of a reliable named-entity recognizer.

5.1 Word Sense Disambiguation

For 51% of the Wikipedia neologisms recognized by *Zeitgeist*, the semantic head (i.e., the word that contributes the suffix to the neologism) denotes an unambiguous WordNet term. The remaining 49% of cases thus require some form of WSD to determine the appropriate sense, or senses, of the semantic head before the neologism can be added to WordNet. While one can employ general purpose WSD techniques on the textual content of a Wikipedia article [9, 10], the topological context of the headword in Wikipedia may, to a certain degree, be self-disambiguating via a system of mutual priming.

For example, the intended WordNet sense of “hero” in the headword “superhero” (not present in WN 1.6) is suggested by the link *superhero* → *Hercules*, since both “hero” and “Hercules” have senses that share the immediate WordNet hypernym {Mythological-Character}. In general, a given sense of the semantic head will be primed by any Wikipedia term linked to the neologism that has a WordNet sense to which the head relates via synonymy, hyponymy or hypernymy.

Priming can also be effected via an intersection of the textual glosses of WordNet senses and the topological context of the Wikipedia article (in a simple Wikipedia variation of the Lesk algorithm [9]). For example, the Wikipedia headword “kickboxing” suggests the ambiguous “boxing” as a semantic head (via schema I). However, because the Wikipedia link *kickboxing* → *fist* is echoed in the gloss of the WordNet sense {boxing, pugilism, fisticuffs} but not in the gloss of {boxing, packing}, only the former is taken as the intended sense.

More generally, the elements of the Wikipedia topological context can be viewed as a simple system of semantic features, in which e.g., *fist* is a feature of *kickboxing*, *fascism* is a feature of *Nazi*, and so on. Furthermore, because blending theory [4,5] claims that blended structures will contain a selective projection of elements from multiple inputs, this projection can be seen in the sharing of semantic features (that is, topological links) between the neological headword and its semantic head. For instance, the Wikipedia terms “Feminazi” and its semantic head, “Nazi”, share three Wikipedia links - to Totalitarianism, Fascism and Nazism - which may be taken as the contribution of the lexical component “Nazi” to the meaning of the word as a whole. In the terminology of blending theory [4,5], these features are *projected* from the input space of *Nazi* into the blended space of *Feminazi*. Projection of this kind occurs in 64neologisms recognized by *Zeitgeist*.

By understanding the projective basis of a word blend, *Zeitgeist* has yet another means of performing disambiguation of the semantic head, since the intended sense of the head will be that sense that visibly contributes semantic features to the blend. In the case of “kickboxing”, the feature *fist* is directly contributed by the pugilistic sense of “boxing”. However, for the blended word “emoticon”, the feature *pictogram* is indirectly contributed by the user-interface sense of “icon” via its hypernym {symbol}.

Overall, topological priming resolves 25% of neologisms to a single WN1.6 sense, while another 1% are resolved to multiple WN senses, which is to be expected when the head element is a polysemous word. For instance, “photophone” (“photograph” + “tele-

phone”) is deemed to hedge both the equipment and medium senses of “telephone”, while “subvertising” (“subversion” + “advertising”) is deemed to hedge the message and industry senses of “advertising”. In all, total WSD coverage in *Zeitgeist* is 77%. Recourse to more general WSD techniques is thus needed for just 23% of cases.

5.2 Literal Versus Figurative Interpretations

Our evaluation reveals that over half (57%) of the neologisms recognized by *Zeitgeist* (via schemas I, VI and VII) are realized in WordNet via a simple hypernymy relationship, while the remainder (43%) are realized (via schemas II, III, IV, V and VII) using the more nuanced *hedge* relationship. It seems clear, for instance, that “Gastropub” really is a kind of “pub” and “cocawine” really is a kind of “wine” (with added cocaine). However, it is not so clear whether Feminazis are truly Nazis (in the strict, National Socialist sense), so hedging may be more prevalent than these figures suggest. Though WordNet defines {Nazi} as a hyponym of {fascist}, the word is often used as a highly charged pseudo-synonym of the latter. “Nazi” seems to be used here in a sense-extensive, metaphoric fashion to suggest totalitarian zeal rather than political affiliation.

Two factors alert us that this use of “Nazi” is hyperbole rather than literal extension. The first is the orthographic form of the word itself, for while “Nazi” is a proper-named class, “Feminazi” employs the word in an uncapitalized form which suggests a process of semantic bleaching or generalization. The second factor is the relative contribution, in terms of projected features, of the semantic head to the blend as a whole. Recall that the word “Nazi” shares the Wikipedia linkages {Totalitarianism, Fascism, Nazism} with “Feminazi”, so these features may be said to originate from this input. However, “fascist” also references the terms {Totalitarianism, Fascism, Nazism} in Wikipedia, suggesting that there is no obvious loss of semantic import if Feminazi is considered an extension of {fascist} rather than of {Nazi}.

In 36% percent of neologisms, one or more semantic features are projected into the blend by a hypernym of the semantic head. In just 2% of neologisms this projection occurs in the context of an *isa* relation (i.e., via schemas I and VI) and is such that all features that are projected from the head are also redundantly projected from the hypernym of the head. (As it happens, only in the case of “Feminazi” does the semantic head denote a proper-named concept). While not conclusive, such redundancy is sufficient cause either to hedge the relationship or to prompt for human guidance in these cases.

6 CONCLUSIONS

We have presented a linguistics-lite approach to harvesting neologisms from Wikipedia and adding them to WordNet. *Zeitgeist* does not employ an explicit morphological analyser, but relies instead on a marriage of partial string-matching and topological constraints. Nonetheless, many of the words that are successfully recognized exhibit a creative and playful use of English morphology. Furthermore, by grounding analyses in the local link topology of Wikipedia articles, *Zeitgeist* gains a semantic insight that one cannot obtain from morphology rules alone. For instance, not only is “microsurgery” recognized as a micro-variant of surgery, the specific meaning of “micro” in this context is localized to the headword “microscopy” via schema I. The concept “microsurgery” is not just “micro-surgery”, but surgery conducted via a microscope.

Even a lightweight approach can, however, bring some degree of semantic insight to bear on the analysis of new words. In this

respect, Wikipedias link topology deserves further consideration as a source of semantic features. Certainly, Wikipedia has great promise as a semi-structured semantic representation. For instance, one can distinguish two kinds of semantic feature in Wikipedia. Strong or highly-salient features are those that are reciprocated; thus, *charity*→*altruism* and *altruism*→*charity* implies that altruism is a highly salient feature of charity, and vice versa. Weak features are those that are not reciprocated in this way. It remains to be seen how far one can go with such a representation without imposing a more rigid logical framework, but we believe that the initial foray described here suggests the scheme has yet more mileage to offer.

We conclude by noting that the linguistics-lite nature of *Zeitgeists* approach means that is not intrinsically biased toward English. In principle, its mix of string matching and topological constraints should validly apply to other languages also. Whether phenomena like lexical blending spring forth with equal regularity in the non-English languages supported by Wikipedia is a subject of future research.

2. Constraints and Search

This page intentionally left blank

Enhancing constraints manipulation in semiring-based formalisms¹

Stefano Bistarelli² and Fabio Gadducci³

Abstract. Many “semiring-like” structures are used in Soft Constraint Satisfaction Problems (SCSPs). We review a few properties of semirings that are useful for dealing with soft constraints, highlighting the differences between alternative proposals in the literature.

We then extend the semiring structure by adding the notion of *division* as a weak inverse operation of product. In particular, division is needed to apply constraint relaxation when the product operation of the semiring is not idempotent. The division operator is introduced via *residuation* and it is also able to deal with partial orders, generalizing the approach given for Valued CSPs.

1 Introduction

Several formalizations of the concept of *soft constraints* are currently proposed in the literature. In general terms, a soft constraint may be seen as a function associating to each assignment (i.e., instantiation of the variables occurring in it) a value in a partially ordered set A , which can be interpreted as a set of preference values or costs. Combining constraints then has to take into account such additional values, and thus the formalism must provide suitable operations for the combination and the comparison of tuples of values and constraints.

The paper focuses on semiring-based frameworks: Assignments take values in a semiring, the order is the one associated to the $+$ operator of the semiring, and the combination is the \times operator. We review the basics of semiring theory and identify a few properties that are needed to deal with constraints. These properties boil down to the notion of commutative, absorptive semiring, an instance of well-known tropical semirings [23]. Based on this characterization, a comparison between several proposals is performed, namely valuation structures [26], c -semirings [4, 7] and semiring valuations [27].

Soft constraint satisfaction problems can be solved by extending and adapting the techniques used for their classical version. For example, a branch and bound search algorithm can be used, instead of backtracking, for finding the best solution. A pivotal component of this generalization is the search for algorithms of constraint relaxation, in order to obtain some form of local consistency (i.e., such that changing the semiring values associated to an assignment does not change the overall solution). More to the point, in this paper we define a technique to move valuation (cost) information from constraints involving multiple variables to simpler, possible unary ones, resulting in an upper bound on the problem valuation.

Elaborating on a proposal by Cooper and Schiex [11, 12, 25], we propose improvements on classical local consistency techniques, in order to apply the framework also whenever the constraint composi-

tion operator is not idempotent. To this end, we extend the semiring structure by adding the notion of *division* as a weak inverse operation of product. The solution we pursue for characterizing that operator is based on *residuation theory* [8], a standard tool on so-called *tropical* arithmetics. It allows for obtaining a division operator *via* an approximate solution to the equation $b \times x = a$.

2 On semirings

Slightly different presentation for the notion of *semiring* occur in the literature. The less constrained definition we are aware of (compare e.g. the survey [24]) is given by a set A equipped with two binary operators, the sum $+$ and the product \times , such that $+$ is associative and commutative (that is, the pair $\langle A, + \rangle$ is a commutative semigroup), and the product operator \times distributes over $+$.

In soft constraints literature the cost/preference associated to each variable instance is modeled as an element of a semiring, and the constraint combination is defined via the semiring product operator [4, 5, 7, 27]. Most often, the sum operator is used just for the induced pseudo order⁴, given by $a \leq b$ iff $a + b = b$.

Which properties should be required for constraint combination?

- Since satisfaction problems are defined by “sets” of constraints, the order of the constraints combination has to be irrelevant. This leads to the *associativity* and *commutativity* for the \times operator;
- since adding constraints decreases the number (and the quality) of the solutions, the combination of constraints has to worsen the value of the operands. This means that the ordering has to be *absorptive* ($a + (a \times b) = a + (b \times a) = a$);
- when dealing with soft constraints there might be the need of representing crisp features. That is, there must be an element in the semiring that has the crisp meaning of total dislike of any solution that involve a specific assignment. Thus, an element $\mathbf{0} \in A$ called *zero* or *annihilator* element ($a \times \mathbf{0} = \mathbf{0} \times a = \mathbf{0}$);
- similarly, there must be an element that has the crisp meaning of “indifference”, i.e., the satisfaction of the specified constraint does not change the overall level of preference for a given tuple. Such an element $\mathbf{1} \in A$ is called *unit* ($a \times \mathbf{1} = \mathbf{1} \times a = a$).

We adopt a terminology inspired by [14] and, in lesser degree, by [24], aiming at a smooth presentation of the main concepts to the reader.

Definition 1 (semirings) A commutative semiring is a five-tuple $\mathcal{K} = \langle A, +, \times, \mathbf{0}, \mathbf{1} \rangle$ such that A is a set, $\mathbf{1}, \mathbf{0} \in A$, and $+, \times : A \times A \rightarrow A$ are binary operators making the triples $\langle A, +, \mathbf{0} \rangle$ and $\langle A, \times, \mathbf{1} \rangle$ commutative monoids (semigroups with identity), satisfying

(**distributivity**) $\forall a, b, c \in A. a \times (b + c) = (a \times b) + (a \times c)$;
 (**annihilator**) $\forall a \in A. a \times \mathbf{0} = \mathbf{0}$.

⁴ A pseudo order is a transitive, antisymmetric, possibly not reflexive relation.

Proposition 1 (absorptive semirings [24, Corollary 2.1]) Let \mathcal{K} be a commutative semiring. Then, these properties are equivalent

(absorptiveness) $\forall a, b \in A. a + (a \times b) = a$,

(top element) $\forall a \in A. a + 1 = 1$.

Semirings verifying the above properties are known as *absorptive* (or *simple*) [10] and represent the structure we put at the base of our proposal since they satisfy the properties absorptiveness, zero and unit element that seem pivotal for any soft constraint framework.

We can now state a simple characterization result linking absorptiveness to idempotency and to the notion of top element.

Proposition 2 (tropical semirings) Let \mathcal{K} be a commutative semiring. If \mathcal{K} is absorptive, then the sum operator is idempotent.

The former result is well-known in the literature, and commutative semirings such that the sum operator is idempotent are called *diodoids* or *tropical semirings*⁵. These structures are well-studied in the literature [1, 2, 23, 24], and we take advantage of some classical constructions in the following sections. Notice in fact that absorptive semirings are just tropical semirings with top element.

2.1 Alternative approaches

We now have a look at some order structures proposed in the literature for interpreting constraints, showing their similarity and highlighting absorptive semirings as a common algebraic structure. More precisely, the section provides a comparison with *c-semiring* [4, 6, 7], valuation structures [26], and semiring valuations [27].

2.1.1 c-semirings

The starting point of our excursus are *c-semirings* [4, 7]: according to our notation, they are tropical semirings with top element. Our analysis, as summed up in Proposition 2, suggests that the intrinsic quality of *c-semirings* is the absorptiveness of the order, whilst idempotency of the sum is merely a side-effect, in the sense that it is implied by the other properties (see Proposition 2).

Note also that most results on local consistency for *c-semirings* require the idempotency of the \times operator [4]. This assumption results in a stronger structure, since $a \times b$ coincides with the greatest lower bound of a and b . Indeed, the focus of this article is also the extension of some algorithms proposed in the *c-semirings* formalism, in order to deal also with non-idempotent product operators.

2.1.2 Valuation structures

Adopting our terminology, a *valuation structure* [26] is a five-tuple $\langle A, \leq, \times, \mathbf{0}, \mathbf{1} \rangle$ such that $\langle A, \times, \mathbf{1} \rangle$ is a commutative monoid, $\langle A, \leq \rangle$ is a total order (with $\mathbf{0}$ and $\mathbf{1}$ as minimum and maximum, respectively), \times is monotonic and $\mathbf{0}$ is its annihilator element.

As noted in [5], a commutative semiring can be associated to each valuation structure by defining the sum operator as $a+b = \max\{a, b\}$, obtaining an absorptive semiring. Moreover, the order in the resulting semiring coincides with the original order of the valuation structure. In fact, note that in a tropical semiring the induced ordering \leq is total iff $a+b \in \{a, b\}$ for all $a, b \in A$, so that there is a one-to-one correspondence between valuation structures and those tropical semirings (known in the literature as *additively extremal* semirings [14, p.11]) such that the associated order \leq is total. We further discuss the properties of these structures later on, when comparing our notion of inverse for the product operator with the proposal in [12].

⁵ The adjective “tropical” was coined by French mathematicians [23] in honor of the Brazilian Imre Simon. The terminology “diodoid” is adopted in [15, 17] to highlight that the structure can not be a ring, but it is “twice a monoid”.

2.1.3 Semiring valuations

Semiring valuations [27] are constraint satisfaction problems taking values in a commutative semiring, where the ordering is the transitive relation $a \leq' b$ iff $\exists c. a + c = b$. The two alternative definitions of orderings coincide for tropical semirings, in the sense that $a \leq b$ iff $a \leq' b$ for all idempotent elements a, b .

The lack of idempotency for the sum operator results in a weaker structure than absorptive semirings, that has proved useful whenever counting the number of solutions is of interest, as for special computations in Bayesian networks. However, the associated reflexive and transitive relation \leq' satisfies relatively few properties, since adding constraints does not lead to worsen the solution, thus resulting in a non-monotonic framework (because of the absence of the absorptive property). These remarks are summed up by the result below.

Proposition 3 Let \mathcal{K} be a commutative semiring. If \leq' is a partial order and $\forall a, b \in A. a \times b \leq' a$, then \mathcal{K} is absorptive.

Semirings such that the relation \leq' is a partial order are known in the literature as *uniquely difference ordered* [14, Section 2]. For these structures, whenever the \times operator worsens the solution, the sum operator is idempotent and thus \leq' equals \leq .

3 Adding division

The search for optimal solutions on constraint satisfaction problems has been mostly based on the idempotency of the \times operator. While the resulting heuristics may have a neat presentation and behavior, many relevant examples fall outside its scope. As we shall see, the viability of local consistency algorithms can be recovered by requiring the existence of a suitable inverse operator.

Among the possible solutions for ensuring the relevant structure, *symmetrisation* embeds the semiring in a larger structure containing an inverse for each element. The approach is quite standard in tropical arithmetics (see e.g. [2, Section 3.4.1.1] and [13, Section 3.8]): the derived semiring has pairs (a, b) as elements, accordingly derived operators, and a minus operator, defined as $-(a, b) = (b, a)$. A related approach is suggested in [11] for obtaining an inverse operator for \times , starting from a *strictly monotonic* valuation structure (i.e., such that $\forall a, b, c \in A. (a < b) \wedge (c \neq \mathbf{0}) \implies a \times c < b \times c$).

These constructions are similar and the properties of the derived inverse operator basically hold due to the totality of the order on valuation structures. This proposal is used in [12, Example 2] as a mechanism for recovering what the authors call *fair* evaluation structures.

The solution we pursue here is based on *residuation theory* [8], a standard tool on tropical arithmetics (see e.g. [2, Section 4.4.2] and [14, Chapter 4]), which allows for obtaining a division operator via an approximate solution to the equation $b \times x = a$. Differently with respect to the use of a completion procedure, no new element is added, leaving the same set of preferences to the user. It is noteworthy that by using the newly defined division operators, suitable consistency algorithms are devised also for non idempotent products.

3.1 Basic definitions and results

This section introduces our notion of invertibility for absorptive semirings: three alternative properties are identified, and they are listed below in the same order of their strength.

Definition 2 Let \mathcal{K} be an absorptive semiring. Then

- \mathcal{K} is invertible if there exists element $c \in A$ such that $b \times c = a$ for all elements $a, b \in A$ such that $a \leq b$;
- it is weakly uniquely invertible if c is unique whenever $a < b$;
- it is uniquely invertible if c is unique whenever $b \neq \mathbf{0}$.

Note that the former definitions do not require the existence for each element a of an inverse, i.e., of an element a^{-1} verifying $a \times a^{-1} = \mathbf{1}$. In fact, the absorptiveness condition $a \times b \leq a$ guarantees that no element, except $\mathbf{1}$ itself, has an inverse.

We now present two results that establish conditions for ensuring invertibility of an absorptive semiring. The first proposition concerns multiplicative idempotent semirings and their order structure.

Proposition 4 *Let \mathcal{K} be an absorptive, multiplicative idempotent semiring. Then, \mathcal{K} is invertible. Moreover, if \leq is a total order, then \mathcal{K} is weakly uniquely invertible.*

The second proposition is for cancellative semirings, i.e., such that $\forall a, b, c \in A. (a \times c = b \times c) \wedge (c \neq \mathbf{0}) \implies a = b$.

Proposition 5 *Let \mathcal{K} be an absorptive, invertible semiring. Then, \mathcal{K} is uniquely invertible iff it is cancellative.*

3.2 On division on residuated semirings

Residuation theory is concerned with the study of sub-solutions of the equation $b \times x = a$. Note that on tropical semirings the relaxed equation $b \times x \leq a$ always has a solution (it is enough to set x to $\mathbf{0}$).

Definition 3 *Let \mathcal{K} be a tropical semiring. Then, \mathcal{K} is residuated if the set $\{x \in A \mid b \times x \leq a\}$ admits a maximum for all elements $a, b \in A$, denoted $a \div b$.*

Note that the previous definition actually suggests an algorithmic heuristics for approximating such a maximal element, intuitively given by the (possibly infinite) sum of all the elements satisfying the inequation [2]. The key point is that the set of sub-solutions of an equation contains also the possible solutions, whenever they exist, and in that case the maximal element is also a solution.

More properties hold if the semiring is absorptive, such as that $b \leq a \implies a \div b = \mathbf{1}$. This fact leads to our notion of invertibility.

Definition 4 *Let \mathcal{K} be an absorptive, invertible semiring. Then, \mathcal{K} is invertible by residuation if the set $\{x \in A \mid b \times x = a\}$ admits a maximum for all elements $a, b \in A$ such that $a \leq b$.*

With an abuse of notation, the maximal element among solutions is denoted $a \div b$. This choice is not ambiguous: if an absorptive semiring is invertible and residuated, then it is also invertible by residuation, and the two definitions yield the same value.

3.3 On complete semirings

Being residuated is implied by a sometimes easier to check property, namely, the existence of elements representing infinite sums.

Definition 5 *Let \mathcal{K} be a tropical semiring. Then, \mathcal{K} is complete if it is closed with respect to infinite sums, and the distributivity law holds also for an infinite number of summands.*

Also associativity and commutativity need to be generalized, and we refer the reader to e.g. [14, Section 3].

Proposition 6 ([2, Theorem 4.50]) *Let \mathcal{K} be a tropical semiring. If \mathcal{K} is complete, then it is residuated.*

The above proposition ensures that all classical soft constraint instances (see Section 4.1) are residuated (because complete) and the notion of division can be applied to all of them.

3.4 Further comparison with valuation structures

We now compare our definition of division with the proposal by Cooper and Schiex in [12, Definition 3.1]. A valuation structure is called *fair* if the set $\{x \in A \mid b \times x = a\}$ has a minimum whenever $a \leq b$ [12, Definition 3.1]. Hence, the division operator is defined as

$$a \div' b = \begin{cases} \min\{x \mid b \times x = a\} & \text{if } a \leq b, \\ \text{undefined} & \text{otherwise.} \end{cases}$$

Let us say that an absorptive semiring is *fair* if it is invertible and the operator \div' above is well defined. How does fairness compare with residuation? By definition $\{x \mid b \times x = a\} \subseteq \{y \mid b \times y \leq a\}$, so that the operation $a \div' b$ returns a smaller value than $a \div b$. Nevertheless, the two notions sometimes coincides, e.g. if a semiring is uniquely invertible, hence whenever the \times operator is cancellative (equivalently, whenever a valuation structure is strictly monotonic).

Proposition 7 (cancellativeness) *Let \mathcal{K} be an absorptive, cancellative semiring. Then, \mathcal{K} is fair iff it is invertible by residuation, and in such a case $a \div' b = a \div b$ for all elements a, b such that $a \leq b$.*

A weakly uniquely invertible semiring is invertible by residuation but it is not necessarily fair: the operation $a \div' a$ might not be defined, while $a \div a = \mathbf{1}$ always holds. In fact, the two operators usually differ for the division of an element by itself, since e.g. $a \div' a = a$ holds for multiplicative idempotent semirings. Combined with Proposition 4, relating weakly invertibility and multiplicative idempotency, the remark above establishes the correspondence result below.

Proposition 8 (idempotency) *Let \mathcal{K} be an absorptive, multiplicative idempotent semiring. Then, \mathcal{K} is fair. Moreover, if \leq is a total order, then \mathcal{K} is invertible by residuation, and in such a case $a \div b = a \div' b = a$ for all elements a, b such that $a < b$.*

For those semirings where \leq is total, the proposition also yields that $b \times (a \div' b) = b \times (a \div b) = a$ for all a, b such that $a \leq b$.

We provide no general correspondence result between the two properties. Note however that by definition a residuated fair semiring is invertible by residuation, hence the proposition below follows.

Proposition 9 (completeness) *Let \mathcal{K} be an absorptive, complete semiring. If \mathcal{K} is fair, then it is invertible by residuation.*

In general, the two operations returns different values, as it happens for the set-based CSPs presented in Section 4.1.4. Note that most case studies in the literature satisfy the completeness property, and are either multiplicative idempotent or cancellative: this fact hold for all the examples presented in Section 4.1.

4 Soft constraints and local consistency

Several formalizations of *soft constraints* are currently available. The first part of this section briefly introduces the semiring-based formalism, directly borrowing from the *c-semirings* approach [4, 7]. The second part of this section represents another technical contribution of our work: It presents an extension of local consistency techniques for invertible semirings, thus generalizing those previously proposed for those cases where the \times operator is idempotent.

4.1 Constraint problems

Let $\mathcal{K} = \langle A, +, \times, \mathbf{0}, \mathbf{1} \rangle$ be an absorptive semiring; V a finite (possibly ordered) set of variables; and D a chosen domain of interpretation for V . Then, a *constraint* $(V \rightarrow D) \rightarrow A$ is a function associating a value in A to each assignment $\eta : V \rightarrow D$ of the variables.

We define \mathcal{C} as the set of constraints that can be built starting from \mathcal{K} , V and D . Note that even if a constraint involves all the variables in V , it must depend on the assignment of a finite subset of them. For instance, a binary constraint $c_{x,y}$ over variables x, y is a function $c_{x,y} : (V \rightarrow D) \rightarrow A$ which depends only on the assignment of variables $\{x, y\} \subseteq V$. We call this subset the *support* of the constraint. Often, if V is ordered, an assignment (over a support of cardinality k) is concisely presented by a tuple in D^k .

More formally, let $c \in \mathcal{C}$ be a constraint. We define its support as $\text{supp}(c) = \{v \in V \mid \exists \eta, d_1, d_2. c\eta[v := d_1] \neq c\eta[v := d_2]\}$, where

$$\eta[v := d]v' = \begin{cases} d & \text{if } v = v' \\ \eta v' & \text{otherwise} \end{cases}$$

While $c\eta$ is the application of a constraint function $c : (V \rightarrow D) \rightarrow A$ to a function $\eta : V \rightarrow D$, obtaining a semiring value, $c\eta[v := d]$ means $c\eta'$ where η' is η modified with the assignment $v := d$.

Later on we implicitly restrict to finitely supported constraints.

4.1.1 Classical CSPs

Classical (crisp) satisfaction problems may be recast to deal with soft constraints by considering the semiring $\mathcal{K}_{CSP} = \langle \{0, 1\}, \vee, \wedge, 0, 1 \rangle$.

The semiring is finite, hence complete (and residuated by Proposition 6). Moreover, the \times operator is idempotent, then the semiring is invertible, and since the order is total, it is weakly uniquely invertible (by Proposition 4). By instantiating the definition of division we get

$$a \div b = \max\{x \mid b \wedge x \leq a\} = (b \implies a)$$

where \implies is the logic implication.

4.1.2 Fuzzy CSPs

Fuzzy CSPs (FCSPs) extend the standard notion by allowing non-crispness features, and can be modeled by the semiring $\mathcal{K}_{FCSP} = \langle [0, 1], \max, \min, 0, 1 \rangle$.

The semiring is clearly complete (and residuated by Proposition 6). Moreover, the \times operator is idempotent, then the semiring is invertible, and since the order is total, it is weakly uniquely invertible (by Proposition 4). By instantiating the definition of division we obtain

$$a \div b = \max\{x \mid \min\{b, x\} \leq a\} = \begin{cases} 1 & \text{if } b \leq a \\ a & \text{if } a < b \end{cases}$$

4.1.3 Weighted CSPs

While fuzzy CSPs associate a level of preference, in weighted CSPs (WCSPs) tuples come with an associated cost to be minimized. The associated semiring structure is in this case $\mathcal{K}_{WCSP} = \langle \mathbb{R}^+ \cup \{\infty\}, \min, \hat{+}, \infty, 0 \rangle$ for $\hat{+}$ the sum of reals.

The semiring is clearly complete (and residuated by Proposition 6). The \times operator is not idempotent, but the semiring is nevertheless invertible, as it can be easily proved by checking the definition itself. Moreover, the semiring is cancellative, hence it is uniquely invertible by Proposition 5. By instantiating the definition of division we obtain

$$a \div b = \min\{x \mid b \hat{+} x \geq a\} = \begin{cases} 0 & \text{if } b \geq a \\ a \hat{-} b & \text{if } a > b \end{cases}$$

where $\hat{-}$ is the arithmetic difference of a and b .

4.1.4 Set-based CSPs

An interesting class of instances of the soft constraint framework is based on set operations like union and intersection, using the semiring $\mathcal{K}_{set} = \langle \wp(A), \cup, \cap, \emptyset, A \rangle$, where A is any set: the order $\leq_{\mathcal{K}_{set}}$ reduces to set inclusion, and therefore it is partial.

The semiring is clearly complete (and residuated by Proposition 6). The \times operator is idempotent, then it is invertible; but the order is not total, so that it is not uniquely invertible (Proposition 4 can not be applied). By instantiating the definition of division we obtain

$$a \div b = \bigcup\{x \mid b \cap x \subseteq a\} = (A \setminus b) \cup a$$

where \setminus is the set difference operator.

4.2 Combining and projecting soft constraints

The *combination* function $\otimes : \mathcal{C} \times \mathcal{C} \rightarrow \mathcal{C}$ is defined as $(c_1 \otimes c_2)\eta = c_1\eta \times c_2\eta$. Thus, combining two constraints means building a new constraint whose support involves all the variables of the original pairs, and which associates with each tuple of domain values for such variables a semiring element which is obtained by multiplying the elements associated by the original constraints to the appropriate subtuples. Let $c \in \mathcal{C}$ be a constraint and $v \in V$ a variable. The *projection* of c over $V - \{v\}$, written $c \Downarrow_v$, is the constraint c' such that $c'\eta = \sum_{d \in D} c\eta[v := d]$. Informally, projecting means eliminating some variables from the support.

4.3 Local consistency

The main point in the generalization of local consistency techniques to soft CSPs concerns the fact that, instead of removing tuples, local consistency means changing the semiring values associated to them. In particular, the change always brings these values towards the worst element of the semiring, that is, 0 .

Arc-consistency [3, 16] (AC) is an instance of local consistency where the information present in the constraints is propagated over the variables. In fact, an arc-consistency rule considers a constraint, say with support over variables x, y_1, \dots, y_n , and all unitary constraints over these variables (that is, constraints whose support is one of the variables), and combines all these constraints to get some information (by projecting) over one of the variables, say x .⁶

Such a *local consistency rule* [7] involves a constraint c with support over the set of variables X and a unary constraint c_x with support over the variable $x \in X$, and consists of three phases

- the computation of the solution of the subproblem $\{c_x, c\}$ by computing $c_x \otimes c$,
- the projection of the computed solution over variable x by computing $c'_x = (c_x \otimes c) \Downarrow_x = c_x \otimes (c \Downarrow_x)$, and then
- substituting the original constraint c_x over x with the new one by the assignment $c_x \leftarrow c'_x$.

The application of a local consistency rule leads to an equivalent problem if multiplicative idempotency holds [7]. We relax this condition by performing two assignments at each step of the new rule.

Definition 6 (local consistency rule) A local consistency rule involving a constraint c and a unary constraint c_x with $\text{supp}(c_x) = \{x\} \subset \text{supp}(c)$ consists of the following phases

- substituting the original constraint c_x with c'_x , computed as usual [7]

$$c'_x = c_x \otimes (c \Downarrow_x)$$

- modifying the constraint c in a new constraint c' that takes into account the changes performed on c_x ⁷

$$c' = c \oplus (c \Downarrow_x),$$

where the constraint division function $\oplus : \mathcal{C} \times \mathcal{C} \rightarrow \mathcal{C}$ is defined as $(c_1 \oplus c_2)\eta = c_1\eta \div c_2\eta$.

⁶ Note that this notion represents a generalized form of arc-consistency, since it was originally defined for binary constraints only [22].

⁷ Since constraint c_x is combined with $c \Downarrow_x$, c' is divided by the same value.

Notice that the two steps of Definition 6 corresponds to the steps performed by the *project* operator used in fair valued CSPs (see e.g. Algorithm 1 in [12, p.207]). The *extend* operator is instead not considered here, but it is worth to notice that it can be emulated by using constraint removal and combination.

The main result of this section is that the application of the above local consistency rules does not change the solution of soft constraint satisfaction problems defined on invertible by residuation semirings.

Proposition 10 (preserving solutions) *Let \mathcal{K} be an absorptive, invertible by residuation semiring, and let us consider a soft constraint satisfaction problem on it. Then, the application of the local consistency rules in Definition 6 does not change the solution of the problem, that is $c_x \otimes c = c'_x \otimes c'$.*

5 Conclusions and further work

Our work represents an investigation on the semiring-based approaches to soft constraints. After revising some basics of (tropical) semirings and of residuation theory, we show how to define a suitable division operator, proving how the latter can be used to generalize current algorithm for local consistency.

The papers that are most related to our study are those by Cooper and Schiex [11, 12, 25]. These authors propose a generalized version of arc-consistency for valued CSPs [5, 26], by defining a difference operation which is the inverse of the aggregation operation (corresponding to our \times operator). As shown in Section 3.4, the two proposals share many similarities. However, our solution differs in two aspects. First of all, it has been explicitly devised for obtaining a total operation that can be applied to absorptive semirings where the induced ordering is partial, such as those arising in set-based CSPs.

More importantly, though, by relying on the notion of residuation, our solution may take advantage on the large family of studies on tropical arithmetics, in particular in finding general criteria establishing when a semiring is invertible by residuation, and for obtaining an algorithmic procedure for the calculus of the result of the division operation (considered as the resolution of a linear equation), as it is illustrated e.g. in [2, Section 4.5]. We consider mandatory a future, exhaustive comparison of our formalism with fair valued CSPs.

Further algorithmic considerations should then be taken into account before proposing an actual implementation of our local consistency rules. For example, note that if the value of a constraint c should coincide with that of its projection $c \downarrow_x$, than the value of the constraint c' in Definition 10 would be 1, thus possibly increasing, hence the chaotic iteration applied to our rules could possibly not terminate. Using a set of *guarded* rules that never perform such (useless) divisions would however guarantee in this case termination.

The papers by Brown, Larrosa, Meseguer, Schiex and Verfaillie consider max and weighted CSPs and define local consistency algorithms also in the presence of a non-idempotent aggregation operator [9, 18, 19, 20, 21]. Our work shares the same aim, even if we do not consider one specific formalism but instead the whole semiring-based approach. It is a matter of further investigation if their proposals could be generalized and applied to our framework.

Current work is now devoted to the introduction of an inverse of the sum operator, and the definition of a framework for soft constraint databases, as well as a throughout analysis of the relationship between these operators in absorptive semirings.

ACKNOWLEDGEMENTS

We are greatly indebted to Nic Wilson for his suggestions, as well as to Paola Cellini, Martin Cooper, Javier Larrosa, and Thomas Schiex for their help in discussing and improving the contents of the paper.

Evaluating ASP and commercial solvers on the CSPLib

Marco Cadoli, Toni Mancini, Davide Micaletto and Fabio Patrizi¹

Abstract. This paper deals with three solvers for combinatorial problems: the commercial state-of-the-art solver Ilog OPL, and the research ASP systems DLV and SMODELS. The first goal of this research is to evaluate the relative performance of such systems, using a reproducible and extensible experimental methodology. In particular, we consider a third-party problem library, i.e., the CSPLib, and uniform rules for modelling and selecting instances. The second goal is to analyze the effects of a popular reformulation technique, i.e., symmetry breaking, and the impact of other modelling aspects, like global constraints and auxiliary predicates. Results show that there is not a single solver winning on all problems, and that reformulation is almost always beneficial: symmetry-breaking may be a good choice, but its complexity has to be carefully chosen, by taking into account also the particular solver used. Global constraints often, but not always, help OPL, and the addition of auxiliary predicates is usually worth, especially when dealing with ASP solvers. Moreover, interesting synergies among the various modelling techniques exist.

1 Introduction

The last decade has witnessed a large effort in the development of solvers for combinatorial problems. The traditional approach based on writing *ad hoc* algorithms, complete or incomplete, or translating in a format suitable for Integer Programming solvers², has been challenged by the use of libraries for Constraint Programming (CP), such as Ilog SOLVER³, interfaced through classical programming languages, e.g. C++ or Prolog. At the same time, the need for a higher level of abstraction led to the design and development of 1) General purpose languages for constraint modelling/programming –e.g. OPL [16], XPRESS^{MP}⁴ or GAMS [1]– and 2) Languages based on specific solvers, such as AMPL [7], DLV [8], SMODELS [11] or ASSAT [9].

This paper focuses on the last class of solvers, which are highly declarative, and characterized by the possibility of decoupling the specification of a problem from the instance, and by having optional procedural information. In particular, we consider one commercial state-of-the-art solver, i.e., Ilog OPL and some ASP solvers, namely DLV and SMODELS. The latter has the interesting property of sharing the specification language with several other solvers through the common parser LPARSE⁵. As a matter of fact, such systems exhibit interesting differences, including availability (OPL and ASP are, respectively, payware and freeware systems, the latter often being open source), algorithm used by the solver (resp. backtracking- and fixpoint-based), expressiveness of the modelling language (e.g.,

availability of arrays of finite domain variables vs. boolean matrices), compactness of constraint representation (e.g., availability of global constraints), possibility of specifying a separate search procedure.

The first goal of this research is to evaluate the relative performance of such systems, using a reproducible and extensible experimental methodology. In particular, we consider a third-party problem library, i.e. the CSPLib⁶, and uniform rules for modelling and instance selection. The second goal is to analyze the effects of a popular reformulation technique, i.e. symmetry breaking, and the impact of other modelling aspects, like the use of global constraints and auxiliary predicates.

As for symmetry-breaking, given the high abstraction level of the languages, an immediately usable form of reformulation is through the addition of new constraints (cf., e.g., [3, 6]). Since previous studies [13] showed that this technique is effective when simple formulae are added, it is interesting to know –for each class of solvers– what is the amount of symmetry breaking that can be added to the model, and still improving performances. As a side-effect, we also aim to advance the state of knowledge on the good practices in modelling for some important classes of solvers.

Comparison among different solvers for CP has already been addressed in the literature: in particular, we recall [5] and [17] where SOLVER is compared to other CP languages such as, e.g., OZ [15], CLAIRE⁷, and various Prolog-based systems. Moreover, some benchmark suites have been proposed, cf., e.g., the COCONUT one [14]. Also on the ASP side, which has been the subject of much research in the recent years, benchmark suites have been built in order to facilitate the task of evaluating improvements of their latest implementations, the most well-known being ASPARAGUS⁸ and ASPLib⁹. However, less research has been done in comparing solvers based on different formalisms and technologies, and in evaluating the relative impact of different features and modelling techniques. In particular, very few papers compare ASP solvers to state-of-the-art systems for CP. To this end, we cite [4], where two ASP solvers are compared to a CLP(FD) Prolog library on six problems: Graph coloring, Hamiltonian path, Protein folding, Schur numbers, Blocks world, and Knapsack, and [12], where ASP and Abductive Logic Programming systems, as well as a first-order finite model finder, are compared in terms of modelling languages and relative performances on three problems: Graph coloring, N-queens, and a scheduling problem.

In this research we consider the CSPLib problem library for our experiments. CSPLib is a collection of 45 problems, classified into 7 areas, and is widely known in the CP community. Since many of them are described only in natural language, this work also provides, as a side-effect, formal specifications of such problems in the modelling languages adopted by some solvers.

2 Methodology

In this section we present the methodology adopted in order to achieve the two goals mentioned in Section 1. For each problem, we define a number of different formulations, a *base specification*, obtained by a straightforward and intuitive “translation” of the CSPLib problem description into the target language, and several *reformulated* ones, obtained by using different techniques proposed in the literature: (i) symmetry-breaking, (ii) addition of global constraints and (iii) addition of auxiliary predicates. Moreover, in order to establish whether merging different reformulations, which are proven to improve performances when used alone, speeds-up even more the computation, we considered additional specifications for the same problems, obtained by *combining* the aforementioned techniques, and exploring the existence of synergies among them. Finally, a preliminary evaluation of the impact of numbers and arithmetic constraints in all the languages involved in the experimentation has been performed on one problem.

We tried to do the modelling task in a way as systematic as possible, by requiring the specifications of the various solvers to be similar to each other. The criteria followed during the modelling task are discussed in Section 3.2. As for the instances, in this paper we opted for problems which input data is made of few integer parameters (with two exceptions, which are discussed in Section 3.1). In order to have a synthetic qualitative measure of the various solvers performance, for each problem we fix all the input parameters but one. Hence in our results we report for each problem and solver the largest instance (denoted by the value given to the selected parameter) that is solvable in a given time limit (one hour).

3 The experimental framework

3.1 Selecting the problems

So far we have formulated and solved 7 problems, which are listed along with their identification number in CSPLib and the parameter that defines problem instances. Such problems cover the 7 areas of the collection. For space reasons, we omit their descriptions, which can be found at www.csplib.org.

Id	Problem name	Instances defined by
017	Ramsey	# of graph nodes
010	Social golfer (decisional version) (32 players, 8 groups of 4)	Schedule length
006	Golomb rulers	# of marks
001	Car sequencing	Benchmark instances
018	Water buckets	Benchmark instances
032	Maximum density still life	Board size
033	Word design (decisional version)	# of words

Some comments are in order. First of all, we considered the decisional versions of two problems, Social golfer and Word design, since our solvers were unable to achieve the optimal solutions. Secondly, for two problems, Car sequencing and Water buckets, instances could not be naturally encoded by a single parameter. Hence, they have been derived from benchmarks taken from the CSPLib. In particular, as for Car sequencing, we considered benchmarks “4/72”, “6/76” and “10/93”. Unfortunately, they were too hard for our solvers. Hence, from any of them, we generated a set of instances by reducing the number of car classes (cf. the CSPLib problem description) to all possible smaller values, and consequently resizing station capacities in order to avoid an undesirable overconstraining that would make instances unfeasible. Thus, instances derived from the same benchmark could be ordered according to the value for the

(reduced) number of classes, which can be regarded as a measure for their size. As for Water buckets instead, we observe that the CSPLib formulation actually fixes the capacities of the three buckets and both the start and goal states. Hence, we built a specification parametric wrt the start and goal states, and designed 11 instances from that considered in the original problem description, which have been proved to be non-trivial by preliminary experiments. Since such instances could not be denoted by a single parameter, solvers’ performance for this problem and the different specifications have been compared by considering the overall time needed to solve them.

The Water buckets problem has been used also to evaluate the impact of numbers and arithmetic constraints in problem models. In fact, it is well known that such issues may greatly degrade solvers’ performance, and that this behavior strongly depends on the underlying solving algorithm. In order to understand how negatively numbers and arithmetic constraints affect the behavior of the various solvers, we built a new set of instances, obtained by the original one by duplicating the capacities of the buckets (originally 3, 5, and 8), and the amount of water in each of them both in the start and goal states. Of course, the new instances are equivalent to the original ones, having the same set of solutions, but force all solvers to deal with larger domains for numbers.

3.2 Selecting the problem models

As claimed in Section 2, in order to build an extensible experimental framework, we followed the approach of being as uniform and systematic as possible during the modelling phase, by requiring the specifications of the various solvers to be similar to each other. Hence, even if not always identical because of the intrinsic differences among the languages that could not be overcome, all of the models share the same ideas behind the search space and constraints definitions, independently of the language. Below, we discuss the general criteria followed during the modelling phase, and the different formulations considered for each problem¹⁰.

General modelling criteria. The first obvious difference between OPL and the ASP solvers concerns the search space declaration. The former relies on the notion of *function* from a finite domain to a finite domain, while the latter ones have just *relations*, which must be restricted to functions through specific constraints. Domains of relations can be implicit in DLV, since the system infers them by contextual information. For each language, we used the most natural declaration construct, i.e., functions for OPL, and untyped relations for DLV. Secondly, since the domain itself can play a major role in efficiency, sometimes it has been inferred through some *a posteriori* consideration. As an example, in Golomb rulers the maximum position for marks is upper-bounded by 2^m (m being the number of marks), but choosing such a large number can advantage OPL, which has powerful arc-consistency algorithms for domain reduction. As a consequence, we used the upper bound $3L/2$ for all solvers, L being the maximum mark value for the optimum of the specific instance.

Finally, since the performance typically depends on the instances being positive or negative, we considered the *optimization* versions of Ramsey, Golomb rulers, Water buckets, and Maximum density still life problems. As a matter of fact, for proving that a solution is optimal, solvers have to solve both positive and negative instances.

Base specifications. The first formulation considered for each problem is the so called *base specification*. This has been obtained by a straightforward translation of the CSPLib problem description into

¹⁰ cf. <http://www.dis.uniroma1.it/~patrizi/ecai06/encodings.html> for their encodings.

the target language, by taking into account the general criteria discussed above, and, arguably, is the most natural and declarative.

Reformulation by symmetry-breaking. The first kind of reformulation considered aims at evaluating the impact of performing symmetry-breaking. Since we deal with highly declarative languages that exhibit a neat separation of the problem specification from the instances, we adopted the approach of adding further constraints to the base specification that break the structural symmetries of the problems. Symmetry-breaking is dealt with in a systematic way, by considering the general and uniform schemes for symmetry-breaking constraints presented in [10]. These are briefly recalled in what follows (examples below are given in the simple case where all permutations of values are symmetries; generalizations exist):

- **Selective assignment (SA):** A subset of the variables are assigned to precise domain values: a good example is in the Social golfer problem, where, in order to break the permutation symmetries among groups, we can fix the group assignment for the first and partially for the second week.
- **Selective ordering (SO):** Values assigned to a subset of the variables are forced to be ordered: an example is given by the Golomb rulers problem, where, in order to break the symmetry that “reverses” the ruler, we can force the distance between the first two marks to be less than the difference between the last two.
- **Lowest-index ordering (LI):** Linear orders are fixed among domain values and variables, and assignments of variables (x_1, \dots, x_n) are required to be such that, for any pair of values (d, d'), if $d < d'$ then $\min\{i|x_i = d\} < \min\{i|x_i = d'\}$. An example is given by the Ramsey problem: once orders are fixed over colors, e.g. red < green < blue, and over edges, we can force the assignments to be such that the least index of red colored edges is lower than the least index of green colored ones, and analogously for green and blue edges.
- **Size-based ordering (SB):** After fixing a linear order on values, we force assignments to be such that $|\{x \in V|x = d\}| \leq |\{x \in V|x = d'\}|$, for any pair of values $d \leq d'$, V being the set of variables. For example, in the Ramsey problem we could require the number of blue colored edges to be greater than or equal to that of green ones, in turn forcing the latter to be greater than or equal to the number of red colored edges. Generalizations of this schema do exist, depending on the way the partition of the variables set into size-ordered sets is defined.
- **Lexicographic ordering (LX):** This schema is widely applied in case of search spaces defined by matrices, where all permutations of rows (or columns) are symmetries. It consists in forcing the assignments to be such that all rows (resp. columns) are lexicographically ordered.
- **Double-lex (lex^2) ordering (L2):** A generalization of the previous schema, applicable where the matrix has both rows and columns symmetries. It consists in forcing assignments to be such that both rows and columns are lexicographically ordered (cf., e.g., [6]). A good example is Social golfer, in which the search space can be defined as a 2D matrix that assigns a group to every combination player/week. Such a matrix has all rows and columns symmetries (we can swap the schedules of any two players, and the group assignments of any two weeks).

Above schemes for symmetry-breaking can be qualitatively classified in terms of “how much” they reduce the search space (i.e., their *effectiveness*), and in terms of “how complex” is their evaluation. In particular they can be partially ordered as follows: SA < SO < LI < LX < L2, and LI < SB, where $s_1 < s_2$ means that schema s_2

better reduces the search space. However, s_2 typically requires more complex constraints than s_1 .

In many cases, more than a single schema is applicable for breaking the symmetries of a given specification and the problem of choosing what is the “right” amount of symmetry-breaking that is worth adding for a given solver arises. In what follows, we give a partial answer to this question.

Reformulation by adding global constraints. Global constraints (GC) encapsulate, and are logically equivalent to, a set of other constraints. Despite this equivalence, global constraints come with more powerful filtering algorithms, and a specification exhibiting them is likely to be much more efficiently evaluable. One of the most well-known global constraints supported by constraint solvers is `alldifferent(x1, ..., xn)` that forces the labeling algorithm to assign different values to all its input variables. Of course, such a constraint can be replaced by a set of binary inequalities $x_i \neq x_j$ (for all $i \neq j$), but such a substitution will result in poorer propagation, hence in less efficiency. Several global constraints are supported by OPL, e.g., `alldifferent` and `distribute`. According to the problems structure, the former has been applied to Golomb Rulers and the latter to Social golfer, Car sequencing and Word design. As for Ramsey, Water bucket and Maximum density still life none of such reformulations applies.

On the other hand, ASP solvers do not offer such a feature, hence no comparison can be made on this issue.

Reformulation by adding auxiliary predicates. A predicate in the search space is called *auxiliary* if its extensions functionally depend on those of the other ones. The use of auxiliary guessed predicates is very common in declarative programming, especially when the user needs to store partial results, to maintain intermediate states. Although the use of auxiliary predicates increases the size of the search space, in some cases this results in a simplification of complex constraints and in a reduction of the number of their variables, and hence may lead to appreciable time savings.

We consider equivalent specifications, obtained by using auxiliary predicates, for all of the selected problems. However, the bottom-up evaluation algorithms of DLV and SMODELS may significantly advantage ASP solvers over OPL on such specifications, since auxiliary predicates are usually defined in rule-heads. To this end, when adding auxiliary predicates to OPL specifications, we also added simple search procedures instructing the labelling algorithm to not branch on auxiliary variables, while maintaining the default behavior on the others.

Reformulation by combining different techniques. In many cases, more than one single reformulation strategy improves performances on a given problem. Hence, the question arises whether synergies exist among them, and what techniques are likely to work well together, for each solver. To this end, for each problem we consider two additional formulations: the first one has been obtained, according to the aforementioned uniformity criteria, by merging the two reformulations (among symmetry-breaking, addition of global constraints and of auxiliary predicates) that, for each solver, resulted to be the most performant. Finally, in order to understand whether there exist better, undiscovered synergies, we relaxed the uniformity hypothesis, and considered some of the other possible combinations of reformulation strategies, with the goal to further boost performances.

4 Experimental results

Our experiments have been performed by using the following solvers: *i*) Ilog SOLVER v. 5.3, invoked through OPLSTUDIO 3.61,

ii) SMODELS v. 2.28, by using LPARSE 1.0.17 for grounding, iii) DLV v. 2005-02-23, on a 2 CPU Intel Xeon 2.4 Ghz computer, with a 2.5 GB RAM and Linux v. 2.4.18-64GB-SMP.

For every problem, we wrote the specifications described in Sections 2 and 3 in the different languages. We then ran the different specifications for each solver on the same set of instances, with a timeout of 1 hour. Table 1 shows a summary of the results concerning base specifications and their various reformulations. In particular, for each problem and solver, we report the largest instance the various systems were able to solve (in the given time-limit) for the base specifications, and the improvements obtained by the different reformulations. A 0^+ (resp. 0^-) means that the size of the largest instance solved within the time limit was unchanged, but absolute solving times were significantly lower (resp. higher). As for Car sequencing, we report, for each set of instances generated from CSPLib benchmarks “4/72”, “6/76” and “10/93”, the largest one solved, i.e., the one with the largest number of classes (cf. the discussion about instance selection for this problems in Section 3.1), and, as for Water buckets, the overall time needed to solve the whole set of instances (instances that could not be solved contributed with 3,600 seconds to the overall time).

Impact of symmetry-breaking. From the experiments, it can be observed that symmetry-breaking may be beneficial, although the complexity of the adopted symmetry-breaking constraints needs to be carefully chosen. As an example, DLV performs much better on the Ramsey problem with LI symmetry-breaking constraints, but it is slowed down when the more complex SB schema is adopted. A similar behavior can be observed on SMODELS.

As for Social golfer, Table 1 does not show significant performance improvements when symmetry-breaking is applied, with the ASP solvers (especially SMODELS) being significantly slowed down when adopting the most complex schemas (LX and L2). However, it is worth noting that, on smaller negative (non-benchmark) instances, impressive speed-ups have been obtained for all systems, especially when using SA. As for LX, we also observe that it can be applied in two different ways, i.e., forcing either players’ scheduling or weekly groupings to be lexicographically ordered. Values reported in Table 1 are obtained by lexicographically ordering weekly groupings: as a matter of fact, ordering players’ scheduling is even less performant on SMODELS, being comparable for the other solvers. General rules for determining the right “amount” of symmetry breaking for any given solver on different problems are currently still unknown, but it seems that the simplest ones, e.g., SA, have to be preferred when using ASP solvers.

Impact of global constraints. Experiments confirm that OPL may benefit from the use of global constraints. As an example, the base specification of the Golomb rulers problem encodes the constraint that forces the differences between pairs of marks to be all different by a set of binary inequalities. By replacing them with an `alldifferent` constraint, OPL was able to solve the instance with 11 marks in the time-limit, and time required to solve smaller instances significantly decreases. Also the Social golfer specification can be restated by using global constraints, in particular the `distribute` constraint. However, in this case our results show that OPL does not benefit from such a reformulation, in that it was not able to solve even the 4-weeks instance (solved in about 11 seconds with the base specification). Global constraints help OPL also on other problems, i.e., Car sequencing, where `distribute` can be used, even if the performance improvements don’t make it able to solve larger instances. Finally, Word Design seems not to be affected by the introduction of `distribute`.

Impact of auxiliary predicates. ASP solvers seem to benefit from the use of auxiliary predicates (often not really needed by OPL, which allows to express more elaborate constraints), especially when they are defined relying on the minimal model semantics of ASP (hence, in rule heads). As an example, SMODELS solves the 6-weeks instance of the Social golfer problem in 6 seconds, when the auxiliary `meet/3` predicate is used, while solving the base specification requires 41 minutes. Even if not as much remarkable, a similar behavior is observed in DLV. Similar results have been obtained for Ramsey, where the auxiliary predicate `color_used/1` is added.

Using the `meet` auxiliary predicate helps also OPL (but only after a simple search procedure that excludes branches on its variables has been added, cf. Section 3.2). In particular, the 5-weeks instance has been solved in just 8 seconds (with respect to the 80 seconds of the base specification). It is interesting to note that, by adding a smarter search procedure, solving time dropped down to less than a second. This is a good evidence that exploiting the peculiarities of the solver at hand may significantly increase the performance.

Synergic reformulations. Specifications obtained by combining, for each problem and solver, the most two performant techniques, in many cases further boost performances, or at least do not affect them negatively. This is the case, e.g., of Social Golfer, Golomb Rulers, and Word design problems when solved by OPL, that proved to be able to deal with larger instances, and Car sequencing, where solving times significantly decreased. Few exceptions do exist, i.e., Ramsey and Maximum density still life, where solving times were a bit higher, but did not prevent OPL to deal with the largest instances previously solved. Similar results can be observed for SMODELS and DLV. This gives evidence that combining “good” reformulations is in general a promising strategy to further boost performance of all solvers. Table 1 also shows some of the results obtained by other possible combinations, without considering any uniformity criteria. It can be observed that in few cases even better results could be achieved (cf., e.g., OPL on Social golfer and the specification with auxiliary predicates and global constraints), but in several others, only worse performances were obtained.

Impact of numbers and arithmetic constraints. Experiments performed on Water buckets, with the most performant specification (i.e., that with auxiliary predicates) on instances obtained by doubling both the buckets capacities and the water contents in the start and goal states, confirm that numbers and arithmetic constraints are a major obstacle for all solvers. In particular, the time needed by OPL to solve the whole set of instances is almost 13 times higher, while for DLV and SMODELS the solving time increases, respectively, of about 130 and 45 times.

5 Conclusions

In this paper we reported results about an experimental investigation which aims at comparing the relative efficiency of a commercial backtracking-based and two academic ASP solvers. In particular, we modelled a number of problems from the CSPLib into the languages used by the different solvers, in a way as systematic as possible, by also applying symmetry-breaking, using global constraints and auxiliary predicates, and evaluating synergies among such techniques. Results show that there is not a single solver winning on all problems, with ASP being comparable to OPL for many of them, and that reformulating the specification almost always improves performances. However, even if our experiments suggest some good modelling practices, an exact understanding of which reformulations lead to the best performances for a given problem and solver remains a

Problems	OPL				DLV			SMODELS

challenge. Finally, we also started an investigation about the impact of numbers and arithmetic constraints in problem specifications.

Our current efforts are aimed at covering a larger part of the CSPLib, extending the set of reformulations involved (e.g., using implied constraints) and considering other systems (e.g. ASP or SAT based).

Automatic Generation of Implied Constraints

John Charnley, Simon Colton¹ and Ian Miguel²

Abstract. A well-known difficulty with solving Constraint Satisfaction Problems (CSPs) is that, while one formulation of a CSP may enable a solver to solve it quickly, a different formulation may take prohibitively long to solve. We demonstrate a system for automatically reformulating CSP solver models by combining the capabilities of machine learning and automated theorem proving with CSP systems. Our system is given a basic CSP formulation and outputs a set of reformulations, each of which includes additional constraints. The additional constraints are generated through a machine learning process and are proven to follow from the basic formulation by a theorem prover. Experimenting with benchmark problem classes from finite algebras, we show how the time invested in reformulation is often recovered many times over when searching for solutions to more difficult problems from the problem class.

1 Introduction

Constraint programming is a successful technology for tackling a wide variety of combinatorial problems in disparate fields, such as scheduling, industrial design, and combinatorial mathematics [19]. To use constraint technology to solve a constraint satisfaction problem (CSP), its solutions must first be characterised, or *by a set of constraints on a set of decision variables. Constraints provide a rich language, so typically many alternative models exist for a given problem, some of which are more effective than others. Formulating an effective constraint program is a challenging task, for which new users lack expertise. Great value is placed, therefore, on any method that helps to reduce this modelling bottleneck.*

One method of improving a model is to introduce constraints implied by the model. We describe here a method for introducing such *implied constraints*. As described in §1.1, this fully automated method is a significant improvement upon the semi-automated method presented in [7]. Given a set of problems from the same problem class, as detailed in §2, we employ a machine learning module to induce relationships in the solutions for small problems and we use a theorem prover to show that the truth of the relationships follow from the CSP model. As described in §3, the relationships are translated and interpreted as implied constraints which are added to the CSP model. On larger instances of the problem class, the additional constraints often lead to a much reduced solving time. In §4, we present the results of applying this approach to some benchmark CSPs, namely finite algebras. We show how the system was able to improve upon the basic solver model in a number of cases and the reformulation time was soon recovered when searching for larger examples. For instance, in one case, we were able to reduce the solving time to 16% of the original, saving around 23 hours of processing.

1.1 Background

In [7], Colton and Miguel describe the application of machine learning and theorem proving to the generation of implied constraints. They employed descriptive machine learning to generate hypotheses about concepts expressed in the basic model of a class of CSPs. They then used a theorem prover to show that certain hypotheses followed from the CSP model, and hence they could be added as implied constraints. While they achieved significant increases in efficiency in this manner, their approach was semi-automatic. In particular, both Miguel and Colton - with expertise in constraint modelling and the domain of application (pure mathematics) respectively - were required to interpret the output from the learning system as constraints and translate them into the language of the constraint solver. Consequently, although the reformulations provided an improvement in solver efficiency, this was offset by the large amount of time and expertise required during the reformulation process.

As described in the next section, our approach makes use of a number of AI techniques to fully automate the process that Colton and Miguel introduced. For brevity, we assume general familiarity with automated theorem proving [8], constraint solving [15] and machine learning [17]. We combine techniques from these areas via usage of the following systems:

- The Otter automated theorem prover, which uses the resolution method to prove theorems by refutation [16].
- The Constraint Logic Programming in Finite Domains (CLPFD) library [4] included with SICStus Prolog.
- The HR automated theory formation system. This performs descriptive learning to speculatively invent concepts and form hypotheses in a domain of interest. HR is extensively described in [6].

Our approach is distinct from, and complementary to, existing automated constraint reformulation methods. For example, the CGRASS system [10] captures common patterns in the hand-transformation of constraint satisfaction problems in transformation rules. Given an input model, CGRASS applies the rules in a forward chaining manner to improve the model gradually. A key difference from the approach presented here is that CGRASS is applicable to single problem instances only, rather than problem classes. The O'CASEY system [13, 14] employs case-based reasoning to capture constraint modelling expertise. Each case records a problem/model pair. Given a new problem, the most similar problem is retrieved from the case base. A model for the new problem is then constructed by following the modelling steps used in the retrieved case. Bessiere et al. present a method for learning the parameters of certain types of implied constraint by considering solutions and non-solutions of relaxations of the original problem [3]. The CONACQ system [1, 2] uses a version space approach to learn a CSP model from scratch given only positive and negative example solutions to the CSP.

2 The Reformulation Process

A CSP *problem class* is a possibly infinite set, $\{P_1, P_2, \dots\}$, of constraint satisfaction problems. *Instances* of the class are obtained by giving values for the *parameters* of the class. We focus on classes parameterised by a single positive integer n . The number of variables in P_n increases with n , making successive members of the class increasingly difficult to solve. However, the core constraints for each P_i can be expressed using the same general relationships over the variables. We have been working with CSPs where each variable has the same domain. For problem instance P_n from a class of CSPs, this domain is $\{1, \dots, n\}$. Hence, in using the term *domain size*, we mean the size of the domain of any variable, namely n for P_n . A good example of such a class of CSPs is Latin squares, where P_n represents the problem of filling in an n by n grid with the integers 1 to n such that no number appears twice in any row or column.

Our aim is to take the core model of a problem class and automatically produce a reformulated core model containing additional constraints. The additional constraints will be proven to be implied by the core model, so that a solution to any P_n is also a solution to the reformulated version of P_n , and vice versa. We have automated the following approach to reformulating CSPs:

1. The user supplies information about a problem class, including the core constraints. We call this formulation of the CSP the *basic model*.
2. The CLPFD solver generates solutions to small problem instances.
3. The solutions are given, along with the core model, to the HR system. This generates empirically true conjectures which relate concepts expressed in the core constraints.
4. Each conjecture is passed to Otter, and an attempt is made to show that the conjecture is implied by the core model.
5. Each proved conjecture is interpreted as an implied constraint and translated into the syntax of the CLPFD solver. As described in §3, automating this aspect of the process was the most challenging.
6. Each implied constraint is added to the basic model to produce a reformulated model. The small problem instances are then solved again using the reformulated model. Every implied constraint used in a reformulation which improves – in terms of efficiency – upon the basic model, is recorded in a set E .
7. Every pair of constraints from E are added to the basic model and tested for an efficiency increase. Every triple of constraints is then tested, etc., until a user-defined limit is reached, or no reformulation improves upon the best model so far in a particular round.
8. All reformulations leading to a speed up for the small problem instances are presented to the user in decreasing order of the efficiency gained from the reformulation.

As an example, we started with the class of QG3 quasigroup problems (defined in §4). We formed the basic model for this from the first order axioms of QG3 quasigroups, using the translator in our system. Using Sicstus to solve small problems from this class, our system generated 8 QG3 examples. HR used these to discover 100 conjectures about QG3 quasigroups, all of which were proved by Otter. The first round of testing highlighted: (i) $\forall b c d ((b * b = c \wedge d * d = c) \rightarrow (b = d))$ and (ii) $\forall b c d ((b * c = d \wedge c * b = d) \rightarrow (b = c))$ as theorems which – when interpreted as constraints – improve the efficiency of the basic model. The constraints arising from these theorems were further combined into a single model in the second round. In total, the reformulation process took approximately 8 minutes, and produced a much improved model (see §4).

3 Constraint Interpretation

The three AI systems we have been working with are all able to work with first order representations. We note that CSP is in NP, and, from Fagin's theorem [9], NP is the set of languages expressible via existential second-order logic. However, in order to provide an initial benefit via commonality of language, at present, we have limited ourselves to working with CSPs that can be expressed in first order logic.

The HR system has been developed to work with Otter-style first order representations, so the major difficulty of translation was in terms of converting conjectures from Otter syntax to CLPFD constraints. Given a proven conjecture from HR expressed as a string in Otter-style first order syntax, the translation process first tokenizes the string and then parses it using a bespoke Definite Clause Grammar (DCG). For example, the first-order string:

$$\text{all } a b (\exists c d (a * c = b \wedge d * a = b))$$

would be parsed as the following expression:

$$\begin{aligned} \text{all}([\text{var}(a), \text{var}(b)], \exists &[\text{var}(c), \text{var}(d)], \\ e(\&, e(=, e(*, \text{var}(a), \text{var}(c)), \text{var}(b)), \\ e(=, e(*, \text{var}(d), \text{var}(a)), \text{var}(b)))) \end{aligned}$$

Once parsed, expressions are translated into constraints in CLPFD syntax. This is achieved via recursion through the nested expression which creates, in most instances, a new predicate for each level of nesting. How the interpretation method deals with quantifiers, expressions and solution variables is described in §3.1 and §3.2 below. To improve the computational efficiency of the implied constraints, further processing via simplification and further interpretation via contraposition and case splitting is undertaken, as described in §3.3.

3.1 Quantifiers

The DCG produces partially translated universal quantifiers in the form $\text{all}(\text{variable_list}, \text{sub_expression})$. This states that sub_expression should hold for each combination of the values of the variables in variable_list . This is further translated by introducing three new predicates. The first predicate creates a list of all possible value combinations (pairs, triples, etc.) as a list of sets determined by the domain size. The second predicate recurses through this list, and makes a call to the third predicate for each value combination. The third predicate represents sub_expression and is constructed accordingly. The next recursion level is passed details of how the first order variables have so far been translated into Prolog variables, so they can be correctly matched.

As an example, the translation of:

$$\text{all}([\text{var}(a), \text{var}(b)], e(=, \text{var}(a), \text{var}(b)))$$

produces the following triple of logic programs:

$$\begin{array}{lll} \text{A_1(N):-} & \text{A_2([]).} & \text{A_3(V1,V2):-} \\ \text{sub_sets(N,2,S),} & \text{A_2([[V1,V2]|Ss]):-} & \text{V1 \#= V2.} \\ \text{A_2(S).} & \text{A_3(V1,V2),} & \\ & \text{A_2(Ss).} & \end{array}$$

Here, N is the domain size and S is a list of value combinations (in this case, pairs) for $\text{var}(a)$ and $\text{var}(b)$, which is produced by the pre-defined sub_sets predicate. Predicate A_1 creates this list and passes it to A_2 , which recursively calls A_3 for each combination.

Existential quantifiers are partially translated to the form $\exists(\text{variable_list}, \text{sub_expression})$, which states that

sub_expression holds for at least one combination of the values of the variables in *variable_list*. We use two methods to translate existential quantifiers. One method creates all combinations of variable values as before and, using the solver's disjunction syntax, produces another predicate which constrains that at least one case should hold. The second method, which is more effective where it can be used, involves representing the existentially quantified variables as new solution variables in the CSP. These new variables are given domains appropriate to the size of the problem and are added to the list of required solution variables. Of course, in finding a solution, the solver must ensure that these variables are given a value, which enforces their existence.

As an example, using the second method with the following partially translated sentence:

```
exists([var(a), var(b)], e(=, var(a), var(b)))
```

produces the following pair of predicates:

B_1(N,OldVarList,NewVarList):- domain(V1,1,N), domain(V2,1,N), B_2(V1,V2), append(OldVarList,[V1,V2],NewVarList).	B_2(V1,V2):- V1 #= V2.
---	---------------------------

Here, predicate B_1 creates two new solution variables, V1 and V2, to enforce the existence of valid values for first order variables *a* and *b*. These values are passed to B_2, which constrains that their value be equal for whatever instantiation the solver chooses to give them.

3.2 Expressions and Solution Variables

Expressions are partially translated as: $e(op, _, _)$, for instance $e(\&, sub_exp_a, sub_exp_b)$ and $e(=, sub_exp_a, sub_exp_b)$. Depending upon the domain of investigation, particular expressions represent solution variables. For example, in single-operator finite algebras, the solution variables are the result of the algebraic operator on all pairs of elements. Consequently, any expression in the form $e(*, n, m)$, where *n* and *m* are ground integers, identifies a specific solution variable. In other domains, different expressions represent the solution variables, for instance the inverse operator in groups.

The majority of first-order expressions that HR produces can be translated such that individual solution variables are explicitly identified. In some instances, however, where operators are nested, it is not possible to identify the exact solution variables that are affected, as they may vary according to the parameters of the constraint. For example, consider the sentence $\forall a b ((a * b) * (b * a) = b)$. Here, we must first know the results of $a * b$ and $b * a$ before we can identify the solution variable whose value must be constrained equal to *b*. The translator identifies nesting and employs the CLPFD *element* constraint, which is common to many solver systems. This built-in constraint is optimised to resolve values within lists during search.

In general, a conjunction is translated using standard Prolog comma syntax. Equality expressions equate the value of two evaluable sub-expressions. For example, $\forall a b (a * b = b * a)$ equates the result of $a * b$ with that of $b * a$. When translating equalities, a new variable is generated to represent this equated result and each sub-expression is recursively translated in such a way that its result is this new variable. For example, $\forall a b (a * b = b * a)$ generates the following triple of predicates:

C_1(N):- sub_sets(N,2,S), C_2(S).	C_2([],_) :- C_2([V1,V2] Ss):- C_3(V1,V2), C_2(Ss).	C_3(V1,V2):- mv(V1,V2,V3), mv(V2,V1,V3).
---	---	--

Here, C_1 and C_2 handle universal quantification. Predicate C_3 calls the mv(*x,y,z*) predicate which finds the solution variable representing $x * y$ and constrains it to be equal to *z*. Equality of the sub-expressions, namely $a * b$ and $b * a$, is enforced by having both calls to mv return V3.

CLPFD syntax requires some expressions, such as implications and negations, to be expressed using reification variables to represent the constraints for the sub-expressions. Reification variables, which take the value *true* if the constraint holds and *false* otherwise, allow the solver to efficiently propagate constraints during search and are attached to constraints using the CLPFD $\#<=>$ syntax. The sub-expressions of expressions requiring reification must also be reified. Consequently, the translator is able to translate all expressions both with or without reification as necessary.

3.3 Case-splitting and Simplification

The translation process can identify where conjectures can be interpreted as case-splits over quantified variable values. Case-splits allow us to consider specific sets of solution variables and can reduce the complexity of some conjectures by expressing them as simple and efficient constraints. Consider, for example, the theorem: $\forall a b ((a * b = b * a) \rightarrow (a = b))$, which states an anti-Abelian property (that no two distinct elements commute). The contra-position of this theorem is: $\forall a b ((a \neq b) \rightarrow (a * b \neq b * a))$, which can be interpreted as a case-split on the variables *a* and *b*, i.e., when they are equal and when they are not equal. Only when they are unequal do we post the inequality constraint.

The translator finds case-splits by considering whether or not the sub-expressions of an implication contain solution variables. If they do not, then the implication is translated as a case-split using the theorem or its contra-position as appropriate. Case-split translations introduce an additional predicate which succeeds if the variable values meet the case-split requirements, in which case the constraints are posted, and fails otherwise. As an example, the translation of the above anti-Abelian property, after universal quantification, is shown below:

D_1(V1,V2):- D_2(V1,V2), D_3(V1,V2).	D_2(V1,V2):- V1 \= V2.	D_3(V1,V2):- mv(V1,V2,V3), mv(V2,V1,V4), V3 \= V4.
--	---------------------------	---

In this example, D_1 represents $((a \neq b) \rightarrow (a * b \neq b * a))$. The predicate D_2 is used to determine the case, if *a* and *b* (V1 and V2) are unequal then it will succeed and a call to D_3 will be made, posting the constraint $(a * b \neq b * a)$. If it fails, i.e., $a = b$, then no constraints are posted.

In some cases, it is possible to remove variables or re-translate theorems without affecting meaning. In some cases, such simplification can improve the effectiveness of the constraints produced from the theorem. For example, $\forall a b c ((a * b = c \wedge b * a = c) \rightarrow (a = b))$ can be simplified to $\forall a b ((a * b = b * a) \rightarrow (a = b))$. Here we see that the variable *c* – which is simply a marker for equality – has been removed. Care is taken to avoid inappropriate simplification. For example, in the theorem: $\forall a b c ((b * c = c \wedge c * d = c) \rightarrow (b = d))$, we cannot simply remove the variable *c* without changing the semantics of the theorem.

4 Experiments and Results

Finite algebras provide first-order benchmark tests for CSP solvers. In particular, QG-quasigroup existence problems have driven much research in constraint solving and other computational techniques. QG-quasigroups are Latin squares with extra axioms, e.g., QG3 quasigroups are Latin squares for which $\forall a b ((a * b) * (b * a) = a)$. Further details are available at the CSPLib.³

Our experimental setup was as follows. We started with the axioms of a particular finite algebra, which effectively defines the core model of a CSP problem class. The axioms were supplied in Otter-style first order syntax and were translated into the basic model of a CSP using the translation process described above. The system ran the basic solver model for sizes up to n , and stopped when the time to solve for size $n + 1$ took over 2 minutes. In this context, and for all the experiments, by *solve* we mean exhausting the search space and finding all solutions. The solutions for the small sizes were passed to HR, which ran until it found 100 proven conjectures (with Otter providing the proofs).

The setup for HR was similar to that in [7]. However, we also supplied two additional background concepts, namely: the concept of two elements in the algebra being equal and two elements being unequal. We have found that this increases the yield of computationally effective constraints found by HR. In addition, we set up HR so that it used Otter to discard any conjectures which were tautologies, i.e., could be proved without the axioms of the domain. This slightly increased HR's processing time, but greatly reduced the number of reformulations to test, hence improved overall efficiency.

The proved conjectures from HR were interpreted and translated as constraints then used to reformulate the CSP using the process described above. For any reformulation shown to improve efficiency on the small – training – problem instances, we compared performance against that of the basic model for problems of size $n + 1$ and larger. Table 1 shows the number and size of small examples found during the reformulation stage, the time taken by HR, the time taken to construct good reformulations and the total reformulation time. This table is ordered by decreasing efficiency gain. Where we improved upon the basic model, table 2 shows the results of taking the best reformulation and applying it to larger problem sizes.

In 8 out of 14 cases, a gain in efficiency was achieved via the reformulated model. Unfortunately, there is a memory bound of 256 Mb. in the Sicstus solver, which effectively meant that we couldn't

Algebra	Domain size	Basic model	Reformulated model	Proportion (%)

Table 2. Solving times (hours:minutes:seconds) and proportion of basic model solving time for testing (larger) domain sizes. Note that only those algebras where a speed-up was identified in table 1 are shown

perform tests for problem instances larger than those shown in table 2. In those cases where we did manage to run longer tests, the benefit of reformulation is clear. In particular, for QG3, QG6, QG7 quasigroups and groups, the time taken to produce the reformulated model was a fraction of the time gained in running the larger tests. In the other cases, it seems likely that the reformulation time would be similarly gained back at larger domain sizes.

In [7], Colton and Miguel studied reformulations for QG-quasigroup problems, which were generated in a partially automated, partially hand-crafted way. It is interesting to note that the fully automated method described here re-created all the best reformulations found by hand in [7], with two exceptions. The first exception was with the reformulations of QG3 and QG4 quasigroups. Here, the best fully automated reformulation for both QG3 and QG4 uses the constraints generated from this pair of theorems:

$$\begin{aligned} \forall b c d ((b * c = d \wedge c * b = d) \rightarrow (b = c)) \\ \forall b c d ((b * b = d \wedge c * c = d) \rightarrow (b = c)) \end{aligned}$$

In [7], however, their best reformulations also used another theorem: $\forall a b (a * a = b \rightarrow b * b = a)$. In our experiments, this theorem was found in some reformulations for QG3 and QG4 which improved efficiency. However, these reformulations were less efficient than the best reformulation. The two theorems above state, respectively, that these quasigroups are anti-Abelian (i.e., no two distinct elements commute) and that the main diagonal elements must all be distinct. As described in §3.3, the system uses simplification and the contra-positive of each of these to post constraints for all cases where $b \neq c$. To illustrate these constraints, at size 6 the first of these theorems results in 15 inequality constraints of the form $X_{ij} \neq X_{ji}$ for $1 \leq i, j \leq 6$ and $i \neq j$.

The second exception represents one of numerous instances where the system discovered implied constraints which were not identified in [7]. In particular, the best reformulation for QG5 quasigroups from [7] was identified as the second best reformulation in our experiments. The best fully automatic reformulation used constraints derived from this new theorem:

$$\forall b c d ((b * c = d \wedge d * b = c) \rightarrow (c = d))$$

For QG5 quasigroups up to size five, on average, the solving time for the second best reformulation (i.e., the reformulation identified in [7]) took 77% of the time taken using the basic model. With the constraints derived from the above theorem, this time reduced to 71.7% that of the basic model.

³ A library of CSP benchmark problems (www.csplib.org).

5 Conclusions and Further Work

We have developed an automatic system, which uses machine learning and automated theorem proving to generate implied constraints for CSPs, thus improving the effectiveness of a CSP solver by reformulating the model of the problem. Using finite algebras as benchmark tests, in many cases, the time taken to reformulate problems represents a worthwhile investment, which is soon recovered when searching for solutions to larger problem instances. We have shown clear progress over the approach presented in [7] by (a) automating their semi-automated approach – which required much domain knowledge and constraint solving expertise – while recreating similar or better efficiency gains (b) successfully applying the procedure to new finite algebras, namely groups, Moufang loops and rings, the last of these being exceptional in that they have two algebraic operators rather than one, and (c) discovering new and effective implied constraints not identified in [7].

There is still room for improvement. In particular, in some cases, the system failed to create an improved solver model. There are a number of possible reasons for this, including:

- The basic model is the best possible. In this case, the approach would never improve the basic model.
- Improving constraints do exist but were not found by HR. We could counter this by running HR for longer or with heuristic guidance specifically tailored to this process. In addition, we plan to implement new ways for HR to make conjectures, for instance by allowing the user greater control over the concept formation process [18], or by directly noticing all-different properties, for which there are efficient solving methods.
- Improving constraints were found by HR but translated inefficiently. We have endeavoured to make the translation process as effective as possible, but we can improve this process. In particular, where possible, we aim to interpret conjectures as all-different constraints rather than sets of inequalities.
- Our method of assessing the effectiveness of constraints fails to identify the most useful constraints. In particular, a constraint may not be effective at low order but its effectiveness may increase as the domain size increases. In contrast, a constraint may be highly effective for small test sizes, but degrade as the domain size increases. For instance, the reformulation for QG6 quasigroups used the idempotency constraint ($\forall b (b * b = b)$), which applies to elements on the main diagonal of a multiplication table. As we see from tables 1 and 2, this achieves a time of around 12% of that for the basic model for problem sizes up to 6, but around 24% for sizes 9 and 10. Hence, we plan to implement techniques for extrapolating the effectiveness of constraints in order to choose them more intelligently.

We have recently extended the translation capabilities to enable the formulation of some first-order theorem proving problems as CSPs [5]. We also plan to generalise this approach further by enabling translation to the syntax of other solvers and extending into higher order logics. It is possible to use empirically plausible – but not necessarily proved – conjectures to define a case-split where two CSPs have to be solved in order to exhaust the search space, and we intend to pursue this possibility. Not only does this open up the possibility of distributing the solving process, but the sum of the times taken for the two cases may be less than the time taken to solve the basic model. Moreover, more complex case-splitting schemes can be used, which have already shown much promise in improving automated theorem proving techniques [12]. We also plan to study the ways in which concepts from HR can be used to streamline [11] constraint

solving. Here, the aim is to find a single solution, rather than all solutions, in which case generality can be sacrificed for efficiency by specialising a CSP. The ability to translate first-order CSPs is a useful tool outside of the application to CSP reformulation. We intend to use this for various applications, such as the comparison of model generators and CSP solvers for benchmark tests [5].

The study presented here adds weight to the argument that combining reasoning techniques can produce AI systems which are more than a sum of their parts. For instance, due to the limited number of examples at small domain sizes, the reformulations of QG6 quasigroups were based on conjectures found by HR using only two examples. Such little empirical evidence probably wouldn't be statistically significant in a straight machine learning exercise, and hence the conjectures might be ignored. However, because they were proved by Otter, they were as valid as ones with greater empirical evidence, which highlights the advantages to be gained by combining different reasoning approaches.

Maintaining Generalized Arc Consistency on Ad-hoc n -ary Boolean Constraints

Kenil C. K. Cheng and Roland H. C. Yap¹

Abstract. Binary decision diagrams (BDDs) can compactly represent ad-hoc n -ary Boolean constraints. However, there is no generalized arc consistency (GAC) algorithm which exploit BDDs. For example, the global `case` constraint by SICStus Prolog for ad-hoc constraints is designed for non-Boolean domains. In this paper, we introduce a new GAC algorithm, `bddc`, for BDD constraints. Our empirical results demonstrate the advantages of a new BDD-based global constraint – `bddc` is more efficient both in terms of memory and time than the `case` constraint when dealing with ad-hoc Boolean constraints. This becomes important as the size of the ad-hoc constraints becomes large.

1 Introduction

Many real-life combinatorial problems such as scheduling can be modeled as a constraint satisfaction problem (CSP). There has been much attention on global constraints which make use of specialized consistency algorithms, for example `all_different` or `cumulative`. However, relatively less effort has been put into dealing with the *ad-hoc (n -ary) constraints*.

An ad-hoc n -ary constraint is defined explicitly either as a set of solutions or alternatively as a set of non-solutions. Obviously these tuples can be stored in an array or a table [3, 13]. The `table` constraint in ILOG Solver uses such an explicit implementation. A drawback of using a table is that the constraint is limited by the number of (non-)solutions. The problem is that the table size can grow exponentially with the arity of the constraint. This means that `table` constraints are restricted to either tight or loose constraints with moderate arity. In practice, large ad-hoc constraints can also be useful. For example, Cheng and Yap [7] demonstrate that improving a model for the Still-Life problem leads to large ad-hoc constraints, e.g. an ad-hoc constraint with 76 million solutions and 30 variables. Another drawback is the slow support checking within large tables. While this can be remedied by means of indexing [14], the additional data structure inevitably requires extra memory and manipulation effort.

One way to tackle the memory explosion problem is to identify or extract some arithmetic or symbolic relations from the solution set (e.g. [6, 10]). Although the final representation is usually more compact, they often need expensive pre-processing and the propagation on the higher-level representation could be weak.

Another approach is to represent the solution set in some compact data structure and build a tailor-made propagation algorithm (or combine existing propagators) on top of it (e.g. [1, 2, 8]). The ad-hoc non-binary `case` constraint provided by SICStus Prolog [17] belongs to this category. The `case` constraint also allows one to

specify the level of consistency (i.e. GAC or bounds consistency) to enforce. To use the `case` constraint, the solutions of the ad-hoc constraint should be represented as a directed acyclic graph (DAG) which is recursively defined as follows. A `case` DAG $G = \text{case}(x_i, [r_1 - G_1, \dots, r_m - G_m])$ defines the finite domain constraint

$$\llbracket G \rrbracket \equiv \bigvee_{k=1}^m (x_i \in r_k \wedge \llbracket G_k \rrbracket)$$

where each G_k is a `case` DAG and r_i specifies its bounding interval of integers. Figure 1 depicts the DAG representation of c_{dag}

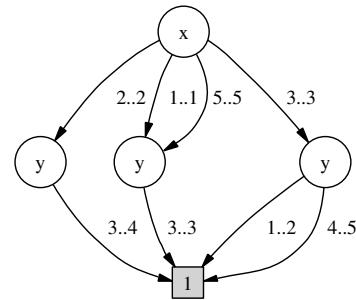

Figure 1. A DAG representation of c_{dag} .

with solutions $\{(x, 1), (y, 3)\}, \{(x, 2), (y, 3)\}, \{(x, 2), (y, 4)\}, \{(x, 3), (y, 1)\}, \{(x, 3), (y, 2)\}, \{(x, 3), (y, 4)\}, \{(x, 3), (y, 5)\},$ and $\{(x, 5), (y, 3)\}$. Each non-terminal node v (denoted by a circle) represents a variable x . An out-going edge of v has a label r that represents the constraint $x \in r$. The 1-terminal (in gray box) means T (true). The details of the consistency algorithm for `case` are not available. Beldiceanu [2] mentions that it traverses the `case` DAG in a depth-first fashion and updates the variable domains incrementally.

When every variable in a `case` constraint has a Boolean domain, the `case` DAG can also be represented by a binary decision diagram (BDD) [5]. BDDs are the state of the art representation for propositional logic in areas such as hardware verification [9]. Because of the success of BDDs for representing Boolean functions compactly, several authors have suggested to manipulate constraints with BDDs. Hawkins et. al. [12] solve CSPs involving set variables with BDDs. In [18] BDDs are used to represent the solution set in configuration problems. Cheng and Yap [7] show how to construct compact `case` constraints with BDDs and modeling with ad-hoc constraints to enhance propagation efficiency for the Still-Life problem. We conjecture BDD is also invaluable to many CSPs such as circuit fault

¹ National University of Singapore, 3 Science Drive 2, Singapore {chengchi,ryap}@comp.nus.edu.sg

diagnosis and balanced incomplete block designs² where Boolean constraints exist naturally.

Although it is always possible to model an ad-hoc Boolean constraint with the `case` constraint, one would expect a specialized consistency algorithm built on top of a BDD constraint representation to be more efficient – a simpler data structure and a less expensive implementation. Consequently, in this paper, we introduce `bddc`, a specialized version of `case` for Boolean domains. Like `case`, we choose to also traverse the BDD depth-first. To make this strategy computationally efficient, we avoid fruitless node visits with two techniques: Δ -cutoff and good/nogood recording. Roughly speaking, the former reduces the amount of nodes visited during the traversal while the latter makes the traversals less frequent. Although nogood recording [11] is an old technique for pruning the search space during search, it has not been applied much to consistency algorithms. We consider good recording as a generalization of support caching [15] for binary constraints. Another difference is that, our (no)goods are shared among identical constraints so that more savings on computation can be achieved.

In the next section we summarize our notations on CSP and BDD. The `bddc` algorithm is introduced in Section 3. Details on its implementation are provided. Section 4 presents and discusses our experimental results. We conclude in the last section.

2 Preliminaries

In this section, we present our terminology and a brief introduction to binary decision diagrams.

2.1 Constraint Satisfaction Problem

A *constraint satisfaction problem* (CSP) is a triple $\mathcal{P} = \langle X, \mathcal{D}, \mathcal{C} \rangle$, where $X = \{x_1, \dots, x_n\}$ is a set of *variables*, $\mathcal{D} = \{D_1, \dots, D_n\}$ is a set of *domains*, and \mathcal{C} is a set of *constraints*.³ Each variable x_i can only take values from its domain D_i , which is a set of integers. A *valuation* θ is a mapping of variables to integer values, written as $\{(x_1, d_1), \dots, (x_k, d_k)\}$. Let $vars$ be the function that returns the set of (free) variables appearing in a constraint or valuation. A k -ary constraint $c \in \mathcal{C}$ on an ordered set of k distinct variables is a subset of the Cartesian product $D_1 \times \dots \times D_k$ that restricts the values the variables in c can take simultaneously. Particularly, if $D_i = \{0, 1\}$ for all $1 \leq i \leq k$, then c is a *Boolean constraint*. The *scope* of c is $vars(c)$ and the *arity* of c is $arity(c) = k$. We say $T(F)$ is the trivially true (false) constraint. A valuation θ *satisfies* c , a.k.a. a *solution* of c , if and only if $\theta \in c$. Solving a CSP requires finding a value for each variable from its domain so that all constraints are satisfied.

Two constraints c_1 and c_2 are *equivalent*, denoted by $c_1 \equiv c_2$, if and only if they define the same relation, i.e. for any valuation θ , we have $\theta \in c_1 \iff \theta \in c_2$.

A constraint c is *consistent* if it is not equivalent to F . Otherwise, c is *inconsistent*. If $c \wedge x_i = d$ is consistent for each $x_i \in vars(c)$ and for each $d \in D_i$, then c is *generalized arc consistent* (GAC) [3, 16].

2.2 Binary Decision Diagrams

A *binary decision diagram* (BDD) [5] is a directed acyclic graph with two terminal nodes: the *0-terminal* which means F and the *1-*

² CSPLib: www.csplib.org

³ In this paper we use the terms “a set of constraints” and “a conjunction of constraints” interchangeably.

terminal which means T . Each non-terminal node u is labeled with a Boolean variable x_i and has two children G_1 and G_0 which are BDDs. Let $G = bdd(x_i, G_1, G_0)$ be the BDD rooted at u . Semantically G represents the Boolean constraint

$$[G] \equiv (x_i = 1 \wedge [G_1]) \vee (x_i = 0 \wedge [G_0]).$$

In BDD terms G_1 is the *1-successor* and G_0 is the *0-successor* of u . We call $[G]$ a *BDD constraint (defined by G)*. For brevity, we write G instead of $[G]$ when its meaning is clear. Figure 2 depicts a BDD which defines the Boolean constraint $(x_1 = 1 \wedge x_3 = 0) \vee (x_1 = 0 \wedge x_2 = 1 \wedge x_3 = 0)$. The solutions are $\{(x_1, 1), (x_2, 0), (x_3, 0)\}$, $\{(x_1, 1), (x_2, 1), (x_3, 0)\}$ and $\{(x_1, 0), (x_2, 1), (x_3, 0)\}$. The solid and the dotted out-going arrows from a node (in circle) point to its 1 and 0-successors respectively. The terminal nodes are drawn as gray boxes. Note that for defining a BDD constraint the presence of the 0-terminal is optional (as for the `case` constraint).

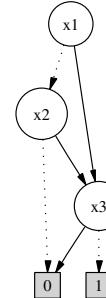

Figure 2. An example BDD.

A BDD constraint, `bddc`, is any BDD $G = bdd(x_i, G_1, G_0)$ that defines a Boolean constraint on variables x_i, \dots, x_k where $1 \leq i \leq k$. G_0 and G_1 are either the 0-terminal, the 1-terminal (when $i = k$), or a BDD $G' = bdd(x_j, G'_1, G'_0)$ where $i < j \leq k$. To ease the presentation and implementation, we require $j = i + 1$, i.e. any path from the root of G to the 1-terminal corresponds to a solution of $[G]$.

3 Maintaining GAC on a BDD Constraint

We now present the `bddc` algorithm which enforces GAC on a BDD constraint. The pseudo-code is given in Figure 3. The input is a BDD (constraint) G . The recursive call `bddc_r` (line 3) traverses G in a depth-first manner and creates the new domains of the variables in $vars(G)$. If G is inconsistent, `bddc_r` returns F and the solver backtracks (line 5). Otherwise, the domains of the variables are updated (line 7) to make G GAC. Good/nogood recording is implemented so that the expensive `bddc_r` is less frequently executed. Let θ be the current valuation of the subset of the variables in $vars(G)$. If `bddc_r` detects G is inconsistent, θ is inserted to *cache* as a *nogood* (line 4). On the other hand, if the new and the current domains are the same for every $x_i \in vars(G)$, θ is added to *cache* as a *good* (line 6) to avoid future consistency checks since the constraint is already GAC with those domains. The cache allows any subsequent call of `bddc` with the same θ , to either immediately trigger a backtrack if G is inconsistent (line 1) or just quit if G is already GAC (line 2).

Figure 4 gives the pseudo-code of `bddc_r`. It works as follows. Let $G = bdd(x_i, G_1, G_0)$. Recall that G defines the Boolean constraint

$$G \equiv (x_i = 1 \wedge G_1) \vee (x_i = 0 \wedge G_0).$$

```

bddc( $G$ )
begin
   $\theta :=$  the valuation of variables in  $vars(G)$ 
1   if  $cache[\theta] = F$  then fail //  $\theta$  is a nogood
2   if  $cache[\theta] = T$  then return //  $\theta$  is a good
   $visited := \emptyset$  // the set of visited nodes in  $G$ 
  foreach  $x_i \in vars(G)$  do
     $D'_i := \emptyset$  // init the new domain of  $x_i$ 
    // invariant:  $D'_i = D_i$  for all  $i \geq \Delta$ 
    // where  $D_i$  is the current domain of  $x_i$ 
     $\Delta := arity(G) + 1$ 
3    $ret := bddc\_r(G)$  // traverse  $G$  to find  $D'_i$ 's
  if  $ret = F$  then
    //  $G$  is inconsistent
     $cache[\theta] := F$  // nogood-recording
    fail // (solver) backtracks
  else
    //  $G$  is generalized arc consistent
    if  $\Delta = 1$  then
      //  $D_i = D'_i$  for all  $1 \leq i \leq arity(G)$ 
       $cache[\theta] := T$  // good-recording
    else
5     foreach  $x_i \in vars(G)$  where  $D'_i \neq D_i$  do
         $x_i \in D'_i$  // update the domain of  $x_i$ 
    end

```

Figure 3. Pseudo-code of bddc.

By induction, we can enforce GAC on G by enforcing GAC on G_d (via the recursive call of $bddc_r$ at line 9) for each d in the current domain D_i of x_i . If G_d is consistent, d is added to the new domain D'_i of x_i (line 10) and $bddc_r$ returns T . In the case there is no consistent successor, G is inconsistent and $bddc_r$ returns F . Finally, G is inserted to the cache $visited$ if it is consistent (line 12) and to the cache $pruned$ if it is not (line 13). These guarantee $bddc_r$ visits every node in G at most once. To make $bddc$ incremental, $pruned$ is not reset to empty at each call of $bddc$. This is because if G is inconsistent, it remains inconsistent when even more variables are assigned. By similar arguments, $visited$ must be zeroed initially.

More work can be saved by using the following optimization which we call Δ -cutoff. It utilizes the invariant (line 11)

$$D'_j = D_j \quad \forall j \geq \Delta$$

Thus, the call of $bddc_r(G_d)$ can be omitted whenever $i \geq \Delta$ and G_{1-d} is consistent (line 8). This is because G must then be consistent and all D'_j 's ($j \geq i$) are already “saturated” (namely, $e \in D_j \iff e \in D'_j$) and, by construction, they never shrink (i.e. once a value is put into D'_j , it will never be removed in subsequent recursive calls).

By induction on the input BDD constraint G , it is straightforward to show the following:

Theorem 1 *The bddc algorithm is sound, complete and always terminates.*

We now analyze the memory requirement for $bddc$. Consider the representation of the input BDD constraint G . Since G is static, we store its nodes in a fixed $n \times 2$ array (bdd) where n is the number of nodes in G . Then $bdd[u]$ refers to the BDD rooted at the

```

bddc_r( $G$ )
begin
  if  $G$  is the 0-terminal then return  $F$ 
  if  $G$  is the 1-terminal then return  $T$ 
  if  $G \in pruned$  then return  $F$  //  $G$  is inconsistent
  if  $G \in visited$  then return  $T$  //  $G$  is GAC
  let  $G = bdd(x_i, G_1, G_0)$ 
  // recall  $G \equiv (x_i = 1 \wedge G_1) \vee (x_i = 0 \wedge G_0)$ 
   $ok_1 := F$  // assume  $G_1$  is inconsistent
   $ok_0 := F$  // assume  $G_0$  is inconsistent
  foreach  $d \in D_i$  (the current domain of  $x_i$ ) do
    if  $ok_{1-d} \equiv T$  and  $i \geq \Delta$  then
      //  $G_{1-d}$  is consistent (so is  $G$ )
      // also, the old and the new domains
      // of  $x_j$  ( $j \geq i$ ) are the equal
      break
    // otherwise, traverse  $G_d$  recursively
     $ok_d := bddc\_r(G_d)$ 
    if  $ok_d \equiv T$  then
      //  $G_d$  is consistent
      // add  $d$  to the new domain of  $x_i$ 
       $D'_i := D'_i \cup \{d\}$ 
      if  $i = \Delta - 1$  and  $D_i = D'_i$  then
         $\Delta := \Delta - 1$  // update the invariant
    if  $ok_0 \equiv T \vee ok_1 \equiv T$  then
      //  $G$  is visited and  $G$  is consistent
       $visited := visited \cup \{G\}$ 
      return  $T$ 
    else
      //  $G$  is inconsistent
       $pruned := pruned \cup \{G\}$ 
      return  $F$ 
  end

```

Figure 4. Pseudo-code of $bddc_r$.

node u (represented as an integer) and $bdd[u][d]$ points to the d -successor of u . The size of the array is $2n[\log_2 n]$ bits, where $[x]$ is the smallest integer larger than x .

The caches $visited$ and $pruned$ are represented as bit vectors of length n . The u -th bit is set to 1 if and only if the BDD rooted at u is in the cache. Note that $bddc$ will be invoked at most $k = arity(G)$ times, whenever a variable in its scope is instantiated. For trailing purpose, the call of $bddc$ at time t must make its copy of $pruned$ updated at time $t - 1$. As a result, there will be up to k copies of $pruned$, and at most $(k + 1)n$ bits are required for the two caches.

We implement $cache$ as a hash table of fixed size h (i.e. no collision resolution). A (no)good θ is encoded as two bit vectors, namely α_0 and α_1 , of length k . The i -th bit of α_d is set to 1 if and only if $(x_i, d) \in \theta$. Another 1 bit is used to identify whether θ is a good or a nogood. The size of $cache$ is therefore $(2k + 1)h$ bits.

Often a CSP consists of several identical constraints on different variables. For example, it is common to have a disequality constraint between every two variables. Since a BDD constraint could be exponentially large, it is especially advantageous to let them share as many data structures as possible. In our implementation of $bddc$, besides the obvious bdd (which is static) and $visited$ (which is basically a local variable), $cache$ is also shared. This is correct because

the encoded valuations are variable independent. The shared *cache* is actually more powerful. It can cut down more fruitless computations – a (no)good detected by one constraint can be reused by all other identical constraints. Theorem 2 summarizes the memory usage:

Theorem 2 Suppose there are m identical k -ary Boolean constraints defined by a BDD G with n nodes, and assume there are h slots in cache. The overall memory requirement for the m constraints is $\Theta((2\lceil \log_2 n \rceil + 1 + mk)n + (2k + 1)h)$ bits.

Note that the $(2k + 1)h$ bits are needed only when good/nogood recording is enabled, and less memory can be used if we restrict the arity of (no)goods. Actually, the memory requirement for bddc are rather low. The alternative of representing the s solutions in a table alone uses at least sk bits and we would expect when BDDs are applicable that $s \gg n$. Extra memory is necessary for trailing.

4 Experimental Results

In this section, we report the runtime performance and memory usage of bddc. We used SICStus Prolog 3.12.3 [17] as our experimental and evaluation platform because it is the only constraint system with an implementation of the *case* global constraint. It would not be fair to compare with a more explicit ad-hoc constraint representation like *table* simply due to the space and time overheads of large tables. The *case* constraint in SICStus Prolog being a generalized version of bddc serves as a more meaningful benchmark.

Our implementation of the bddc solver is in C and uses the built-in global constraint APIs as well as the C-Prolog interface in SICStus Prolog. Experiments were run on a PC running Windows XP, with a P4 2.6 GHz CPU and 1 GB physical memory.

We have experimented with two sets of benchmarks of 25 instances each. One set contains many small BDD constraints (BDD size $\approx 3K$) while the other is the opposite; large BDD constraints (BDD size $\approx 22K$) but fewer constraints. Thus, the intention is to investigate the performance of bddc with respect to the two major scaling factors: the number of constraints and the size of an ad-hoc constraint.⁴ An instance in the benchmark is described using the notation, (v, m, k, p) , which denotes a problem with v Boolean variables and m copies of a random k -ary BDD constraint on different (randomly chosen) subset of variables. The tightness p means the BDD constraint has about $(1 - \frac{p}{100}) \times 2^k$ solutions. The values of m and p were chosen by trial-and-error such that each benchmark has both satisfiable and unsatisfiable instances, and the instances are neither too simple nor too difficult to solve. The BDD is generated in a depth-first, post-order manner where identical sub-BDDs are merged and the terminal nodes are chosen randomly based on p .

To compare the efficiency of the bddc solver, it is necessary to take into account the instantiation order from different search/labeling strategies. Intuitively, as we will see, one would expect a difference between a top-down and bottom-up search strategy. We have evaluated the following four instantiation orderings (*ord*) on a bddc constraint as follows. *Top-down* (*TD*) means the natural, bddc lexicographic order. *Bottom-up* (*BU*) is the reverse of *TD*. *Zip-zap* (*ZZ*) interleaves *TD* and *BU* (i.e. $x_1, x_k, x_2, x_{k-1}, \dots, x_{\frac{k}{2}}$). *Middle-out* (*MO*) reverses *ZZ*.

Table 1 gives the results on the first benchmark (21, 2713, 15, 79) with many small bddc constraints. The figures given are the mean

⁴ Our CSP instances have significantly more constraints than the ones used in a recent paper [14] about the ILOG *table* constraint. The arity and the size of the constraints in the two papers are comparable.

of the results obtained over the 25 instances. Each instance has 2713 identical 15-ary BDD constraints with 3576 nodes on average. The column *t* (in seconds) gives the search time⁵ for a solution of an instance, when the BDD constraints are implemented with bddc. The column *̄n* lists the average number of nodes visited during a BDD traversal. This can be computed as

$$\bar{n} = \frac{\text{total number of } \text{bddc_r} \text{ called during search}}{\text{total number of } \text{bddc} \text{ called during search}}.$$

The last column gives the search time when *case* is used instead. We highlight the fastest execution time in **bold**. The search times given here do not include the time for initialization. On average *case* takes 4.8 seconds to initialize in the first benchmark (with small BDDs) and 14.5 seconds in the second one (with large BDDs). In both tests, bddc builds its own data structures within 1 second. The number of backtracks is given in the column *bt*. During search the zero branch (i.e. $x_i = 0$) is always explored first. We experimented with three variations of bddc as follows. *DF* is a basic depth-first algorithm which does not have the good/nogood recording nor Δ -cutoff. *DF + Δ* uses only Δ -cutoff. *DF + Δ + c* is the full version of bddc as in Figures 3 and 4. There are 2^{20} slots in *cache*. Each cache entry is defined as *unsigned long long* (8 bytes) and hence the memory used for *cache* is 8 MB.

<i>ord</i>	<i>bt</i>	<i>DF</i>		<i>+Δ</i>		<i>+Δ + c</i>		<i>case</i>
		<i>t</i>	<i>̄n</i>	<i>t</i>	<i>̄n</i>	<i>t</i>	<i>̄n</i>	
<i>TD</i>	2131	77.2	111.5	45.9	36.5	24.5	0.3	90.8
<i>BU</i>	2144	298.9	681.9	81.2	129.4	25.0	1.2	236.5
<i>ZZ</i>	2150	171.6	323.4	61.7	68.8	26.0	0.9	141.7
<i>MO</i>	1503	102.5	280.9	43.9	68.4	18.2	1.0	118.1

Table 1. Experimental results on (21, 2713, 15, 79).

Our first observation is that, to enforce (restore) GAC on a BDD constraint after a variable assignment, on average *DF* visits only 111.5 nodes when the variables are assigned top-down, but 681.9 nodes when the labeling is done bottom-up. Notice that *̄n* is independent to the exact search tree because bddc is called only at each node of the search tree and by definition *̄n* is the average number of *bddc_r* invoked in a bddc call. As a result, despite the number of backtracks under *TD* and *BU* which are more or less equal, the search is 2.9 times slower under *BU* since *BU* leads to more nodes visited.

The explanation for the variations in *̄n* is as follows. When the variables are assigned top-down, the BDD shrinks (implicitly) and by definition, the valuation leads to the 0-terminal if the constraint is inconsistent. Consequently *DF* can detect inconsistency or enforce GAC within a few node visits. On the other hand, under the bottom-up labeling order, *DF* must then traverse a large (upper) part of the BDD to reach the assigned variables at the bottom; also, the BDD does not necessarily reduce in size with the number of assigned variables. We can see that *TD* and *BU* correspond respectively to the best and the worst scenarios for *DF*. For similar reason, *DF* visits less nodes under *MO* than *ZZ*. Compared with *case*, *DF* is faster under *TD* and *MO* but slower under *BU* and *ZZ*.

Given that ad-hoc constraints may be rather large, memory usage may actually be a more relevant factor than solver efficiency. Here,

⁵ Time was reported by the built-in predicate *statistics* with parameter *runtime*.

we can see the effect of the specialized `bddc` on memory usage. On average `bddc` uses 32.5 MB while the average memory usage for `case` is 728.3 MB.⁶ Note that in both cases, we are already exploiting the use of a directed acyclic graph representation, and the difference shows the contrast between `bddc` and `case`. We also see that for `case`, the memory usage is getting close to the maximum physical memory on our PC. In other words, the benchmark size seems to be nearing the limits of `case`.

Δ -cutoff drastically reduces the computation effort of `bddc`. $DF + \Delta$ visits only 19 (*BU*) to 33 (*TD*) percent of nodes visited by DF . It is particularly effective when the variables are assigned bottom-up since there is a higher chance to “saturate” the domains of the (instantiated) variables at the bottom and push up the cutoff level (Δ). This makes $DF + \Delta$ up to 2.7 times faster than DF .

Since there are 2713 identical BDD constraints in an instance, the use of good/nogood recording is expected to cut down the amount of wasteful work by a huge margin. Our empirical results show that, every call of $DF + \Delta + c$ visits up to 1.2 nodes on average. In the case of *TD*, it is just 0.3 node on average. The cache usage is very effective with up to 43000 cache slots filled and a cache hit rate of around 99 percent. As a consequence, representing the BDD constraints with `bddc` instead of `case` speeds up the search by 2 to 9 fold approximately. There is a dramatic improvement in the time for *BU* which speeds up about 12 fold. Thus, caching is important in making the `bddc` solver more robust – the execution time is now fairly independent of the labeling order.

The results on the second benchmark (21, 133, 18, 78) with fewer but larger constraints are summarized in Table 2. There are 133 identical BDD constraints. The arity is now increased to 18 and each BDD constraint has 22575 nodes on average. The memory usage for `case` is 166.8 MB and that for `bddc` is 30.4 MB.

ord	bt	DF		$+\Delta$		$+\Delta + c$		<code>case</code>
		t	\bar{n}	t	\bar{n}	t	\bar{n}	
<i>TD</i>	17768	43.1	81.6	31.3	33.7	11.2	1.8	53.7
<i>BU</i>	16379	155.0	651.8	54.7	160.2	12.3	10.9	217.7
<i>ZZ</i>	16670	91.5	310.2	40.6	82.5	12.1	7.4	99.3
<i>MO</i>	14657	67.7	242.4	37.3	77.0	11.5	6.5	98.9

Table 2. Experimental results on (21, 133, 18, 78).

Although the statistics in the two benchmarks share similar patterns, there are two subtle differences. First, Δ -cutoff is slightly less effective in the second benchmark. This is because when the arity is large, the cutoff level becomes relatively low, even if the absolute value is unchanged. Second, as the instances are more difficult to solve (i.e. more backtracks) and there are less identical constraints, the efficiency of good/nogood recording degrades. Our cache log reports up to 151114 slots are filled and the cache hit rate is more or less 90%. On the other hand, `bddc` scales well. The full version is about 4 to 17 times faster than `case`. Now even the naive DF outperforms `case`. Our results demonstrate the effectiveness of the full `bddc` algorithm in terms of runtime and memory.

⁶ The memory used by SICStus Prolog was measured by `statistics` with parameter `memory`. For `bddc`, the memory allocated in C was calculated based on Theorem 2, except that in actual the implementation uses `unsigned long bdd[] []` and `unsigned long long cache[]`.

5 Concluding Remarks

We have proposed a new algorithm, `bddc`, which enforces GAC on ad-hoc n -ary Boolean constraint defined in a BDD. Our experimental results show `bddc` always outperforms `case` in terms of memory usage and computation efficiency. This justifies the need for a tailor-made GAC algorithm on BDD constraint particularly as the size of the ad-hoc constraint becomes large.

The implementation techniques we have presented in this paper are not restricted to `bddc` – Δ -cutoff can as well be used to prune unnecessary node visits during the traversal of a `case` DAG; also, as suggested in [15], caching should be helpful for arbitrary consistency algorithms, especially for the computationally expensive ones.

One unaddressed issue is to enforce GAC on a conjunction of (BDD) constraints (e.g. [4]). Working on ad-hoc constraints directly opens up new possibilities to tackle this problem, for example, by combining several constraints into a single one (e.g. [7]). We also plan to investigate the more general non-boolean case.

A Study on the Short-Term Prohibition Mechanisms in Tabu Search

Luca Di Gaspero¹ and Marco Chiarandini² and Andrea Schaerf¹

Abstract. Tabu Search (TS) is a well known local search method which has been widely used for solving AI problems. Different versions of TS have been proposed in the literature, and many features of TS have been considered and tested experimentally. The feature that is present in almost all TS variants is the so called (short-term) tabu list which is recognised as the crucial issue of TS. However, the definition of the parameters associated with the tabu list remains in most TS applications still a handcrafted activity.

In this work we undertake a systematic study of the relative influence of few relevant tabu list features on the performances of TS solvers. In particular, we apply statistical methods for the design and analysis of experiments. The study focuses on a fundamental theoretical problem (GRAPH COLOURING) and on one of its practical specialisation (EXAMINATION TIMETABLING), which involves specific constraints and objectives. The goal is to determine which TS features are more critical for the good performance of TS in a general context of applicability.

The general result is that, when the quantitative parameters are well tuned, the differences with respect to qualitative parameters become less evident.

1 INTRODUCTION

Local search is a search paradigm which has evidenced to be very effective for a large number of AI problems [18]. Tabu Search (TS) [15] is one of the most successful local search methods, which has been widely used for solving AI problems. Different versions of TS have been proposed in the literature, and many features of TS have been considered and tested experimentally. They range from long-term tabu, to dynamic cost functions, to strategic oscillation, to elite candidate lists, to complex aspiration criteria, just to mention some (see [15] for an overview).

The feature that is included in virtually all TS variants is the so called (*short-term*) *tabu list*. The tabu list is indeed recognised as the basic ingredient for the effectiveness of a TS-based solution, and its behaviour is a crucial issue of TS.

Despite the importance of a correct empirical analysis, which has been emphasised in the general context of heuristic methods [2, 19] and even in the specific case of TS [28], the definition of the parameters associated with the tabu list remains in most research work still a handcrafted activity. Often, the experimental work behind the parameter setting remains hidden or is condensed in a few lines of text

reporting only the final best configuration. Even the recently introduced *racing* methodology for the tuning of algorithms [4] only allows to determine the best possible configuration. These procedures are certainly justified from a practical point of view, but a more detailed description of the behaviour and sensibility of the algorithm with respect to its different factors and parameters is surely of great interest in the research field.

In this work, we aim at determining which factors of basic TS are important and responsible for the good behaviour of the algorithm and its robustness (i.e., the capability of exhibiting a stable behaviour across several set of instances). In contrast to the one-factor-at-a-time approach used in [28], we use different experimental design techniques [23], with parametric and non-parametric analysis of variance and racing algorithms. The suitability and comparison of these techniques in the field of search algorithms is still an open issue, hence we use more than one method to provide complementary support to their conclusions. We focus the analysis on both a fundamental theoretical problem, namely the GRAPH COLOURING problem, and on one of its practical specialisation, the EXAMINATION TIMETABLING problem, for which there is a consistent literature and many benchmark instances.

Although the statistical methods applied indicate that an algorithmic configuration of general validity does not arise, they point out that for these problems TS is robust enough w.r.t. the qualitative features, and thus it is reasonable to focus mainly on tuning the quantitative parameters. In addition, we strengthen our analysis with a comparison with previous work thus providing absolute validity to the results here presented and avoiding the pitfall of a self-standing work. We show indeed that the so-configured solution algorithm produces results that are comparable with the state-of-art.

2 PROBLEM DEFINITIONS

The first problem we consider is the classical GRAPH (VERTEX) COLOURING problem in its chromatic number formulation [14]. Given an undirected graph $G = (V, E)$, the GRAPH COLOURING problem consists in finding the minimal number of colours such that there exists an assignment of exactly one colour to each vertex and vertices connected by an edge $e \in E$ receive different colours.

The EXAMINATION TIMETABLING problem consists in scheduling the exams of a set of university courses in rooms and timeslots. In doing this, overlaps of exams with students in common must be avoided, exams must be fairly spread for each students, and room capacity constraints must be satisfied [26]. Among the different EXAMINATION TIMETABLING versions, we focus on the formulation proposed by Burke *et al.* [5]. According to this formulation, the examination session consists of a given fixed number of periods, and each period belongs to a specific day. Exams with common students

cannot be scheduled in the same period (first order conflicts), but they should also be not scheduled in adjacent periods of the same day (second order conflicts). It is easy to see, that this formulation corresponds to the GRAPH COLOURING problem in which the exams represent the vertices, the periods the colours, and two nodes are connected if they have students in common. The differences stem from the fact that for the EXAMINATION TIMETABLING the number of periods is fixed, whereas the objective function consists in the second order conflicts (weighted by the number of students).

3 TABU SEARCH BASICS

Local search is based on the idea of navigating a space of solutions (called *search space*) by iteratively moving from one state to one of its “neighbours”, which are obtained by applying a simple local change to the current solution. Several criteria for the selection of the move can be defined upon this idea. In particular, TS explores the full current neighbourhood and selects, as the new current state, the neighbour that gives the minimal value of a cost function, independently of whether its cost is less or greater than the current one. This selection allows the search to *escape* from local minima, but creates the risk of cycling among a set of states. In order to prevent cycling, TS uses a prohibition mechanism based on memory of past iterations: a list (called tabu list) stores the most recently accepted moves, so that the *inverses* of the moves in the tabu list are forbidden (i.e., the moves that are leading again toward the just visited local minimum).

The precise instantiation of the above general scheme can be done in different ways. In details, the three main features related to the tabu list are the following:

Neighbourhood exploration: Often exploring the full neighbourhood and determining the best move can be computationally too expensive for a tabu search algorithm to perform well. The exploration of the neighbourhood is therefore reduced to a part of it. The part of the neighbourhood explored can be determined probabilistically, heuristically or through considerations on structural properties of the problem that guarantee no improvement for the neighbours omitted.

Prohibition power: The prohibition power determines which moves are prohibited by the fact that a move is in the tabu list. A move is normally composed of several attributes; depending on the prohibition power, the tabu status can be assigned only to the move with the same values for all attributes or to the set of moves that have one or more attribute equal.

List dynamics: The list dynamics determines for how many iterations a move remains in the tabu list. This can be a fixed value, or a value selected randomly in an interval, or a value selected adaptively on the basis of the current state of the search.

In the next section, we propose different alternatives for the definition of the above features in the two case studies.

4 INSTANTIATION OF TABU SEARCH FEATURES

The search space considered is the same for both problems and is composed by one variable for each vertex (resp. exam) whose domain corresponds to the set of colours (resp. periods). The neighbourhood of a state is composed by all states reachable by changing exactly one colour at a vertex. In this setting, a local search move m

can be identified by three attributes: a vertex v , its old colour o and its new colour n and it can be identified by the triple $m = \langle v, o, n \rangle$. Note that the two attributes v and n suffice to identify the move uniquely.

The exploration of the neighbourhood can be restricted to only those vertices involved in a conflict (i.e., adjacent vertices that are assigned the same colour). In this way, it is guaranteed that no improving move is missed and, although the worst case complexity remains $O(kn)$, in practise we obtain a large reduction of search effort especially when the search explores states that are close to good solutions. This reduction is very helpful, and we do it in all cases. A further possible reduction of the neighbourhood exploration could be achieved by means of the MinConflict heuristic [22]. Consequently, we decide to implement the following three neighbourhood exploration reductions:

No reduction (NoRed): for each vertex involved in a conflict all the colours are tried and the overall best move is taken.

MinConflict Vertex (MinConf_v): for a vertex randomly chosen among those involved in a conflict the colour that yields the best move is chosen.

MinConflict Colour (MinConf_c): for all vertices involved in a conflict a colour is selected at random and the best overall move is taken.

For the prohibition power, assuming that the move $\langle v, n, o \rangle$ is in the tabu list, we consider the following three alternatives (where the underscore means “any value”):

Strong: All moves of the form $\langle v, _, _ \rangle$ are prohibited.

Medium: All moves of the form $\langle v, _, o \rangle$ are prohibited

Weak: Only the single move $\langle v, n, o \rangle$ is prohibited

In other terms, in the first case, it is not allowed to recolour the vertex in the tabu iterations. In the second case, it is not allowed to recolour the vertex with its old colour. In the third case, it is not allowed only to make the reverse of the tabu move.

Finally, in regards to the list dynamics, we also consider two possibilities:

Interval: The size of the list can vary in the range $[t_b, t_b + w]$ of width w . Each accepted move remains in the list for a number t of iterations equal to $t_b + \text{Random}(0, w)$, where $\text{Random}(a, b)$ is the uniform integer-valued random distribution in $[a, b]$

Adaptive: The value t depends on the current state. We use the formula (proposed in [13]) $t = \lfloor \alpha * c_s \rfloor + \text{Random}(0, t_b)$ where t_b and α (real value) are parameters, and c_s is the number of conflicts in the current state s .

A special case of Interval is the case, called Fixed, in which $w = 0$, so that the tabu list is a queue of size t_b . At each iteration, the accepted move gets in and the oldest one gets out. All moves remain in the list for exactly t_b iterations.

As a final remark, it is worth to note that according to the common practise in Tabu Search applied to the GRAPH COLOURING problem (e.g., [16]), the issue of finding the minimum number of colours is solved as a sequence of decision problems. The procedure stops and returns the value k , as soon as no solution with $k - 1$ colours can be found.

5 EXPERIMENTAL METHODOLOGY

It is recognised that studying local search algorithms in an analytical way is a complex task which often yields results with scarce practical

implications [17, 24]. The assessment of these algorithms is therefore carried out through empirical tests and the experimental design theory, largely applied in the engineering fields, provides the guidelines to do this in a methodological way [25, 3, 8].

The tabu search features introduced above are *treatment factors* (i.e., aspects that are hypothesised to have an effect on the behaviour of the algorithm) and they can be subdivided in two types: quantitative and qualitative. The three qualitative factors are the neighbourhood exploration, the prohibition power and the list dynamics, and consist each of different levels. The quantitative factors are the numerical parameters of the list dynamics strategy and may assume an unlimited number of values. There are two issues that complicate the factorial design: (i) the qualitative parameters do not cross with all other factors (for example, there is no α parameter with Interval list dynamics); (ii) the importance of each of the two qualitative factors strongly depends on the values assigned to the underlying quantitative parameters.

We follow two approaches in the analysis: a *bottom-up* approach consisting in first studying the best configurations of quantitative parameters for each combination of qualitative factors and then analysing the effects of the latter; and a *top-down* approach consisting in analysing the effects of the qualitative factors in a first step and then refining the analysis on the quantitative parameters for the best configuration. Both these approaches have a drawback: the bottom-up approach may require a huge amount of experiments and analysis; the top-down approach may be biased by the few values chosen for the qualitative parameters.

A further issue is the level of the analysis to be undertaken. Clearly discriminating results on single instances is not meaningful in practise; however, both an aggregate analysis and a separated analysis on single classes of instances are relevant for practical applications. We include, therefore, in the case of GRAPH COLOURING six classes of instances³ determined by the type of random graphs (geometric and uniform) and edge density (0.1, 0.5, 0.9). We maintain, instead, the size of the graph fixed to 1000 vertices.

Finally, a matter of concern in the statistical analysis of algorithms is the choice between parametric and non-parametric methods. We opt even in this case for maintaining both approaches. Indeed, being based on two different transformations of the results (normalisation and ranking) the two approaches are likely to produce a different statistical inference. From a theoretical perspective, the parametric analysis of variance through the F -ratio (ANOVA) is a procedure which has been recognised as particularly robust against deviation from the assumption of normal distribution of data [23]. The non-parametric analysis of variance through the Friedman test [9] by ranks is instead grounded on less assumptions but is unable to study interactions between factors.

6 ANALYSIS

We split our analysis in two parts, one for each problem, and we report the results on the two problems separately.

6.1 Graph Colouring

The experimental designs and the values considered for the factors of analysis are reported in Table 2a. We consider the random seed to generate different instances as a blocking factor [10]. The distinction between two designs, \mathcal{D}_A and \mathcal{D}_B , is necessary because of

³ Instances are newly generated using the Culberson's generator available at www.cs.alberta.ca/~joe/Coloring

the different meaning of parameter t_1 . Note that the degenerate case $t_1 = w = 0$ in Interval list dynamics corresponds to a fixed tabu length depending only on the parameter $t_2 = t_b$.

For each algorithmic configuration we collect one run on each instance. The response variable is the minimal number of colours found in a run after 10 million algorithm iterations. In the parametric analysis the number of colours $r(i)$ obtained by each algorithmic configuration on an instance i is normalised by the formula $e(r, i) = \frac{r(i) - r_{best}(i)}{r_{RLF}(i) - r_{best}(i)}$, where r_{best} is the best result achieved on instance i by all algorithms and r_{RLF} is the average solution produced by the RLF heuristic [20], which is used as the starting solution for the tabu search. Therefore, we consider $e(r, i)$ as our response variable. In the non-parametric analysis, instead, results are ranked within instances and no normalisation is needed. A level of significance of 5% is maintained over all the statistical tests.

In the top-down approach we maintain the two designs \mathcal{D}_A and \mathcal{D}_B separated. A parametric analysis of variance (ANOVA) by means of the F -ratio provides a general view of the significant effects. ANOVA assumes a linear model of responses and treatments. We use an automated stepwise model selection based on AIC [1] to distinguish which treatment combinations are significant enough to be included in the model. Accordingly, all main effects and interactions between two factors result significant. The analysis should therefore discriminate too much and this approach is not helpful. It is important to remark however that also the two instance class factors interact with the algorithm factors hence indicating that results might vary between instance classes.

In the bottom-up approach we use a sequential testing methodology for tuning of the parameters t_1 and t_2 . In particular we adopt the RACE algorithm proposed by Birattari [4] based on t -test for multiple comparisons and Holm's adjustment of the p-value. This procedure determines the best t_1 and t_2 for each combination of the other factors and allows to remove the quantitative parameters from the analysis. What remains is a unique design \mathcal{D} of 5 qualitative factors that can be analysed by ANOVA. Interaction with instance type and density is significant and indicates that a fine grained analysis should discriminate among the instance classes. We decide to focus, however, primarily on robust results, i.e., settings that are robust across multiple classes of instances. Hence, simplifying the analysis we remain with 3 algorithmic factors and study their main effects and interactions. In Table 3a and Figure 1 we report the results of this analysis. The most important result, emphasised from the visualisation of the analysis through interaction plots in Figure 1, is the bad performance of the MinConf neighbourhood exploration strategy on the colour. Another ineffective choice is the employment of a Strong prohibition power.

The non-parametric analysis through the Friedman analysis of variance followed by its extension in to multiple comparisons [9] confirms these results. In these tests, the factors studied are the combination of neighbourhood exploration, prohibition power and list dynamics (hence, a unique factor with $3 \times 4 \times 2$ levels) and the instance blocking factor. The conclusions above are recognised by the fact that all levels composed by the MinConf_c neighbourhood exploration strategy or Strong prohibition power are statistically inferior to the others.

6.2 Examination Timetabling

For space limits, we restrict the presentation of results of the bottom-up analysis only. Given the results on the GRAPH COLOURING we consider only the NoRed neighbourhood. The values of the param-

eters tested are shown in Table 2b.

The RACE algorithm is used for the selection of the quantitative parameters. Experiments are carried out on 7 instances taken from Carter's data-set [7]. Each run of a configuration was granted 120 seconds of CPU time on an AMD Athlon 1.5GHz computer running Linux. The outcomes of the RACE procedure are reported in Table 3 that shows the configurations for which no significant difference was found after 50 stages.

Table 3: RACE results for EXAMINATION TIMETABLING

Prohibition power / List dynamics	t_1-t_2	avg $z(r, i)$
Weak/Adaptive	0.3-5 0.5-10 0.5-20 0.3-30	-0.085
Medium/Adaptive	0.3-5 0.8-5 0.3-20 0.5-20 0.8-20	-0.087
Strong/Adaptive	0.3-10 0.5-10 0.5-30	0.010
Weak/Interval	5-5	-0.128
Medium/Interval	5-5 20-25 20-30	-0.084
Strong/Interval	25-25	0.068

Once good values for the parameters have been determined we study main effects and interactions of the two remaining qualitative factors, list dynamics and prohibition power. To this aim, we run a full factorial design collecting 25 replicates per instance. Each experimental unit exploits a different combination of list dynamics, prohibition power and test instance. The result $r(i)$ is the penalty

Main Effects	Pr(> F)	Interaction Effects	Pr(> F)
Prohibition power	0.0669	Prohibition p. List dyn.	0.3738
List Dynamics	0.6896		—

(b) Numerical results of ANOVA on EXAMINATION TIMETABLING

for constraint violation, which has to be minimised. In order to have comparable values across all the tested instances we consider the z-score $z(r, i) = \frac{r(i) - \bar{r}(i)}{s[r(i)]}$ as the response variable in our analysis.

In the analysis of variance instances are treated as blocks and hence their influence on the performance of the algorithms, though recognised, is not taken into account (this entails that the results of the analysis are robust with respect to the set of instances). The results of the F-ratio and the Friedman test indicate as non significant both the main effects and the interactions (The F-ratios are shown in Table 3b, whereas the Friedman test yields a p-value of 0.54).

The visual investigation of results by means of box-plots in Figure 2 reveals indeed that the numerical differences in results are apparently negligible. In conclusion, if the quantitative parameters are well chosen by means of a statistically sound procedure, all configurations of qualitative parameters are equally good.

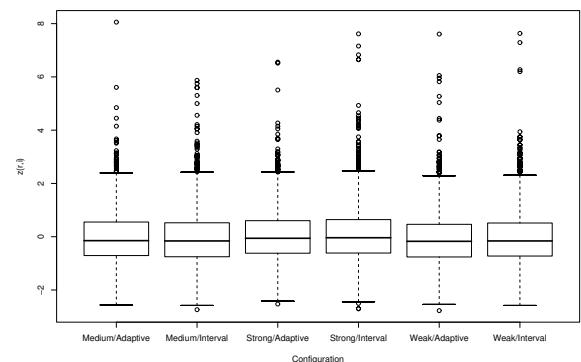

Figure 2: Results of the six configurations for the qualitative features

Finally we compare, in Table 4, our overall best results (in bold) with the currently published ones (see references on the column labels). (The use of best results to infer performance is known in Statistics to be a biased procedure, here however it is justified by the usual practise in the literature.) From Table 4 it is evident that we improved significantly w.r.t. both our previous best results [11] and other results obtained by using similar local search techniques [6]. In addition, although our results are still far from the best results attained by Merlot et al. [21], they are in most cases the second best ones.

Table 4: Best results found for each configuration and comparison with the best known results.

7 RELATED WORK & CONCLUSIONS

This study has been inspired by the works [2] and [19], and by the more recent work [3], which in different ways trace the guidelines for a correct empirical analysis of algorithms. The application of these guidelines to analyse TS features has been proposed in [28]. With respect to these works, we take into consideration also interaction effects between factors and hence remove the bias of a one-feature-at-a-time procedure.

The work in [27] proposes a similar analysis, although it considers specifically the *lesser* used features of TS, whereas we focus on the most used ones. In addition, also that work uses the one-feature-at-a-time approach, thus missing the interactions among them.

We adopted different statistical procedures, such as ANOVA, Friedman test and racing procedures to corroborate the results and guarantee fairness to all TS features. On the GRAPH COLOURING we have been able to discriminate which components of neighbourhood exploration and prohibition power are important to be selected correctly. Less relevant is instead the choice of the tabu length.

On the EXAMINATION TIMETABLING the analysis provides a similar indication to the results found on the GRAPH COLOURING. No significant influence of both main and interaction effects on the qualitative factors considered have been detected. Nevertheless, the analysis permits to improve the tuning of the numerical parameters and improve over previously published configurations. The results of the final algorithm are comparable with the state-of-the-art solvers.

A common conclusion arising in both studies is that, once a good setting has been found for the quantitative parameters, the differences between some of the qualitative parameters are less pronounced.

More features could be added to TS implementations. One example is the case in which the neighbourhood explored is the union of a set of basic neighbourhood relations (see [12]). In this case, typically, there are different tabu dynamics for moves of different sort. Another example, is the use of long term memory or reactive mechanisms. Extending the scope of this analysis to these and similar cases will be the subject of future work.

Random Subset Optimization

Boi Faltings and Quang-Huy Nguyen¹

Abstract. Some of the most successful algorithms for satisfiability, such as Walksat, are based on random walks. Similarly, local search algorithms for solving constraint optimization problems benefit significantly from randomization. However, well-known algorithms such as stochastic search or simulated annealing perform a less directed random walk than used in satisfiability. By making a closer analogy to the technique used in Walksat, we obtain a different kind of randomization called *random subset optimization*. Experiments on both structured and random problems show strong performance compared with other local search algorithms.

1 Introduction

Large combinatorial optimization problems often cannot be solved exactly. Approximations are obtained using *local search*: starting from an initial state, the algorithm makes a sequence of local changes, called *moves*, chosen to improve the quality of the current solution as much as possible. One of the main drawback in this strategy is that it often gets stuck in local optima, where the objective function can only be improved by making changes beyond the neighbours of the current state.

To keep such procedures from getting stuck in local optima, many such algorithms use some form of randomization. The first such process was simulated annealing ([7]), where with some probability *LocalChoice* accepts a move that degrades the objective function. These moves let the search escape from local optima and give it the possibility to restart hillclimbing from a hopefully better starting point. Other algorithms, such as stochastic local search ([2]), randomly allow moves to neighbouring states that only give some, but not necessarily the maximal improvement in the objective function. Purely random moves have the disadvantage that they are not guided towards actually breaking out of a local optimum. An exception are the algorithms for SAT problems, in particular Walksat and its variants ([11, 9]), where only moves that satisfy at least one currently unsatisfied clause are considered. This kind of random walk is more directed towards actually improving some aspect of the solution.

A direct analog to the Walksat strategy for combinatorial optimization would be to randomly choose a part of the optimization function, and make a move that is optimal with respect to this part only. It turns out that this results in a more focussed optimization strategy while retaining the power to escape from local minima. In this paper, we explore this strategy, which we call random subset optimization, in more detail.

2 Definitions

Definition 1 A discrete constraint optimization problem (*COP*) is a tuple $\langle X, D, C, R \rangle$ where:

- $X = \{x_1, \dots, x_n\}$ is a set of variables.
- $D = \{d_1, \dots, d_n\}$ is a set of domains of the variables, each given as a finite set of possible values.
- $C = \{c_1, \dots, c_p\}$ is a set of hard constraints, where c_i is a function $d_{i1} \times \dots \times d_{il} \rightarrow \{0, 1\}$ that returns 1 if the value combination is allowed and 0 if it is not.
- $R = \{r_1, \dots, r_o\}$ is a set of soft constraints, where r_i is a function $d_{i1} \times \dots \times d_{il} \rightarrow \mathbb{R}$ giving the weight of each combination of values.

A solution to a COP is an assignment of values to all variables that satisfies all hard constraints and maximizes (or minimizes) the sum of the soft constraints. We also call the sum of soft constraints the *objective function* of the COP.

Many optimization problems can be formulated as a COP. For example, soft graph coloring can be formulated as a COP where vertices are represented by variables, domains are sets of available colors, and soft constraints correspond to weighted edges of the graph. Another direct example is the weighted Max-SAT problem where the goal is to minimize the sum of unsatisfied clause weights. These problems have all been shown to be NP-complete or NP-hard [4].

The local search framework we assume in this paper is given in Algorithm 1.

Algorithm 1 Local search algorithm for COP

```

procedure LocalSearch( $X, D, C, R$ )
     $\underline{v} \leftarrow SelectInitialSolution(X, D, C, R)$ 
    repeat
         $\underline{v}^{old} \leftarrow \underline{v}$ 
         $x_k \leftarrow ChooseRandom(X)$ 
         $N \leftarrow ChooseNeighbours(x_k, \underline{v}^{old}, X, D, C, R)$ 
         $\underline{v} \leftarrow LocalChoice(N, R)$ 
    until termination condition met
    return  $\underline{v}$ 
end procedure

```

The algorithm starts from a complete assignment of values to all variables, and then proceeds iteratively by local improvements. The initial assignment can be chosen randomly, but must be consistent with the hard constraints. If such a solution is too difficult to find, it may be useful to change some of the hard constraints to soft constraints with high penalty.

Search is governed by an iterative application of two functions. First, function *ChooseNeighbours* provides a set of candidate assignments that are close to the current one and could possibly improve

it. In our implementation, they assignment that are equal to \underline{v} except that they assign a randomly selected variable x_k all other values in its domain that are consistent with the rest of \underline{v} according to the hard constraints. Second, the assignment \underline{v} is updated using the function *LocalChoice*. It chooses a new assignment to optimize the sum of soft constraints in R .

The iteration continues until a termination condition is met, for example when there is no further improvement for some number of steps. To avoid getting stuck in local optima, the performance of a local search procedure is significantly improved by randomization. This means that occasionally *LocalChoice* chooses a value that may even decrease the objective function ([7, 11]).

3 Algorithms

We propose a new algorithm called *random subset optimization* (RSO). In this algorithm, the local choice is made by changing a randomly selected variable x_k . Whenever an improvement of the entire objective function is possible, i.e. the algorithm has not reached a local optimum, it chooses the value for x_k that maximizes the entire objective function R . When the algorithm has reached a local optimum, with some probability p it randomly chooses a subset of the objective function and finds a new value for x_k that only optimizes this part. In this way, the search avoids moves that only degrade the solution and rapidly lead back to the original optimum, and focusses on moves that actually have a chance to break out of it. This technique can be applied whenever the objective function can be decomposed into parts, as for example when it is given as a set of soft constraints.

Algorithm 2 Random subset local search algorithm for COP

```

procedure RSO(X,D,C,R,p,d)
1:  $\underline{v} \leftarrow SelectInitialSolution(X, D, C)$ 
2: repeat
3:    $\underline{v}^{old} \leftarrow \underline{v}$ 
4:    $x_k \leftarrow ChooseRandom(X)$ 
5:    $N \leftarrow ChooseNeighbours(x_k, \underline{v}^{old}, X, D, C, R)$ 
6:   if LocalOptimum( $\underline{v}$ ) then
7:     if random(0..1)  $\leq p$  then
8:        $R \leftarrow ChooseRandomSet(R, d)$ 
9:        $\underline{v} \leftarrow LocalChoice(N, \tilde{R})$ 
10:    else
11:       $\underline{v} \leftarrow ChooseRandom(N)$ 
12:    end if
13:   else
14:      $\underline{v} \leftarrow LocalChoice(N, R)$ 
15:   end if
16: until termination condition met
17: return  $\underline{v}$ 
end procedure

```

Algorithm RSO, shown as Algorithm 2, is a development of Algorithm 1 and introduces two random elements. First, the neighbourhood N is generated by randomly choosing a variable x_k and considering as neighbours all assignments that differ in the value given to that variable. Second, when the algorithm reaches a local optimum, the algorithm chooses with probability p to optimize only for a subset \tilde{R} of the constraints making up the objective function, and with probability $(1 - p)$ to choose a random neighbour regardless of whether it improves the objective function or not. The subset \tilde{R} is chosen by function *ChooseRandomSet* that takes as an additional parameter

d the number of soft constraints that are dropped from the set R . The algorithm terminates when a termination condition is met, for example, when there is no improvement after a certain number of steps, or when a maximum number of steps is reached.

In the experiments we report later, it appears that the best performance is reached when d is small and p is close to 1.

In another variant, called *adaptive* random subset optimization (ARSO), we let the parameter d start with a high value and decrease over time, similarly to the cooling schedule used in simulated annealing. At each value of d , the algorithm performs a linear number of LocalChoice steps w.r.t the number of variables. In our implementation, d is simply reduced by 1 after each iteration. When d decreases below 0, the algorithm terminates.

4 Completeness

The outcome of randomized algorithms cannot be predicted with certainty, and so the notion of completeness cannot be applied directly here. However, Hoos [5] has defined the notion of *probabilistically approximately complete*:

Definition 2 A randomized search algorithm is probabilistically approximately complete (PAC) if for all soluble problem instances, the probability $p(t)$ that it finds the optimal solution in time less than t goes to 1 as t goes to infinity.

Pure random walk strategies, such as picking random values without regard for whether they improve or degrade solution quality, make a local search algorithm PAC: starting with any initial state, there is a sequence of moves that sets each variable x_i to the value it has in an optimal assignment v_i^* , and this sequence of moves has a non-zero probability.

The RSO strategy by itself, reached when the parameter p of Algorithm 2 is set to 1, is clearly not PAC, as there are problems where the optimal assignment \mathbf{v}^* is not reachable by the algorithm at all. This is the case when the optimal assignment is a compromise among all relations, i.e. there is no subset of the relations for which \mathbf{v}^* is also optimal. However, when $p < 1$, the algorithm also performs a random walk with some probability and does become PAC.

5 Experimental results

We evaluated the performance of our algorithms both on structured and unstructured problems. As a structured problem, we chose network resource allocation. As unstructured problems, we chose soft k-coloring and graph coloring optimization on random graphs.

5.1 Network resource allocation problem

The network resource allocation problem consists of allocating tracks in the train network shown in Figure 1 to different operators. To avoid collisions, each arc in the graph can only be allocated to one operator who can then run trains on it. Operators transport goods between nodes in the network. Each transportation task can take one of 3 feasible routes and generates one variable whose domain is the agent and route assigned to it. For example, if task 3 (*London, Manchester*) is assigned to agent a_1 on the route (*London* \rightarrow *Birmingham* \rightarrow *Manchester*), the corresponding variable x_3 is assigned the value ($a_1, \text{London} \rightarrow \text{Birmingham} \rightarrow \text{Manchester}$). The problem is representative of a large class of resource allocation problems, for example in communication networks or in chemical plants.

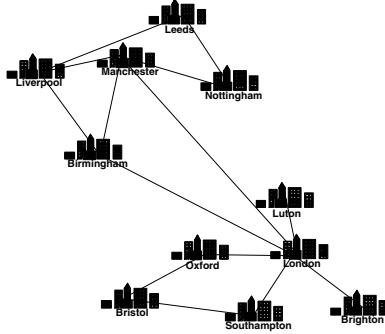

Figure 1. Network of transputers and the structure of individual processes

The network capacity is modelled by binary constraints between any pair of tasks whose routes share at least one arc. The constraint rules out assigning it to such overlapping routes but different agents. Each operator has a different and randomly generated profit margin for being assigned a demand/route combination, and declares these through its relations. These relations are modelled as soft constraints, and the objective is to maximize their sum.

We randomly generated tasks and routes and simulated the problem starting from a situation where no task is assigned to any agent. The number of agents is 30. A set of 100 tasks is generated randomly; for each task, we generate up to 3 different paths for carrying it. We always report the average performance over 100 runs.

In the first experiment, we want to see how the level of randomness affects the performance of the RSO algorithms. Figure 2 shows the average total profit obtained as we varied parameter p from 0 to 1 and kept the number of relations to be left out d always at 1. The shape of this curve does not seem to depend significantly on the value of d . It clearly shows that the performance is best with p close to 1. Thus, in the following experiments, we always set p to 1.

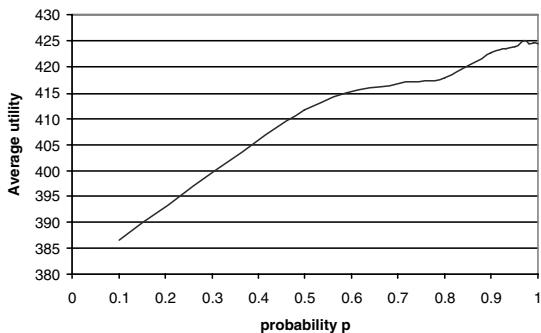

Figure 2. Variation of the average cost of the random subset optimization algorithm on network resource allocation problem, for different values of p .

Next, we are interested in what the best value of parameter d would be for the network resource allocation problem. We run the RSO algorithms with the parameter p set to 1 and with different number of relations to leave out at a local minimum. Figure 3 shows the average solution quality reached in 100 runs. The results show that the best results are obtained for small d . Thus in the following experiments, we always set the parameter p to 1 and d to 2.

To determine whether the RSO algorithms would be efficient for the network resource allocation problems, we compare the perfor-

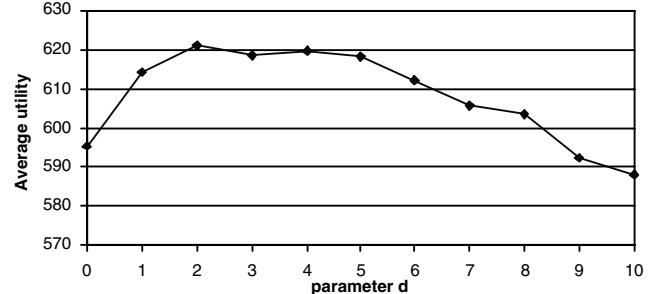

Figure 3. Variation of the average cost of the random subset optimization algorithm on network resource allocation problem, for different values of d .

mance of two versions of the RSO algorithms, RSO for Algorithm 2 with $p = 1, d = 2$ and ARSO for Adaptive RSO, with the following known local search techniques:

- HC: hill-climbing without randomization, included as a baseline comparison. To achieve better results for hill-climbing algorithm, we allow equal moves in the hill-climbing process: the algorithm stops when there is no further improvement for several iterations.
- RHC: hill-climbing with random restarts, similar to the GSAT algorithm [10]. For a fair comparison, we set the parameters so that the total number of iterations is similar to the other algorithms. The hill-climbing stops when there is no improvement for several iterations or the number of iterations exceeds 5 times of the number of variables and is then followed by a restart. The total number of iterations is limited to 2000 as for the other algorithms.
- SA: simulated annealing [7]. The temperature is initialized such that the acceptance rate at the beginning is 97%, and updated according to a geometric cooling schedule with $\alpha = 0.97$; for each temperature value, $n(n - 1)$ search steps are performed, where n is the number of variables. The search is terminated when there is no improvement of the evaluation function for five consecutive temperature values, and the acceptance rate of new solutions falls below 1%.
- SLS: stochastic local search [3, 12]. We tested different versions of the SLS algorithm on the network resource allocation problem and took the best one (corresponding to DSA-B in [12]) with the probability p set to 0.3.

All the algorithms start from an empty assignment, i.e., all the tasks are unassigned. In Figure 4, we show the gain in utility as a function of the number of steps. We observe that ARSO clearly outperforms the other algorithms, while the SA algorithm is slightly better than RSO. However, RSO converges much faster than all other algorithms, and seems to be a clear winner for this application.

5.2 Soft k-coloring

In the next experiment, we considered the soft graph coloring problem also used as a benchmark in [3, 12]. A soft k -coloring problem consists of a graph $G = (V, E)$ where V is the set of vertices and E is the set of edges. Each vertex of the graph can be colored by one of k different colors. Each edge $(u, v) \in E$ is associated with a real valued weight $w(u, v)$. An edge (u, v) is violated if u and v have the same color. Given a number k , the goal is to minimize the sum of the weights of violated edges.

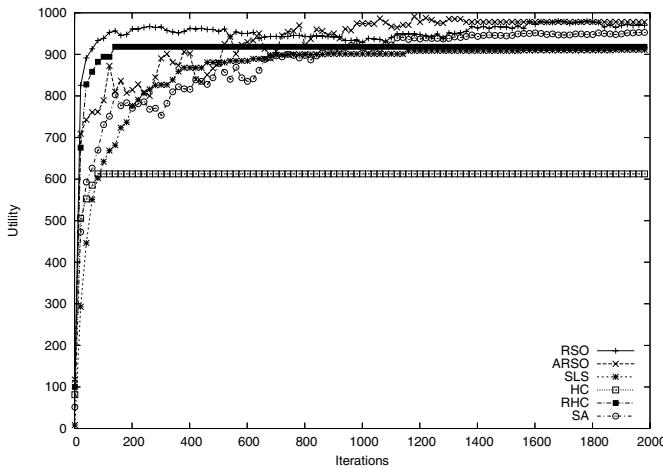

Figure 4. Average utility gain of different local search algorithms on the networks resource allocation problem as a function of the number of steps.

This problem can be modeled as a COP where each vertex is represented as a variable whose domain is the set of available colors. The set of hard constraints is empty. For every edge E in the problem, there is a soft constraint between the variables corresponding to its vertices u and v . It has value $w(u, v)$ if the colors assigned to the corresponding variables are different, and 0 otherwise.

We ran experiments on randomly generated k-coloring problems with 100 vertices and the degree of connectivity is $\approx k + 1$ where k is the number of colors used. We let the algorithms run for a large number of steps until either the overall quality does not improve for $10*n$ steps, or a timeout limit of l steps is reached, where l is variable to indicate the performance of the algorithms. We always report the average performance over 100 runs.

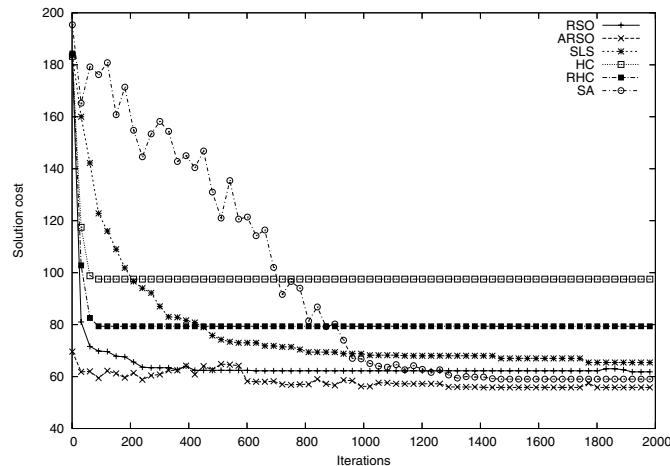

Figure 5. Average solution cost of various optimization algorithms on the soft-k-coloring problem as a function of the number of steps.

Figure 5 shows the results after 2000 iterations. We can observe that SA and RSO eventually reach about the same solution quality, and again ARSO is significantly better than the others. However, RSO converges more than 10 times faster than the SLS and simulated annealing algorithms.

5.3 Coloring graphs with a minimum number of colors

A third set of experiments was carried out on a non-decomposable problem, namely coloring graphs with a minimum number of colors. It involves an unweighted graph $G = (V, E)$ where V is the set of vertexes and E the set of edges. The goal is to find a minimum number of colors to color the vertexes of the graph so that no two vertexes connected by an edge have the same color.

This problem can be modeled as a COP where each vertex is represented as a variable whose domain is the set of available colors, and there is an extra variable x_c that represents a bound on the number of colors used. The hard constraints are that adjacent vertexes must have different colors. There are two types of soft constraints:

- Soft constraint on x_c : the smaller value the better ($cost = x_c$)
- Soft constraints on all variables: the color has to be less than x_c or else there is a penalty of ($cost = 2 * (color - x_c)$). This forces colors to be lower than the maximum number, and is modelled as a soft constraint so that local moves that change only one variable can easily move between consistent assignments.

The initial state is assigned randomly such that all neighbouring nodes have different colors, for example by choosing a different color for every node. The modifications of the variables during the search are chosen so as to continuously satisfy these hard constraints. Note that this is a minimization problem.

We ran the same local search algorithms on random hard 3-coloring problem instances with 100 vertices generated by the procedure of [1]. We started with 10 colors ($x_c = 10$) and set the initial assignment of the COP such that all the vertices have different colors. Figure 6 compares the performance of random subset optimization (RSO) and adaptive random subset optimization (ARSO) with the same algorithms as for the graph coloring problem (HC-hillclimbing without randomization, RHC-hillclimbing with random restarts, SLS-stochastic local search, and SA-simulated annealing). Figure 7 shows the average number of colors used in different local search algorithms.

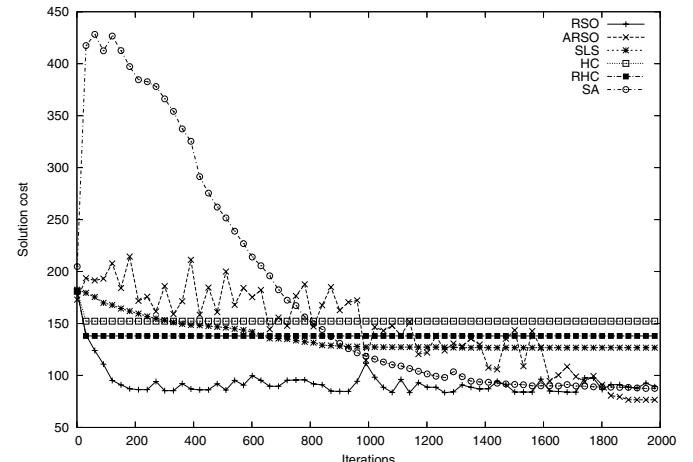

Figure 6. Average solution cost of different local search algorithms on the min-coloring problem as a function of the number of steps.

We can see that among the earlier local search algorithms, only the ARSO algorithm achieves a significant optimization of the number of colors used and thus outperform all other algorithms. RSO and

SA have similar performance. However, RSO converges much faster than the others. This fact was surprising to us, given that we cannot guarantee any completeness result on such a non-decomposable problem.

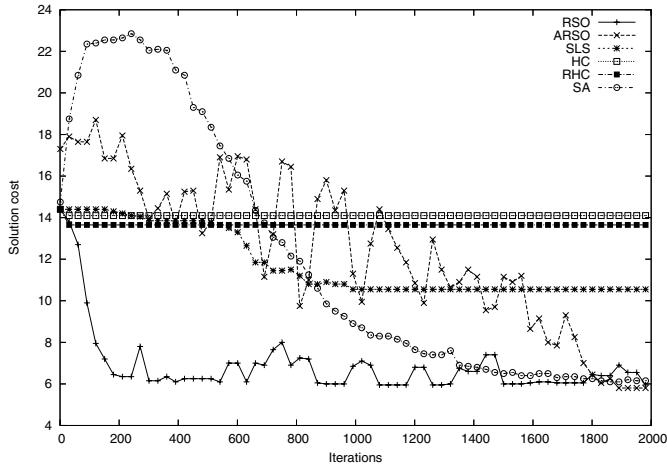

Figure 7. Average number of colors used of different local search algorithms as a function of the number of steps.

One aspect that may appear strange is that in simulated annealing (SA) and adaptive random subset optimization (ARSO), the number of colors appears to be very low in the beginning and only increases gradually. This is explained when considering the evolution of the cost of constraint violations shown in Figure 6. Both algorithms are very tolerant of soft constraint violations, and thus can start with a small limit on the number of colors that is often violated. As the number of constraint violations decreases, both algorithms use more and more colors. Only towards the end does the number of colors decrease while also satisfying the coloring constraints. We also see that the high degree of randomization in these algorithms makes their behavior very unstable initially, so that care must be taken to allow sufficient time for convergence.

5.4 Comparison of computation times

Table 1 shows the running time of the algorithms on the three benchmark problems, using an Intel PC with a 2GHZ clock rate. For RSO, ARSO, HC, RHC, and SLS, the computation times to complete one iteration are similar as they all perform a single local move. Hill-climbing (HC and RHC) often terminate earlier when they reach a local optimum so have shorter run times. The SA algorithm takes significantly longer as it makes many moves at for each temperature value.

Problem	RSO	ARSO	SLS	HC	RHC	SA
NRA	89.01	113.45	96.23	3.53	7.87	1905.73
soft k-coloring	21.25	26.74	14.19	1.06	2.84	352.5
Min-coloring	19.71	25.37	12.43	0.97	2.63	351.32

Table 1. Running times in seconds of different algorithms, for convergence or 2000 iterations.

6 Conclusions

Local search algorithms are often the only possibility to solve large optimization problems. Randomization has been shown to be key to obtaining results that are close to the optimal solution. This strategy has been particularly successful for SAT problems.

For general optimization problems, simulated annealing often achieves the best results, but has the drawback that it converges very slowly. By drawing an analogy with techniques that have been successful for SAT problems, we developed the technique of random subset optimization that empirically converges much faster than known algorithms while obtaining solutions of equal or better quality.

We are now conducting further experiments to determine the influence of different parameters and variations on the performance of the algorithms.

Search for Compromise Solutions in Multiobjective State Space Graphs

Lucie Galand and Patrice Perny¹

Abstract. The aim of this paper is to introduce and solve new search problems in multiobjective state space graphs. Although most of the studies concentrate on the determination of the entire set of Pareto optimal solution paths, the size of which can be, in worst case, exponential in the number of nodes, we consider here more specialized problems where the search is focused on Pareto solutions achieving a well-balanced compromise between the conflicting objectives. After introducing a formal definition of the compromise search problem, we discuss computational issues and the complexity of the problem. Then, we introduce two algorithms to find the best compromise solution-paths in a state space graph. Finally, we report various numerical tests showing that, as far as compromise search is concerned, both algorithms are very efficient (compared to MOA*) but they present contrasted advantages discussed in the conclusion.

1 INTRODUCTION

Traditionally, heuristic search problems in state space graphs are considered in the framework of single objective optimization. The value of a path between two nodes is defined as the sum of the costs of its arcs and the problem amounts to finding one path with minimum cost among all paths from a source node to the goal. This problem is solved by classical constructive search algorithms like A^* [5] which provide, under certain assumptions, the optimal solution-path, using a heuristic function to concentrate the search on the most promising nodes and sub-paths. Thus, during the search, preferences over sub-paths or nodes candidate to development are measured by a scalar evaluation function inducing a complete weak-order over competing feasible paths.

However preferences are not always representable by a single criterion function. Indeed, in many practical search problems considered in Artificial Intelligence (e.g. path planning, game search, preference-based configuration), comparison of solutions includes several aspects or points of view (agents, criteria, scenarios). In such problems, an action allowing a transition from a node to another is evaluated with respect to these different points of view, thus leading to multiple conflicting evaluations non-necessarily reducible to a single overall cost. For this reason, the vector-valued generalization of the initial problem have been investigated and several extensions of the so-called A^* algorithm are now available. Let us mention, among others, MOA* the multiobjective extension of A^* finding all Pareto optimal paths [13] and its recent refinement [9], U* a variation of A^* used to find a maximal path with respect to a multiattribute utility function [2], ABC* to find paths which best satisfy a set prioritized goals [8] and finally preference-based generalizations of MOA* [6] and [10].

As soon as several objectives must be optimized simultaneously, most of the studies concentrate on the determination of the entire set of Pareto optimal solutions (here solution-paths having cost vector that cannot be improved on a criterion without being degraded on another criterion). However, the size of the Pareto set in combinatorial problems being often very large, its determination induces prohibitive response times and requires very important memory space.

Nevertheless, in many contexts, there is no need to determine the entire set of Pareto optimal elements, but only specific compromise solutions within this set. This is particularly the case in multiobjective path-planning problems where the most preferred solution-paths are those achieving a good compromise between various conflicting objective (minimize time, energy consumption, risk, . . .). This is also the case in vector-valued path problems issued from robust optimization. In such problems involving a single cost function, several plausible scenarios are considered, each having a different impact on the costs of transitions between nodes. The aim is to find a *robust path*, that is a path which remains suitable in all scenarios (e.g. the minimax path [7, 11]). In such examples, the type of compromise solution sought in the Pareto set is precisely defined and this can be used to speed up the search.

When preference information is not sufficient to formulate a stable overall preference model, iterative compromise search can still be used to explore the Pareto set. One starts with a “neutral” initial preference model used to generate a well-balanced compromise solution within the Pareto set and the model progressively evolves with feedbacks during the exploration to better meet decision maker’s desiderata. Such an interactive process is used in multiobjective programming on continuous domains to scan the Pareto set which is infinite, see e.g. [12]. The same approach is worth investigating in large size combinatorial problems when complete enumeration of the Pareto set is not feasible.

Motivated by such examples, we consider in this paper multiobjective search problems in state space graphs with a specific focus on Pareto solution-paths achieving a good compromise between the conflicting objectives. After introducing the basic notations and definitions used in the paper, we define formally the compromise search problem in Section 2 and discuss computational issues. In section 3 we recall the basic principles of MOA* and introduce two original algorithms to find the best compromise solution-paths in a state space graph. The first one, called BCA* (Best Compromise A^*), is a variant of MOA* specially designed to focus directly on a target compromise solution. The second one called kA* achieves the same goal while working on a scalarized version of the problem. Section 4 is devoted to the presentation of numerical tests allowing the relative performance of MOA*, BCA* and kA* to be compared, in the determination of the best compromise solution-paths.

2 COMPROMISE SEARCH

We introduce now more formally the framework of multiobjective optimization and compromise search in state space graphs.

2.1 Notations and Definitions

A^* algorithm and its multiobjective extensions look for “optimal” paths (in some sense) in a state space graph $G = (N, A)$ where N is a finite set of nodes (possible states), and A is a set of arcs representing feasible transitions between nodes. Formally, we have $A = \{(n, S(n)), n \in N\}$ where $S(n) \subseteq N$ is the set of all successors of node n (nodes that can be reached from n by a feasible elementary transition). Then $s \in N$ denotes the source of the graph (the initial state), $\Gamma \subseteq N$ the subset of goal nodes and $\mathcal{P}(s, \Gamma)$ denotes the set of all paths from s to a goal node $\gamma \in \Gamma$, and $\mathcal{P}(n, n')$ the set of all paths linking n to n' . We call *solution-path* a path from s to a goal node $\gamma \in \Gamma$. Throughout the paper, we assume that there exists at least one finite length solution path.

We consider a finite number of criteria $v_i : A \rightarrow \mathbb{N}$, $i \in Q = \{1, \dots, q\}$. We assume that v_i 's are cost functions to be minimized. Hence, state space graph G is endowed with a vector valuation function $v : A \rightarrow \mathbb{N}^q$ which assigns to each arc $a \in A$ the cost vector $v(a) = (v_1(a), \dots, v_q(a))$.

For any path P , the vector $p = v(P) = \sum_{a \in P} v(a)$ gives the costs of P with respect to criteria v_i , $i \in Q$ (costs are supposed to be additive). In other words, p is the image of P in the space of criteria \mathbb{N}^q . For any asymmetric dominance relation \succ defined on a set $X \subseteq \mathbb{N}^q$, the set $\{x \in X : \nexists y \in X, y \succ x\}$ is said to be the set of *non-dominated elements in X with respect to \succ* . It is non-empty as soon as \succ is acyclic. We recall now the basic dominance relations and related non-dominated sets used in multiobjective optimization:

Definition 1 The Pareto dominance relation (*P-dominance* for short) on cost-vectors of \mathbb{N}^q is defined by:

$$x \succ y \iff [\forall i \in Q, x_i \leq y_i \text{ and } \exists i \in Q, x_i < y_i]$$

Within a set $X \subseteq \mathbb{N}^q$ any element x is said to be dominated when $y \succ x$ for some y in X , and non-dominated when there is no y in X such that $y \succ x$.

Definition 2 The strict Pareto dominance relation (*SP-dominance* for short) on cost-vectors of \mathbb{N}^q is defined by:

$$x \succ y \iff \forall i \in Q, x_i < y_i$$

Within a set $X \subseteq \mathbb{N}^q$ any element x is said to be strictly dominated when $y \succ x$ for some y in X , and weakly non-dominated when there is no y in X such that $y \succ x$.

Within X the set of P-non-dominated elements (also called the Pareto set) is denoted $ND(X)$ whereas the set of weakly P-non-dominated elements is denoted $WND(X)$. Note that $ND(X) \subseteq WND(X)$ since $x \succ y \Rightarrow x \succ y$ for all $x, y \in \mathbb{N}^q$. For any set $X \in \mathbb{N}^q$, the Pareto set $ND(X)$ is bounded by the ideal point α and the nadir point β with components $\alpha_i = \inf_{x \in ND(X)} x_i = \inf_{x \in X} x_i$ and $\beta_i = \sup_{x \in ND(X)} x_i$, for all $i \in Q$. The multiobjective optimization problem can be stated as follows:

Multiobjective Search Problem. We want to determine the entire set $ND(\{v(P), P \in \mathcal{P}(s, \Gamma)\})$ and the associated solution paths.

This problem is solved by MOA* (see [13]), a vector-valued version of A^* designed to determine the Pareto set in multiobjective problems. Unfortunately, the computation of the whole Pareto set

can be prohibitive in practice due to the size of the Pareto set which grows, in worst case, exponentially with the number of nodes. This can easily be shown by considering the family of instances introduced in [4]:

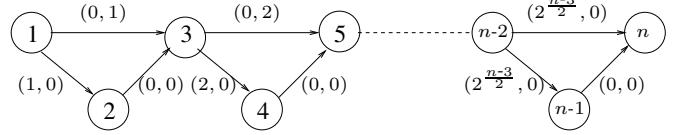

Figure 1. Hansen Graph

In the graph of Figure 1, we have an odd number of nodes n and $2^{\frac{n-1}{2}}$ distinct paths from node 1 to node n , leading to $2^{\frac{n-1}{2}}$ distinct points $(v_1(k), v_2(k)) = (k, 2^{\frac{n-1}{2}} - 1 - k)$, $k \in \{0, \dots, 2^{\frac{n-1}{2}} - 1\}$ in the space of criteria. By construction, these points are on the same line (they all satisfy $v_1(k) + v_2(k) = 2^{\frac{n-1}{2}} - 1$) orthogonal to vector $(1, 1)$; therefore, they are all Pareto optimal. Although pathological, such instances show that the determination of the Pareto set might reveal intractable in practice on large size instances. Numerical tests presented in Section 4 will confirm this point.

Moreover, even when the size of Pareto set is “reasonable”, the great majority of its elements do not provide interesting compromise solutions in practice. For instance, as soon as the criteria are conflicting, which is frequent in practice (e.g. cost vs quality, efficiency vs energy consumption), a path reaching the optimal value with respect to one criterion is often bad with respect to the other criteria. Such a path would not be a good compromise solution, yet it is a Pareto optimal solution. For this reason, it is worth defining more precisely the type of compromise sought in the Pareto set, so as then to focus the search on that type of compromise solution.

2.2 Looking for compromise solutions

A natural attitude to characterize good compromise solutions within the Pareto set is to define a scalarizing function: $s : \mathbb{N}^q \rightarrow \mathbb{R}$ in such a way that the comparison of two paths P and P' represented by performance vectors p and p' reduces to the comparison of scalars $s(p)$ and $s'(p)$. In this respect, one might think that resorting to linear scalarization of type: $s_1(p, \omega) = \sum_{i \in Q} \omega_i p_i$ where ω is a strictly positive weighting vector, is appropriate. Indeed, on the one hand, the path minimizing $s_1(p, \omega)$ over $\mathcal{P}(s, \Gamma)$ can easily be obtained. It is sufficient to scalarize the problem by considering the valuation $w : A \rightarrow \mathbb{R}$ derived from v by setting $w(a) = s_1(v(a), \omega)$ and to apply A^* with valuation w . On the other hand, weighted sum is often seen as a natural aggregator to identify good compromise solutions. Although the first argument (procedural) is perfectly correct, the second is not valid on a non-convex set (which is the case here). The point is that minimizing s_1 over the set of solution paths can only reach *supported solutions*, i.e. those P-non-dominated solutions lying on the boundary of the convex hull of the points representing feasible solution-paths in the space of criteria. Hence there might exist feasible paths achieving a very well-balanced compromise solution that cannot be obtained by optimizing $s_1(p, \omega)$, whatever the choice of the weighting vector ω . This problem, well known in multiobjective optimization, is illustrated by Example 1.

Example 1 Consider the bicriteria problem illustrated in Figure 2. In this graph, we have 4 paths from 1 (source node) to 4 (goal node): $P_1 = \langle 1, 2, 4 \rangle$, $P_2 = \langle 1, 2, 3, 4 \rangle$, $P_3 = \langle 1, 3, 4 \rangle$ and $P_4 = \langle 1, 3, 2, 4 \rangle$ with $v(p_1) = (20, 2)$, $v(p_2) = (12, 11)$, $v(p_3) = (3, 19)$ and $v(p_4) = (16, 15)$.

The graph to the right in Figure 2 represents the image of these solution-paths in the space of criteria. However we have $s_1(p_1, \omega) = 20\omega_1 + 2\omega_2$, $s_1(p_2, \omega) = 12\omega_1 + 11\omega_2$, $s_1(p_3, \omega) = 3\omega_1 + 19\omega_2$ and $s_1(p_4, \omega) = 16\omega_1 + 15\omega_2$. Since s_1 is to be minimized, P_1 is optimal when $\omega_1 < \omega_2$, P_3 is the optimal solution-path when $\omega_2 < \omega_1$ and both P_1 and P_3 are optimal when $\omega_1 = \omega_2$. We can notice that P_2 and P_4 cannot be optimal, whatever the choice of ω_1 and ω_2 . Although this is quite justified for P_4 which is P -dominated by P_2 this is problematic for P_2 which is clearly the best compromise solution path in this example. This is due to the fact that P_2 lies inside the convex hull of solutions (the grey triangle) and not on the boundary.

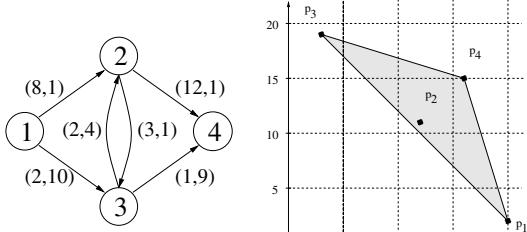

Figure 2. A bicriteria problem and its representation in the space of criteria

A better way of defining the notion of compromise solution for a solution-path P is to consider the distance between $p = v(P)$ and a prescribed reference vector r (representing ideal performances, or DM's aspirations levels). This leads to formulate the following scalarizing function:

$$s(p, r, \omega) = \| \omega \cdot (p - r) \|_{\infty} = \max_{i \in Q} \{ \omega_i |p_i - r_i| \}$$

in which ω is a weighting vector. The choice of Tchebycheff norm focus on the worst component and therefore guarantees that only feasible solutions close to reference point r on every component will receive a good score. This promotes well-balanced solutions. It also implies that iso-preference curves of type $s(x, r, \omega) = k$, for fixed r, ω and k , perfectly match P -dominance cones, which implies two important properties on any subset $X \subseteq \mathbb{N}^q$ (see [15]):

P1. If $\forall i \in Q, \omega_i > 0$, then all solutions x minimizing $s(x, r, \omega)$ over the set X of feasible cost vectors belongs to $WND(X)$. Moreover at least one of these solutions belongs to $ND(X)$.

P2. If $r > \alpha$ then for all $x \in ND(X)$ there exist strictly positive weights $\omega_i, i \in Q$ such that x is the unique solution minimizing $s(x, r, \omega)$ over X .

Property P1 shows that minimizing s yields well-balanced Pareto optima located in the set $ND(X) \cap S(X) \neq \emptyset$ where $S(X) = \arg \min_{x \in X} s(x, r, \omega)$. Property P2 shows that any type of compromise solution can be obtained within the Pareto set, with the appropriate choice of parameters r and ω . This second property explains why s , as a scalarizing function, is preferred to s_1 in multiobjective optimization on non-convex sets [15, 12].

We define normalization weights as follows $\omega_i = \delta_i / (\beta_i - \alpha_i)$, for all $i \in Q$ where $[\alpha_i, \beta_i]$ represents the range of possible values for criterion i in the subarea of interest. Optimizing s generates a weakly non-dominated path as close as possible to reference point r for the weighted Tchebycheff metric. Weights used in the metric can possibly be modified via coefficients δ_i so as to give more importance to some criteria. Function s induces a new dominance relation \succ_s on \mathbb{N}^q , defined by $x \succ_s y \Leftrightarrow s(x, r, \omega) < s(y, r, \omega)$ which means that x is a better compromise than y .

As mentionned in the introduction, compromise search can be seen as an interactive process. Initial parameters of function s are initially chosen so as to focus on the center of the Pareto set but are dedicated

to evolve during the interactive exploration using standard updating techniques [12]. To save space, we now concentrate on the main technical difficulty: the fast generation on the s -optimal path at a given step. This leads to the compromise search problem.

2.3 The compromise search problem

Compromise Search Problem. We want to determine all P -non-dominated s -optimal feasible cost-vectors (i.e. $ND(X) \cap S(X)$ with $X = \{v(P), P \in \mathcal{P}(s, \Gamma)\}$) and the associated solution-paths.

Coming back to Example 1, with $r = (0, 0)$ and $\omega = (1, 1)$ we get: $s(p_1, r, \omega) = 20$, $s(p_2, r, \omega) = 12$, $s(p_3, r, \omega) = 19$ and $s(p_4, r, \omega) = 16$. Hence the preferred compromise according to \succ_s is P_2 with cost-vector $p_2 = (12, 11)$ which seems quite natural here. Moreover, sub-paths from node 1 to node 3 are P with cost $p = (11, 2)$ and P' with $p' = (2, 10)$. Since $p' \succ_s p$ the locally best compromise-path at node 3 is P' . However, appending path $P'' = \langle 3, 4 \rangle$ with cost $p'' = (1, 9)$ to P and P' respectively yields $p + p'' = (12, 11)$ and $p' + p'' = (3, 19)$, so that $p' + p'' \prec_s p + p''$, a preference reversal. Notice that the optimal path $P_2 = P \cup P''$ would be lost during the search if P is pruned at node 3 due to P' . Although the dominance relation \succ_s is much more discriminating than P -dominance \succ , which should improve pruning possibilities and fasten the search, this example shows that the determination of s -optimal solutions presents a new difficulty: we cannot construct a s -optimal path from s -optimal sub-paths. In other words, the Bellman principle [1] does not hold. Moreover, the compromise search problem is NP-hard. This can easily be derived from a result of Yu and Yang in [16] which proves that the Robust Deviation Shortest Path problem (RDSP for short) is NP-hard. In RDSP the goal is indeed to determine solution-paths minimizing function: $s(p, r) = \max_{i \in Q} \{ |p_i - r_i| \}$. Optimizing our function $s(p, r, \omega)$ with equal weights $\omega_i, i = 1, \dots, q$ clearly reduces to RDSP.

3 ALGORITHMS

Knowing that solutions of the compromise search problem lie in the Pareto set, we first recall how Pareto-optimal paths are generated by MOA* algorithm.

3.1 Using MOA* for compromise search

Algorithm MOA* is a heuristic search algorithm generating all efficient paths of G . It relies on the same foundations than A^* , adapted to the field of vector-valued evaluation. In particular, the Bellman principle holds: any s -to- k subpath of a P -non-dominated solution-path, is P -non-dominated in $\mathcal{P}(s, k)$. Hence, the algorithm constructs incrementally the P -non-dominated solution-paths from Pareto optimal subpaths. Let us briefly recall some essential features of MOA* (for more details, see [13]).

In a graph valued by cost-vectors, there possibly exists several P -non-dominated paths to reach a given node. Hence, at each detected node n , one stores a set $G(n)$ of cost-vectors $g(n)$ corresponding to the valuations of P -non-dominated paths, among the set of already detected path arriving in n . Thus, $G(n)$ is an approximation of the set $G^*(n)$ of all P -non-dominated cost vectors of paths in $\mathcal{P}(s, n)$. Moreover, the algorithm uses a vector-valued heuristic. Since a path arriving at node n can be continued with different incomparable subpaths to reach Γ , a set $H(n)$ of heuristic cost-vectors $h(n)$ is assigned to each node n . Thus, $H(n)$ is an approximation

of $H^*(n)$, the set of all P-non-dominated cost vectors of paths in $\mathcal{P}(n, \Gamma)$. As in A^* , already detected nodes of the graph are partitioned, at any step of the search, in two sets called OPEN (non-expanded nodes) and CLOSED (already expanded nodes able to be expanded again). During the search, for any open node n , the set $F(n) = \text{ND}(\{g(n) + h(n) : g(n) \in G(n), h(n) \in H(n)\})$ is computed from all possible combinations $f(n) = g(n) + h(n)$. Such vectors are called the *labels* of node n . Thus $F(n)$ is a set of labels (vectors) approximating the set $F^*(n)$ of all P-non-dominated cost-vectors containing node n .

The principle of the search is, at the current step, to expand a node n in OPEN such that $F(n)$ contains at least one P-non-dominated label among the labels of open nodes. The process is kept running until all open labels are either P-dominated by another label at the same node or by a vector solution-path already detected. It ensures to generate all efficient paths in $\mathcal{P}(s, n)$ provided heuristic H is admissible, i.e. $\forall n \in N, \forall h^* \in H^*(n), \exists h \in H(n) \text{ s.t. } h \succ h^*$.

Knowing that s -optimal solutions are also P-non-dominated solutions, the best compromise solution-path with respect to the Tchebycheff criterion s should be sought within the Pareto set. Hence, a straightforward way of determining best compromise solutions is 1) use MOA* to generate the Pareto set, and 2) determine the s -optimal solutions in the output of MOA*. Such a two-stages procedure should not be very efficient in practice due to the size of the Pareto set. For this reason, we introduce now two algorithms aiming at directly focusing on good compromise solutions.

3.2 BCA*

BCA* is a variant of MOA* aiming at finding a best compromise path, i.e. a solution-path P minimizing $s(v(P), r, \omega)$ over $\mathcal{P}(s, \Gamma)$ for a predefined r and ω . The basic principle is to work on P-non-dominated sub-paths while managing a current upper-bound λ to store the value $s(v(P), r, \omega)$ of the best compromise path P among already detected paths.

A preliminary stage consists of performing q monodimensional optimizations (one per criterion) with A^* so as to get one optimal path P^i for each criterion $i \in Q$. If $p^i = v(P^i)$ for all i , the ideal point α is given by: $\alpha_i = p^i$ for all $i \in Q$. The nadir point β is difficult to find in practice because the Pareto set is not known [3]. For this reason we use a classical approximation obtained by setting: $\beta_i = \max_{j \in Q} p_j^i$ for all $i \in Q$, whichs allows to compute weights $\omega_i = \delta_i / (\beta_i - \alpha_i)$, $i \in Q$. Then the choice of a given reference point r specifying the target in the space of criteria completely defines function s (by default choose r close to α , see property P2). Then the value of λ is initialized to $\lambda_0 = \min\{s(p^i), i \in Q\}$. Hence the main features of BCA* are:

Output: the best compromise solution-paths according to s .

Principle: as in [9], we expand labels (attached to subpaths) rather than nodes. We distinguish g -labels (without heuristic h) from f -labels (those used in MOA*). The search is totally ordered by function s . Thus, for any open node n and any f -label in $F(n)$ we compute the score $s(f(n))$ and we expand one of the f-labels having minimal score (the more promising compromise subpath).

Pruning: We use the following pruning rules: 1) at node n , we prune any subpath with a g -label P-dominated by the g -label of another subpath at the same node n . 2) we prune any subpath P at node n if its f -label $f(n)$ is such that $s(f(n)) > \lambda$. This second rule allows an early elimination of subpaths that cannot lead to the best compromise solutions. These rules are justified by the following proposition:

Proposition 1 $\forall x, y \in \mathbb{N}^q, x \succ y \Rightarrow x \succ_s y$. Moreover $\forall x, y, z \in \mathbb{N}^q, (x \succ_s y \text{ and } y \succ z) \Rightarrow x \succ_s z$.

Indeed, during the search, if a subpath P is P-dominated by another subpath P' at the same node n according to g -labels, any extension of P will be P-dominated by the same extension of P' , and therefore s -dominated. Similarly, if a subpath P is such that $f(v(P)) > \lambda = v(P^*)$, P^* being the best already detected solution-path, any extension of P will also be s -dominated by P^* .

Heuristics: we use any admissible heuristic that can be used in MOA*. In particular, we do not need to require that for all nodes n , $H(n)$ contains at least one perfectly informed label, as it is done to justify U^* [14].

Stopping condition: Each time a node of Γ is reached with a new path P such that $\lambda > s(v(p), r, \omega)$, the bound λ is updated. The algorithm is kept running until all open labels of type $f(n)$ satisfy $s(f(n)) > \lambda$. Termination obviously derives from the termination of MOA*. In worst case, BCA* performs the same enumeration as MOA* and finds the best compromise at the last step. Of course, in average, BCA* stops much earlier, as we shall see in the next section.

3.3 kA*

The second algorithm, called kA*, relies on the enumeration of k best paths in a scalarized version G' of the multiobjective graph G . Scalarization is obtained by considering the valuation $w : A \rightarrow \mathbb{R}$ derived from v by setting $w(a) = s_1(v(a), \omega)$ for all $a \in A$ (linear aggregation of criteria). Hence, any path P initially valued by a vector $p \in \mathbb{N}^q$ is now valued by the scalar cost $w(P) = s_1(p, \omega)$. Actually, using function s_1 is interesting even if its optimization does not provide directly compromise solutions. The point is that s -optimal solutions often achieve a good performance according to s_1 . Hence, we propose to enumerate solution-paths in G by increasing order of s_1 , which amounts to enumerating solution-paths in G' by increasing order of w . During enumeration, the s -optimal path can be identified thanks to the following proposition:

Proposition 2 $\forall x, y \in \mathbb{N}^q, s_1(y, \omega) > s_1(\bar{x}_\omega, \omega) \implies s(y, r, \omega) > s(x, r, \omega) \text{ with } \forall i \in Q, \bar{x}_{\omega_i} = r_i + \frac{1}{\omega_i} s(x, r, \omega)$.

Indeed, denoting P^1, \dots, P^j the first solution-paths in the enumeration, we have $s_1(p^1, \omega) \leq \dots \leq s_1(p^j, \omega)$. Suppose that P^j is the first of these paths satisfying $s_1(p^j, \omega) > s_1(p_\omega^*, \omega)$ where $p^* = \arg \min_{i=1, \dots, j} s(p^i, r, \omega)$ is the cost of the current best path P^* , then proposition 2 implies that all forthcoming paths $P^k, k > j$ in the enumeration will satisfy $s(p^k, r, \omega) > s(p^*, r, \omega)$. Therefore P^* is the best compromise solution-path with respect to s and we can stop the enumeration. Hence the main features of kA* are:

Output: the best compromise solutions according to s .

Principle: The ordered enumeration of best paths according to s_1 can easily be performed using a modified version of A^* that works on labels attached to paths instead of labels attached to nodes. More precisely, to any detected path $P_{s,n}^i$ from s to n , we assign a label of type $f^i(n) = g^i(n) + h(n)$ where $g^i(n) = w(P_{s,n}^i)$ and $h(n)$ is the value of an admissible heuristic function at node n ($\forall n \in N, h(n) \leq h^*(n)$ where $h^*(n)$ is the cost of the optimal path in $\mathcal{P}(n, \Gamma)$). Hence, we have as many labels at a given node n as detected sub-paths from s to n . Here $G(n)$ (resp. $F(n)$) denotes the set of g -labels (resp. f -labels) of detected sub-paths from s to n . So we have $F(n) = \{f^i(n) = g^i(n) + h(n), g^i(n) \in G(n)\}$. At node n , $f^{(i)}(n)$ denotes the i^{th} smallest value in $F(n)$. At the current step, we expand the label $f^{(1)}(n) = \min_{t \in \text{OPEN}} f^{(1)}(t)$. Since $f^{(1)}(n)$ is also the best current f -label in $F(n)$, there is no need to expand

another label of $F(n)$ before the best solution-path corresponding to $f^{(1)}(n)$ is developed. Therefore n is put in CLOSED. If n is a goal node then the k^{th} path P^k is found. In this case, for all nodes t along P^k , we delete the label $f^{(1)}(t)$ in $F(t)$. In order to expand the new $f^{(1)}$ -label of these nodes, we set all these nodes t in OPEN. If $s(p^k, r, \omega) < s(p^*, r, \omega)$ (where p^* is the best detected cost vector) and we set $P^* \leftarrow P^k$.

Heuristics: any type of admissible scalar-valued heuristic, e.g., any h derived by linear scalarization of an admissible heuristic used in MOA* since s_1 is strictly monotonic with respect to P-dominance.

Stopping condition: thanks to proposition 2, path enumeration is kept running until a solution-path P^k such that $s_1(p^k, \omega) > s_1(\bar{p}_\omega^*, \omega)$ (where P^* is the best current path) is detected.

4 EXPERIMENTATIONS

Numerical experiments have been performed to compare the three solutions discussed in the paper for compromise search: MOA*(completed with the determination of s -optimal solutions in the Pareto-set) BCA* and kA*. The computational experiments were carried out with a Pentium IV with 2.5GHz processor. Algorithms were implemented in C++. We first present result on randomly generated instances and then on pathological instances.

Randomly generated graphs. We relate here results obtained by executing algorithms on randomly generated graphs. The number of nodes in these graphs varies from 200 to 1,000 and the number of arcs from 7,500 (for 200 nodes) to 200,000 (for 1,000 nodes). Cost vectors are randomly determined for each arc. In practice, good admissible heuristics depend on the application domain. Independently of the context, we can generate admissible heuristic for tests, by setting $H(n) = \mu(n)H^*(n)$ for vector valued optimization, where $\mu(n)$ is a randomly generated number within the unit interval at node n . For kA*, the heuristic is obtained from the previous one by linear scalarization. Table 1 presents the average execution times (in second) obtained by the three algorithms for different class differing by the size of instances (number of nodes, number of criteria). In each class, average times are computed over 50 different instances. Symbol “-” means that execution time exceeds one hour.

Table 1. Execution time (s) on Random Graphs

#obj.	MOA*			BCA*			kA*		
	5	10	20	5	10	20	5	10	20
200	0.1	8.2	583	0	0	0.1	0	0	2.2
500	3.3	506	-	0.1	0.3	1.5	0.1	0.3	4.5
800	8.3	-	-	0.2	1.1	7.9	0.3	1.1	5.7
1,000	15.2	-	-	0.2	1.6	13	0.7	1.2	6.3

These results show that BCA* and kA* determine the s -optimal solution paths significantly faster than MOA*. Indeed, for a graph containing more than 500 nodes and 10 criteria, MOA* requires more than one hour to generate the s -optimal solutions whereas BCA* and kA* need some seconds. We see that the sophistication proposed in BCA* really speed-up the search of the best compromise solutions. Moreover, we can notice that BCA* is slightly faster than kA* when the size of the graph is small, but kA* outperforms BCA* as the size of the instance increases.

Hansen graphs. Now, algorithms are compared on Hansen graphs (Figure 1). All feasible paths in this family of graphs are P-non-dominated. Then MOA* generates all solution-paths. Since for any path P in Hansen's family, we have $s_1(\bar{p}_\omega^*, \omega) > s_1(p, \omega)$ (where P^* is the best compromise path), kA* generates all feasible paths too. Table 2 summarizes execution times obtained on these graphs.

Table 2. Execution time (s) on Hansen Graphs

#nodes	MOA*	BCA*	kA*
21	0.01	0	0
25	3.1	1.1	0
29	70.2	25.5	0.15
33	1147	427.9	0.61

These results show the advantage of resorting to a scalarized version of the graph. Indeed kA* reveals very efficient when the number of P-non-dominated paths is important, because scalarization avoids numerous Pareto-dominance tests.

5 CONCLUSION

We have introduced two admissible algorithms to determine the best compromise paths in multivalued state space graphs. Although they produce the same solutions, BCA* is based on a focused exploration of the Pareto-set in a multiobjective space while kA* solves the same problem by working on a scalarized version of the graph. As expected, tests confirm that the two approaches are much more efficient than explicit enumeration of the Pareto set to solve the compromise search problem. An advantage of the approach used in kA* is that it applies to any other multiobjective problem, provided the scalar version can be solved efficiently. Both algorithms perform a fast generation of the best current compromise solution and could be incorporate into an interactive exploration procedure of the Pareto set.

MINION: A Fast, Scalable, Constraint Solver¹

Ian P. Gent² and Chris Jefferson³ and Ian Miguel²

Abstract. We present MINION, a new constraint solver. Empirical results on standard benchmarks show orders of magnitude performance gains over state-of-the-art constraint toolkits. These gains increase with problem size – MINION delivers *scalable* constraint solving. MINION is a general-purpose constraint solver, with an expressive input language based on the common constraint modelling device of matrix models. Focussing on matrix models supports a highly-optimised implementation, exploiting the properties of modern processors. This contrasts with current constraint toolkits, which, in order to provide ever more modelling and solving options, have become progressively more complex at the cost of both performance and usability. MINION is a black box from the user point of view, deliberately providing few options. This, combined with its raw speed, makes MINION a substantial step towards Puget’s ‘Model and Run’ constraint solving paradigm.

1 Introduction

Constraint programming supports the solution of combinatorial problems in two stages. First, by characterising or *modelling* them by a set of constraints on decision variables that their solutions must satisfy. Second, by searching for *solutions* with a constraint solver: assignments to the decision variables that satisfy all constraints. The success of constraint programming is based upon its flexibility and expressivity; constraints provide a rich language allowing most problems to be expressed straightforwardly once the model is selected.

Modern constraint solving techniques are typically provided to users in the form of constraint toolkits. These are libraries for programming languages such as C++ (e.g. ILOG Solver, GeCode), Java (e.g. Choco, Koalog) or Prolog (e.g. Eclipse, Sictus). This approach supports a high degree of customisation. For example, it is usually possible for users to add propagation rules for an as-yet undefined constraint to the library. When such additions prove to be generally useful, they are often included in future versions of the popular constraint toolkits. Hence, as Puget pointed out [20], constraint toolkits have become increasingly complex in an effort to provide ever more functionality. The result is that constraint programming for large, realistic problems requires a great deal of expertise and fine tuning. Furthermore, to provide this flexibility,

toolkits have a necessarily complex internal architecture. This results in large overheads in many parts of the solver, with a detrimental effect on efficiency and scalability.

Puget suggests that today’s constraint toolkits are far too complex to achieve widespread acceptance and use [20]. He advocates a ‘model and run’ paradigm for constraints similar to that achieved by propositional satisfiability (SAT) and mathematical programming (MP). Our hypothesis is that we can achieve this by taking two important steps. The first step is to supply constraint *solvers* (instead of toolkits) that accept *models* rather than *programs*. These solvers should be black boxes that reduce the bewildering array of options provided by constraint toolkits to a select few. Furthermore, the reliance of constraint programming on heavy fine tuning to achieve an acceptable level of performance is in conflict with ‘model and run’. The second step is therefore to create *fast* constraint solvers that promote implementation efficiency. Efficiency in turn will reduce the sensitivity of performance to minute parameter changes. Fast solvers will also be more *scalable* to large constraint problems. This methodology follows the closely-related fields of propositional SAT and MP where solvers scale to very large problems, and where ‘model and run’ is absolutely standard.

To test our hypothesis, we have built a fast and scalable constraint solver, named MINION. Throughout, MINION has been optimised for solving *large* and *hard* problems. Experimental results show that MINION typically runs between 10 and 100 times faster than state-of-the-art constraint toolkits such as ILOG Solver and GeCode on large, hard problems. On smaller problems or instances where solutions are found with little search, gains are less impressive. MINION takes an expressive input language for matrix models over integer domains, allowing a variety of fundamental constraints such as all-different, sum, reification, and others. A number of our design decisions are modelled on those of zChaff, which revolutionised modern SAT solving [23]. In particular, we paid special attention to using very small data structures, making memory usage very small and greatly increasing speed on modern computer architectures.

2 Background

A *constraint satisfaction problem* (CSP [3]) is a set of decision variables, each with an associated domain of potential values, and a set of constraints. An *assignment* maps a variable to a value from its domain. Each constraint specifies allowed combinations of assignments of values to a subset of the variables. A *solution* is an assignment to all the variables that satisfies all the constraints. A *constrained optimisation problem* is a

CSP with an objective function, which must be optimised.

We focus on systematic search for solutions in a space of assignments to subsets of the variables. We use constraint *propagation* algorithms that make inferences, recorded as domain reductions, based on the domains of the variables constrained and the assignments that satisfy the constraint.

MINION uses a language based upon *matrix models*, i.e. CSP formulations employing one or more matrices of decision variables, with constraints typically imposed on the rows, columns and planes of the matrices. To illustrate, consider the *Balanced Incomplete Block Design* (BIBD, CSPLib problem 28), which is defined as follows: Given a 5-tuple of positive integers, $\langle v, b, r, k, \lambda \rangle$, assign each of v objects to b blocks such that each block contains k distinct objects, each object occurs in exactly r different blocks and every two distinct objects occur together in exactly λ blocks. The matrix model for BIBD has b columns and v rows of 0/1 decision variables. A ‘1’ entry in row i , column j represents the decision to assign the i th object to the j th block. Each row is constrained to sum to r , each column is constrained to sum to k and the scalar product of each pair of rows is constrained to equal λ . Matrix models have been identified as a very common pattern in constraint modelling [6] and support, for example, the straightforward modelling of problems that involve finding a function or relation — indeed, one can view the BIBD as finding a relation between objects and blocks.

3 Modelling in MINION

MINION’s input language is simple yet expressive enough to model the majority of problems without resorting to complex and expensive modelling devices. Critically, we include a range of the most important non-binary constraints as primitives. We do not go so far as restricting the input language to (for example) binary constraints in extensional form, which is sufficient to express any CSP. Reformulation into binary constraints can lead to weaker propagation and far more search.

MINION has four variable types. These are: 0/1 variables, which are used very commonly for logical expressions, and for the characteristic functions of sets; Bounds variables, where only the upper and lower bounds of the domain are maintained; Sparse Bounds variables, where the domain is composed of discrete values, e.g. $\{1, 5, 36, 92\}$, but only the upper and lower bounds of the domain are updated during search; and Discrete variables, where the domain ranges from the lower to upper bounds specified, but the deletion of any domain element in this range is permitted. (A fifth type, of Discrete Sparse variables, is not yet implemented.) Sub-dividing the variable types in this manner affords the greatest opportunity for optimisation, as we will see. MINION’s input language supports the definition of one, two, and three-dimensional matrices of decision variables (higher dimensions can be created by using multiple matrices of smaller dimension). Furthermore, it provides direct access to matrix rows and columns since most matrix models impose constraints on them.

The input language for MINION is detailed in Figure 1. The set of primitive constraints provided by MINION is small but expressive. It includes necessities such as *equality*, *disequality*, *inequality*, *sum*, *product*, and *table* (extensional form) but also global constraints that have proven particularly useful as reported in the literature over several years, such as

Figure 1. Syntax of MINION input. Although some non-terminals are unexpanded, their meanings should be clear.

all-different [21] and *occurrence*. We include the crucial *element* constraint, which allows one to specify an element of a vector using the assignment to a decision variable. This is often useful when *channelling* between matrix models [2]. Logical expressions are supported by using 0/1 variables with the *min* (conjunction), *max*, *sum* (both disjunction) and inequality (implication) constraints. *Reification* is to assign the satisfaction (1) or unsatisfaction (0) of a given constraint to a 0/1 decision variable. Since this decision variable can participate as normal in other constraints this adds significant expressive power to the language. We include the *lexicographic ordering* constraint, which has been shown to be a cheap and effective way to exclude much of the symmetry in a matrix model [8]. The current version of MINION uses ‘watched literals’ to implement the element, table, and 0/1 sum constraints. We believe this to be an important innovation, but we describe it in detail elsewhere [12]. MINION allows only static variable and value ordering heuristics. Dynamic heuristics could be implemented, but are currently omitted to avoid unnecessary overheads when *not* being used. The only design decisions taken for reasons of time were the omission of the global cardinality constraint, and that MINION’s all-different performs the same propagation that a clique of not-equals constraints would (though far faster). The implementation of some propagators in MINION is simplified by the use of views [22], which allow complex propagation algorithms to be built from simpler ones by applying simple transformations to the variables of the constraint.

MINION deliberately does not allow arbitrary operator nesting. Most toolkits support this feature by adding hidden decision variables to ‘flatten’ the input. For example, $x_1 * x_2 + x_3 = x_4$ might become $h_1 = x_1 * x_2$, $h_2 = h_1 + x_3$ and $h_2 = x_4$. The flattening scheme is often inaccessible to the user, and may not be optimal. Expecting pre-flattened input has two important consequences. First, it simplifies the input language. Second,

the user is not forced to use a flattening scheme chosen by us, but can choose one most appropriate to the model. Removing this layer of hidden variables is especially important with the advent of automated constraint modelling systems such as CONJURE [9] that, in order to choose among candidate models, need maximum control over the final model.

4 Architecture and Design of MINION

Our principal challenge was to develop a constraint solver that is optimised to the same degree as those found in SAT (e.g. zChaff [23]) and mathematical programming (e.g. CPLEX [14]). A main design principle is compactness. This lets us take advantage of modern cache-based hardware architectures, which has paid substantial dividends in the SAT community [25]. Further, modern processors attempt to execute many instructions in parallel, and so branching, indirection and the use of offsets should be avoided where possible, as they can stall this parallel execution. Many design decisions were made after extensive code profiling. For example, profiling shows that there are many more calls to access variable domains than there are to change them. We thus optimise data structures for variables to make access fast at the expense of slower domain updates, even where this conflicts with keeping data structures small.

This section includes ideas we believe to be novel. It also includes description of numerous implementation techniques, not contributions to knowledge in themselves, which are important in obtaining our fast running times. MINION is the experimental apparatus with which we are testing our overall hypothesis, that fast constraint solvers can be built. It is thus essential that MINION is described in detail, so that our work can be scientifically judged and also reproduced and built on. In this spirit, we have made MINION open source, and it is available at <http://minion.sourceforge.net>.

Variable representation: Variables' values have to be restored on backtracking, so the smaller the space they occupy, the less work has to be done. Also, a smaller block of memory is more likely to fit into L2 cache on a modern CPU, greatly increasing access speed. In each of the four types of variable, storage is split into two: a *backtrackable* and a *non-backtrackable* part. This reduces backtrackable memory usage, and thus the amount of work on backtracking. To the best of our knowledge, these representations are novel.⁴

We use two bits to store the state of a 0/1 variable's domain. However, it is unnecessary to restore both bits on backtracking. Bit 1 indicates whether the variable is assigned. Bit 2 gives the value *if it is assigned*. Before search, bit 1 is 0 and bit 2 is arbitrary. When the variable is assigned, bit 1 is set to 1, while bit 2 is given the correct value. When backtracking past this point, we reset bit 1 to 0, but do not restore bit 2. Bit 2's value is irrelevant until the variable is reassigned, when it will be set to 0 or 1 irrespective of its current value. Hence, we maintain k 0/1 variables by saving and restoring a block of just k bits at each choice point. In non-backtrackable memory, we store the second block of k bits.

Next, consider bounds variables. Suppose a variable is declared with non-sparse bounds $[lb, ub]$. We store the initial

lower bound lb in non-backtrackable memory. In backtrackable memory we store the current bounds relative to lb , initialised to $[0, ub - lb]$. The amount of backtrackable memory required is therefore twice the smallest C++ type which will store the initial domain size $ub - lb$. For sparse bounds variables, the storage in backtrackable memory is identical. In non-backtrackable memory, we store an array containing the initial domain. When, say, a request is made to increase the lower bound, we undertake a binary search for the smallest allowed value which is greater than or equal to the new bound, and the backtrackable lower bound is set to this value.

For discrete variables, we store in backtrackable memory (as is conventional) one bit per value, indicating whether or not the value is still in the domain. We also store the current lower and upper bounds of the domain similarly to bounds variables. This redundant storage conflicts with our key principle of minimising backtrackable memory, but is justified because many constraints check only the bounds of domains. For example, by profiling we found that Choco can spend 33% of its time finding the bounds of domains. Our technique also lets us optimise updating the bounds of discrete domains: we do *not* take the linear time required to zero the relevant parts of the bit array. Instead, we adapt the check for domain membership. The bit array is only checked if the domain value is between the upper and lower bounds, so bits outside that range are irrelevant. This slightly improves the speed of domain checks when the value proves to be outside the current range, but slows down those where it is in range. Bit arrays are stored in blocks of 8, 16, 32, or 64 bits as these can be efficiently stored and accessed while reducing wasted space.

Finally, MINION implements a special constant variable type, which is assigned a single value and uses no backtrackable memory. For most constraints in MINION, the compiler is able to optimise code using this variable type as efficiently as an implementation of the constraint designed to take advantage of the fact the variable is known to be constant.

Memory Management: Variables of each type are stored together in backtrackable memory. For example, all Boolean variables are stored in a single bit array. Thus, 1,088 Boolean variables would need 136 bytes of backtrackable memory. Boolean variables are accessed during search with three values computed at initialisation: two pointers to the words containing the bit in backtrackable and non-backtrackable memory, and a mask that contains a 1 at the relevant bit position in those words and is otherwise 0. This lets us access the relevant bits in a small number of machine instructions. Other variable types are compressed similarly. For example, on CPUs with 64-bit words, each word stores the domains of four discrete domain variables with 16 values, with lower and upper bounds stored elsewhere in backtrackable memory. After backtrackable variables, we allocate storage for backtrackable data needed by constraint propagators. We have blocks of space for binary flags, integers up to 255, up to 65,535, and unstructured space for backtrackable data not in one of these forms. By design, we have minimised the fragmentation in this memory map, although this leads to an initialisation overhead. We allocate space in two passes: first we place variables arbitrarily, but when all variables and constraints have been constructed, we then rearrange memory as described above.

State restoration on backtracking is simple. At a choice point, we copy the entire block of backtrackable memory.

⁴ It remains possible that some have escaped our notice in publications or simply used in solvers not described in publications.

When we return to that point, we copy the entire archived copy over the active backtrackable memory. Block copying is sped up considerably because all backtrackable memory is allocated together and because we have minimised the size of backtrackable memory so much. In our preliminary investigations memory copy did not rise above 7% of runtime. In BIBD experiments we report below, as much as 750 MB of backtrackable memory was copied per second. This shows both the capabilities of modern processors, and also the importance of keeping memory sizes small. We could save 50% of memory copies by redirecting all pointers to the stored copy on backtracking, saving the memory copy on backtracking. However, this would not let us use fixed pointers for each variable. We trade extra copying against reduced pointer arithmetic. Many techniques can reduce the amount of memory changed on backtracking, e.g. dancing links [17], but we have not found one that repays even low time overheads.

Low-level Optimisations: Most MINION constraints accept any variable type. Traditionally such functions are implemented via virtual function calls, which select the correct function at run-time based on the variable type. Instead, we generate a copy of the constraint at compile-time for each variable type using C++ templates. The compiler can then optimise each constraint for each variable type, inlining small domain access methods and avoiding run-time branches depending on variable type. On the $\langle 7, 315, 135, 3, 45 \rangle$ BIBD for example, compiling each constraint for the Boolean type provides a fourfold speed-up. This method limits the number of variable types per constraint. For example, the lexicographic ordering constraint allows only one variable type per input vector to avoid exponential explosion in the copies of the constraint that must be compiled. This limitation is not serious. In most CSPs each constraint contains only one or two variable types — but we do provide a fall-back implementation of each constraint for arbitrary combination of types via virtual function calls. While the compiler optimises each constraint for different variable types, it may not be able to perform all possible optimisations. For example when the lower bound of a Boolean variable changes, the variable must now be assigned 1, but the compiler does not identify this. We have identified and implemented optimisations for some such special cases.

MINION constraints contain pointers to the locations of their variables in memory. This uses more memory than storing this information once globally for each variable, and initialisation requires storing the locations of all references to variables as the problem is constructed. This accounts for the higher initialisation cost of MINION than, say, ILOG Solver, but allows extremely fast variable access during search.

5 Empirical Analysis

We show that MINION outperforms state-of-the-art constraint solvers (ILOG Solver, Eclipse and GeCode), and scales to much larger instances. We consider a portfolio of instances from diverse, challenging problem classes: a satisfaction problem (BIBD), two optimisation problems (Steel Mill Slab Design [11] and Golomb Rulers [4]) and a fixed-length planning problem (English Peg Solitaire [16]). Our goal was to compare raw search speed on identical models.

We compared implementations in each system of the same model: that of the BIBD described earlier, for Steel Mill and Peg Solitaire the basic models from the cited papers, and for

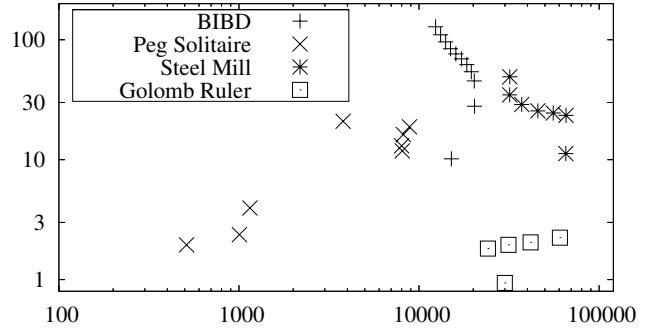

Figure 2. MINION Backtracks/Sec. (x axis) vs Speedup against ILOG Solver (y axis) on four problem classes

Golomb a basic model using simple all different propagation. We used straightforward implementations in each solver of the chosen model, with the same static variable and value orderings in each case.⁵ Our generators for MINION instances are part of the source distribution. We used revision r170 of MINION, ILOG Solver 5.3, and GeCode 1.1.0. Experiments ran under Windows XP SP2, on a Pentium 4 3GHz with 2GB RAM, compilation being done using g++ 3.4.4 under cygwin (and Visual C++ for Solver.) We omit detailed results for Eclipse, as it was slower than ILOG Solver in each case.

Figure 2 and Table 1 summarise our results. These show that MINION is faster and much more scalable than other state-of-the-art solvers. Our results show particularly dramatic improvements on large constraint problems requiring a lot of search. MINION ran faster than ILOG Solver on every instance except the smallest Golomb Ruler instance ($n = 7$), which both solved in less than 0.02sec. Our least impressive gains are on the Golomb Ruler, which are small problems, where we were 1.8 times as fast on the largest instance we tested ($n = 11$). Speedups were also relatively low on the simplest Solitaire instances. These result from MINION’s greater initialisation time, a part of its design which has not been optimised highly but which is important for instances requiring more search. On Solitaire instances where MINION needs at least 2sec. to solve, it is at least 10 times faster than Solver. For very large instances where much search is required, MINION’s speedup reaches 128 for the largest BIBD instance and 49 for the largest Steel Mill instance. Where we compared against GeCode, results were similar except that GeCode was usually faster than ILOG Solver. Again we were faster on each Golomb instance but $n = 7$, but gains were even more marginal here, e.g. a negligible 2.9% on $n = 11$. However, Table 1 shows increasing speedups with problem size on BIBD instances, up to 51 times on the largest we tested.

It is possible that greatly improved runtimes might be obtained in GeCode or Solver using the flexibility that each toolkit provides. Non-optimal behaviour on some instances goes hand-in-hand with using the ‘model and run’ methodology, so we should point out some of its advantages. First, improvements in *modelling* can be duplicated in MINION. Other improvements might require significant expertise in the relevant toolkit, such as implementing specialised constraints or heuristics. Second, a 10-fold speedup obviates the need for much optimisation. For example, finding five independent op-

⁵ We were unable to compare GeCode and MINION directly on the Steel Mill and Peg Solitaire problems because of the differing modelling facilities offered by each system at the time of writing.

timisations to reduce run time by a third is less effective than a 10-fold speedup since $\frac{2}{3}^5 > \frac{1}{8}$. Finally, by making MINION open source, we are helping other researchers either to implement key techniques in MINION, or to use our insights to improve their own solvers or toolkits.

6 MINION and Modelling Languages

Although MINION’s input language is expressive, by design it is free from syntactic sugar to aid human modellers. The intention is that it will be used with constraint modelling languages that prioritise expressing models naturally. One popular example is the *Optimization Programming Language* (OPL [24]). We believe that building an OPL to MINION translator will be straightforward. In cases such as set variables, which OPL has but MINION does not, encodings into more primitive variables are well known [15]. By a similar process, translators to MINION could also be written for other constraint modelling languages, such as Constraint Lingo [5] and EaCL [18]. The abstract constraint modelling languages ESRA [7] and F [13], which support relation and function variables respectively, have translators to OPL. This supports a two-stage translation to MINION, given an OPL to MINION translator. NP-SPEC [1] also supports abstract decision variables, such as sets, permutations, partitions and functions. Currently NP-SPEC specifications are translated into SAT. This translator could be modified to produce MINION models instead.

MINION should combine very well with the CONJURE automated modelling system. Given an abstract specification of a constraint problem in the ESSENCE language [10], a set of rules can formalise the generation of alternative models [9]. These rules are embedded in CONJURE, which *refines* an ESSENCE specification into an ESSENCE’ model. ESSENCE’ is a generic constraint language, straightforwardly translated into the input for ILOG Solver, Eclipse, or MINION. Although alternative models can be produced automatically, there is as yet no mechanism for model selection in CONJURE. Model selection must consider both model *and* solver. Given the transparent nature of MINION – without hidden modelling as discussed in Section 3 – model selection should be significantly simpler.

7 Conclusion and Future Work

MINION is a strong platform for future constraints research in modelling and solving. Once constraint modelling languages interface to it, researchers should be able to get a much better idea of how well a particular model performs, without fear of failing to exploit a given toolkit optimally. We have

described a methodology for building fast and scalable constraint solvers. While we chose a particular feature set and optimised accordingly, similar design principles should help to build very different solvers: for example, fast and scalable solvers using backjumping [19] and learning.

Asynchronous Forward-Bounding for Distributed Constraints Optimization ¹

Amir Gershman and Amnon Meisels and Roie Zivan ²

Abstract.

A new search algorithm for solving distributed constraint optimization problems (*DisCOPs*) is presented. Agents assign variables sequentially and propagate their assignments asynchronously. The asynchronous forward-bounding algorithm (*AFB*) is a distributed optimization search algorithm that keeps one consistent partial assignment at all times. Forward bounding propagates the bounds on the cost of solutions by sending copies of the partial assignment to all unassigned agents concurrently. The algorithm is described in detail and its correctness proven. Experimental evaluation of *AFB* on random *Max-DisCSPs* reveals a phase transition as the tightness of the problem increases. This effect is analogous to the phase transition of *Max-CSP* when local consistency maintenance is applied [3]. *AFB* outperforms Synchronous Branch & Bound (*SBB*) as well as the asynchronous state-of-the-art *ADOPT* algorithm, for the harder problem instances. Both asynchronous algorithms outperform *SBB* by a large factor.

1 Introduction

The Distributed Constraint Optimization Problem (*DisCOP*) is a general framework for distributed problem solving that has a wide range of applications in Multi-Agent Systems and has generated significant interest from researchers [12, 18]. Distributed constraints optimization problems (*DisCOPs*) are composed of agents, each holding its local constraints network, that are connected by constraints among variables of different agents. Agents assign values to variables and communicate with each other, attempting to generate a solution that is globally optimal with respect to the costs of constraints between agents (cf. [12, 14]).

Distributed *COPs* are an elegant model for many every day combinatorial problems that are distributed by nature. Take for example a large hospital that is composed of many wards. Each ward constructs a weekly timetable assigning its nurses to shifts. The construction of a weekly timetable involves solving a constraint optimization problem for each ward. Some of the nurses in every ward are qualified to work in the *Emergency Room*. Hospital regulations require a certain number of qualified nurses (e.g. for Emergency Room) in each shift. This imposes constraints among the timetables of different wards and generates a complex Distributed COP [16, 2].

Several distributed search algorithms for *DisCOPs* have been proposed in recent years [17, 12, 14]. The present paper proposes a new distributed search algorithm for *DisCOPs*, *Asynchronous Forward-Bounding* (*AFB*). In the *AFB* algorithm agents assign their variables

sequentially to generate a partial solution. The innovation of the proposed algorithm lies in propagating partial solutions asynchronously. Propagation of partial solutions enables asynchronous updating of bounds on their cost, and early detection of a need to backtrack, hence the algorithm's name - Asynchronous Forward Bounding.

The overall framework of the *AFB* algorithm is based on a *Branch and Bound* scheme. Agents extend a partial solution as long as the lower bound on its cost does not exceed the global bound, which is the cost of the best solution found so far. In the proposed *AFB* algorithm, (similar to the *AFC* algorithm for *DisCSPs* [11]) the state of the search process is represented by a data structure called *Current Partial Assignment* (*CPA*). The *CPA* starts empty at some initializing agent that records its assignments on it and sends it to the next agent. The cost of a *CPA* is the accumulated cost of constraints involving the value assignments it contains. Each agent which receives the *CPA*, adds assignments of its local variables such that the *CPA*'s cost will not exceed the global upper bound. If it cannot find such assignments, it backtracks by sending the *CPA* to the last assigning agent, requesting it to revise its assignment.

The innovation of the *AFB* algorithm lies in the asynchronous use of the *CPAs* by the participating agents. An agent that succeeds to extend the assignment on the *CPA* sends forward copies of the updated *CPA*, requesting all unassigned agents to compute lower bound estimations on the cost of the partial assignment (*PA*). The assigning agent will receive these estimations asynchronously over time and use them to update the lower bound of the *CPA*. Using these bounds, the assigning agent can detect if any extension of this partial assignment into a complete assignment will cause it to exceed the global upper bound, and in such cases it will backtrack. Backtracking is performed by creating a new *CPA*, a clone of the previous one, and sending it to the last assigning agent, to have that assignment replaced. A time stamp mechanism for forward checking in *DisCSPs* is used by agents to determine the most updated *CPA* and to discard obsolete *CPAs* (cf. [13]).

The concurrency of the *AFB* algorithm is achieved by the fact that forward-bounding is performed concurrently and asynchronously by all agents.

The *AFB* algorithm is described in detail in Section 3 and its correctness is proven in Section 4. The performance of *AFB* is compared to that of Synchronous Branch and Bound (*SBB*) and *ADOPT* on randomly generated *DisCOPs*. *AFB* outperforms *SBB* as well as the best asynchronous optimization algorithm *ADOPT* by a large factor, on the harder instances of random problems. This is true for two measures of distributed performance: the number of non concurrent steps of computation and the total number of messages sent (see section 5). A phase transition for problems of very high tightness is observed for *AFB*, similarly to the one that is reported for extended local consistency maintenance on *Max-CSPs* [3, 4].

2 Distributed Constraint Optimization

A distributed constraint optimization problem (*DisCOP*) is composed of a set of **agents** A_1, \dots, A_n , each holding a set of constrained **variables**. Each variable X_i has a **domain** D_i - a set of possible values. **Constraints** (or relations) exist between variables. Each constraint involves some variables (possibly belonging to different agents), and defines a non-negative **cost** for every possible value combination of these variables. A **binary constraint** is a constraint involving only two variables. An **assignment** (or a label) is a pair including a variable, and a value from that variable's domain. A **partial assignment** (PA) is a set of assignments, in which each variable appears at most once. The **cost of a partial assignment** is computed using all constraints that involve only variables that appear in the partial assignment. Each such constraint defines some cost for the value assignments detailed in the partial assignment. All these costs are accumulated, and the sum is denoted as the cost of the partial assignment. A **full assignment** is a partial assignment that includes all the variables. A **solution** to the *DisCOP* is a full assignment of minimal cost.

A widely used special case of *DisCOPs* is to use a cost of 1 unit for each broken (unsatisfied) constraint. This type of problem is termed *Max-DisCSPs*, in accordance with *Max-CSPs* for the centralized case [3, 6]. In this paper, we will assume each agent is assigned a single variable, and use the term “agent” and “variable” interchangeably. We will assume that constraints are at most binary and the delay in delivering a message is finite. Furthermore, we assume a static final order on the agents, known to all agents participating in the search process. These assumptions are commonly used in *DisCSP* and *DisCOP* algorithms [17, 12]. For the experimental section we used *Max-DisCSPs* [3, 12]. *Max-DisCSPs* are a special class of *DisCOPs* in which all costs of binary constraints are exactly one.

3 Asynchronous Forward Bounding - AFB

In the *AFB* algorithm a single most up-to-date current partial assignment is passed among the agents. Agents assign their variables only when they hold the up-to-date *CPA*. The *CPA* is a unique message that is passed between agents, and carries the partial assignment that agents attempt to extend into a complete and optimal solution by assigning their variables on it. The *CPA* also carries the accumulated cost of constraints between all assignments it contains, as well as a unique time-stamp.

Only one agent performs an assignment on a *CPA* at a time. Copies of the *CPA* are sent forward and are concurrently processed by multiple agents. Each unassigned agent computes a lower bound on the cost of assigning a value to its variable, and sends this bound back to the agent which performed the assignment. The assigning agent uses these bounds to prune sub-spaces of the search-space which do not contain a full assignment with a cost lower than the best full assignment found so far.

More specifically, every agent that adds its assignment to the *CPA* sends forward copies of the *CPA*, in messages we term *FB_CPA*, to all agents whose assignments are not yet on the *CPA*. An Agent receiving an *FB_CPA* message computes a lower bound on the cost increment caused by adding an assignment to its variable. This estimated cost is sent back to the agent who sent the *FB_CPA* message via *FB_ESTIMATE* messages. The following two paragraphs describe how exactly this estimation is computed.

Denote by $\text{cost}((i, v), (j, u))$ the cost of assigning $A_i = v$ and $A_j = u$. For each agent A_i and each value in its domain $v \in D_i$, we denote the minimal cost of the assignment (i, v) incurred by an agent

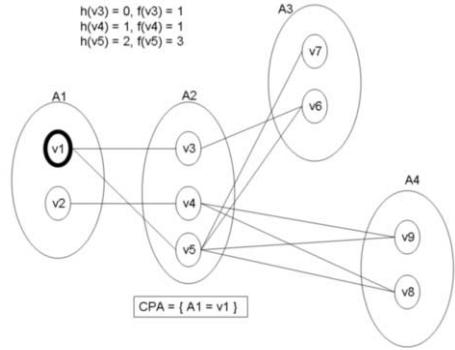

Figure 1. A simple DisCOP, demonstration

A_j by $h_j(v) = \min_{u \in D_j} (\text{cost}((i, v), (j, u)))$. We define $h(v)$, the total cost of assigning the value v , to be the sum of $h_j(v)$ over all $j > i$. Intuitively, $h(v)$ is a lower bound on the cost of constraints involving the assignment $A_i = v$ and all agents A_j such that $j > i$. Note that this bound can be computed once per agent, since it is independent of the assignments of higher priority agents.

An agent A_i , which receives an *FB_CPA* message, can compute for every $v \in D_i$ both the cost increment of assigning v as its value, i.e. the sum of the cost of conflicts v has with the assignments included in the *CPA*, and $h(v)$. The sum of these, is denoted by $f(v)$. The lowest calculated $f(v)$ among all values $v \in D_i$ is chosen to be the lower bound estimation of agent A_i .

Figure 1 presents a constraint network, in which A_1 already assigned the value v_1 and A_2, A_3, A_4 are unassigned. Let us assume that the cost of every constraint is one. The cost of v_3 will increase by one due to its constraint with the current assignment thus $f(v_3) = 1$. Since v_4 is constrained with both v_8 and v_9 , assigning this value will trigger a cost increment when A_4 performs an assignment. Therefore $h(v_4) = 1$ is an admissible lower bound of the cost of the constraints between this value and lower priority agents. Since v_4 does not conflict with assignments on the *CPA*, $f(v_4) = 1$ as well. $f(v_5) = 3$ because this assignment conflicts with the assignment on the *CPA* and in addition conflicts with all the values of the two remaining agents.

Since $h(v)$ takes into account only constraints of A_i with lower priority agents (A_j s.t. $j > i$), unassigned lower priority agents do not need to estimate their cost of constraints with A_i . Therefore, these estimations can be accumulated and summed up by the agent which initiated the forward bounding process to compute a lower bound on the cost of a complete assignment extended from the *CPA*. Asynchronous forward bounding enables agents an early detection of partial assignments that can not be extended into complete assignments with cost smaller than the known upper bound, and initiate backtracks as early as possible.

The *AFB* algorithm is run on each of the agents in the *DisCOP*. Each agent first calls the procedure *init* and then responds to messages until it receives a *TERMINATE* message. The algorithm is presented in Figure 2

3.1 Algorithm description

The algorithm starts by each agent calling **init** and then awaiting messages until termination. At first, each agent updates B to be the cost of the best full assignment found so far and since no such assignment was found, it is set to infinity (line 1). Only the first agent (A_1) creates an empty *CPA* and then begins the search process by

```

procedure init:
1.  $B \leftarrow \infty$ 
2. if ( $A_i = A_1$ )
3.   generate_CPA()
4.   assign_CPA()

```

when received (**FB_CPA**, A_j , PA)

```

5.  $f \leftarrow$  estimation based on the received  $PA$ .
6. send (FB_ESTIMATE,  $f$ ,  $PA$ ,  $A_i$ ) to  $A_j$ 

```

when received (**CPA_MSG**, PA)

```

7.  $CPA \leftarrow PA$ 
8.  $TempCPA \leftarrow PA$ 
9. if  $TempCPA$  contains an assignment to  $A_i$ , remove it
10. if ( $TempCPA.cost \geq B$ )
11.   backtrack()
12. else
13.   assign_CPA()

```

when received (**FB_ESTIMATE**, estimate, PA , A_j)

```

14. save estimate
15. if ( $CPA.cost + \text{all saved estimates} \geq B$ )
16.   assign_CPA()

```

when received (**NEW_SOLUTION**, PA)

```

17.  $B\_CPA \leftarrow PA$ 
18.  $B \leftarrow PA.cost$ 

```

procedure **assign_CPA**:

```

19. clear estimations
20. if  $CPA$  contains an assignment  $A_i = w$ , remove it
21. iterate (from last assigned value) over  $D_i$  until found
     $v \in D_i$  s.t.  $CPA.cost + f(v) < B$ 
22. if no such value exists
23.   backtrack()
24. else
25.   assign  $A_i = v$ 
26.   if  $CPA$  is a full assignment
27.     broadcast (NEW_SOLUTION,  $CPA$ )
28.      $B \leftarrow CPA.cost$ 
29.     assign_CPA()
30.   else
31.     send(CPA_MSG,  $CPA$ ) to  $A_{i+1}$ 
32.     forall  $j > i$ 
33.     send(FB_CPA,  $A_i$ ,  $CPA$ ) to  $A_j$ 

```

procedure **backtrack**:

```

34. clear estimates
35. if ( $A_i = A_1$ )
36.   broadcast(TERMINATE)
37. else
38.   send(CPA_MSG,  $CPA$ ) to  $A_{i-1}$ 

```

Figure 2. The procedures of the AFB Algorithm

calling **assign_CPA** (lines 3-4), in order to find a value assignment for its variable.

An agent receiving a CPA (when received **CPA_MSG**), first makes sure it is relevant. The time stamp mechanism suggested by [13] is used to determine the relevance of the **CPA**.

If the CPA's time-stamp reveals that it is not the most up to date

CPA, the message is discarded. In such a case, the agent processing the message has already received a message implying that an assignment of some agent which has a higher priority than itself, has been changed. When the message is not discarded, the agent saves the received PA in its local CPA variable (line 7). Then, the agent checks that the received PA (without an assignment to its own variable) does not exceed the allowed cost B (lines 8-10). If it does not exceed the bound, it tries to assign a value to its variable (or replace its existing assignment in case it has one already) by calling **assign_CPA** (line 13). If the bound is exceeded, a backtrack is initiated (line 11) and the CPA is sent to a higher priority agent, since the cost is already too high (even without an assignment to its variable).

Procedure **assign_CPA** attempts to find a value assignment, for the current agent, within the bounds of the current CPA. First, estimates related to prior assignments are cleared (line 19). Next, the agent attempts to assign every value in its domain it did not already try. If the CPA arrived without an assignment to its variable, it tries every value in its domain. Otherwise, the search for such a value is continued from the value following the last assigned value. The assigned value must be such that the sum of the cost of the CPA and the lower bound of the cost increment caused by the assignment will not exceed the upper bound B (lines 20-22). If no such value is found, then the assignment of some higher priority agent must be altered, and so backtrack is called (line 23). Otherwise, the agent assigns the selected value on the CPA.

When the agent is the last agent (A_n), a complete assignment has been reached, with an accumulated cost lower than B , and it is broadcast to all agents (line 27). This broadcast will inform the agents of the new bound for the cost of a full assignment, and cause them to update their upper bound B .

The agent holding the CPA (A_n) continues the search, by updating its bound B , and calling **assign_CPA** (line 29). The current value will not be picked by this call, since the CPA's cost with this assignment is now equal to B , and the procedure demands the cost to be lower than B . So the agent will continue the search, testing other values, and backtracking in case they do not lead to further improvement.

When the agent holding the CPA is not the last agent (line 30), the CPA is sent forward to the next unassigned agent, for additional value assignment (line 31). Concurrently, forward bounding requests (i.e. **FB_CPA** messages) are sent to all lower priority agents (lines 32-33).

An Agent receiving a forward bounding request (when received **FB_CPA**) from agent A_j , again uses the time-stamp mechanism to ignore irrelevant messages. Only if the message is relevant, then the agent computes its estimate (lower bound) of the cost incurred by the lowest cost assignment to its variable (line 5). The exact computation of this estimation was described above (it is the minimal $f(v)$ over all $v \in D_i$). This estimation is then attached to the message and sent back to the sender, as a **FB_ESTIMATE** message.

An agent receiving a bound estimation (when received **FB_ESTIMATE**) from a lower priority agent A_j (in response to a forward bounding message) ignores it if it is an estimate to an already abandoned partial assignment (identified using the time-stamp mechanism). Otherwise, it saves this estimate (line 14) and checks if this new estimate causes the current partial assignment to exceed the bound B (line 15). In such a case, the agent calls **assign_CPA** (line 16) in order to change its value assignment (or backtrack in case a valid assignment cannot be found).

The call to **backtrack** is made whenever the current agent cannot find a valid value (i.e. below the bound B). In such a case, the agent clears its saved estimates, and sends the CPA backwards to agent A_{i-1} (line 38). If the agent is the first agent (nowhere to backtrack

to), the terminate broadcast ends the search process in all agents (line 36). The algorithm then reports that the optimal solution has a cost of B , and the full assignment with such cost is B_CPA .

4 Correctness of AFB

In order to prove correctness for *AFB* two claims must be established. First, that the algorithm terminates and second that when the algorithm terminates its global upper bound B is the cost of the optimal solution. To prove termination one can show that the *AFB* algorithm never goes into an endless loop. To prove the last statement it is enough to show that the same partial assignment cannot be generated more than once.

Lemma 1 *The AFB algorithm never generates two identical CPAs.*

Assume by negation that A_i is the highest priority agent (first in the order of assignments) that generates a partial assignment *CPA* for the second time. The replacement of an assignment can only be triggered by one of two messages arriving at A_i from a lower priority agent A_j ($j > i$). Either a backtrack *CPA* message, or a *FB_ESTIMATE* message. In the first case the next assignment on the *CPA* will be generated by the procedure *assign_CPA*. Each of the values in the domain of A_i is considered exactly once. When the agent's domain is exhausted the agent backtracks and under the above assumption will never receive the same partial assignment again. If the received message is an estimate that clashes with the upper bound (e.g. the second case), a new *CPA* is generated. The generated *CPA* is a clone of the last *CPA* the agent received from a higher priority agent. Only values which were not considered on the previous *CPA* are left in its current domain. Therefore, the situation with the new *CPA* is similar to the first case.

Termination follows immediately from Lemma 1.

Next we prove that on termination, the complete assignment, corresponding to the optimal solution is in B_CPA (see Figure 2). There is only one point of termination for the *AFB* algorithm, in procedure *backtrack*. So, one needs to prove that during search no partial assignment that can lead to a solution of lower cost than B is discarded. But, this fact is immediate, because the only place in the code where values are discarded is in the third line of procedure *assign_CPA* (line 21). Within this procedure, values are discarded only when the calculated lower bound of the value being considered is higher than the current bound on the cost of a global solution. Clearly, this cannot lead to a discarding of a lower cost global solution.

One still needs to show that whenever the algorithm calls the procedure *assign_CPA*, it does not loose a potential lower cost solution. There are altogether 4 places in the algorithm, where a call to procedure *assign_CPA* is made. One is in procedure *init*, which is irrelevant. The three relevant calls are in the code performed when receiving a *CPA* or receiving a *FB_ESTIMATE*, and in the procedure *assign_CPA* itself.

The third case is trivially correct. Before calling the procedure the global bound B is updated and the corresponding complete solution is stored. Consequently, the current solution is not lost. The first two calls (see Figure 2) appear in the last lines of the procedures processing the two messages. When processing a *FB_ESTIMATE* message, the call to *assign_CPA* happens after the lower bound of the current value has been tested to exceed the global bound B (line 15). This is correct, since the current partial solution cannot be extended to a lower cost solution. The last call to *assign_CPA* occurs in the last line of processing a received *CPA* message. Clearly, this

call extends a shorter partial solution and does not discard a value of the current agent. This completes the correctness proof of the *AFB* algorithm.

5 Experimental Evaluation

All experiments were performed on a simulator in which agents are simulated by threads which communicate only through message passing. The Distributed Optimization problems used in all of the presented experiments are random *Max-DisCSPs*. *Max-DisCSP* is a subclass of *DisCOP* in which all constraint costs (weights) are equal to one [12]. The network of constraints, in each of the experiments, is generated randomly by selecting the probability p_1 of a constraint among any pair of variables and the probability p_2 , for the occurrence of a violation (a non zero cost) among two assignments of values to a constrained pair of variables. Such uniform random constraints networks of n variables, k values in each domain, a constraints density of p_1 and tightness p_2 are commonly used in experimental evaluations of CSP algorithms (cf. [15]). *Max-CSP* was used in experimental evaluations of constraint optimization problems (*COPs*) by [3, 6]. Other experimental evaluations of *DisCOPs* include graph coloring problems [12, 18], which are a subclass of *Max-DisCSP*.

In order to evaluate the performance of distributed algorithms, two independent measures of performance are commonly used - run time, in the form of non-concurrent steps of computation, and communication load, in the form of the total number of messages sent [7, 17]. We use the method described in [10] for counting non-concurrent computational steps.

AFB is compared with the *ADOPT* algorithm, which is the state-of-the-art algorithm for *DisCOPs*. Our implementation of *ADOPT* is based on [12] as well as open code published by the designer of *ADOPT*, Jay Modi.

The *ADOPT* algorithm (as described in [12]) starts by first constructing a pseudo-tree of the agents. After this initial construction, each agent informs agents below it in the tree of its current value assignment. Each agent is responsible for reporting to its parent the optimal assignment cost of the sub problem for which it is a root.

The algorithm is asynchronous, therefore each agent reports only lower and upper bounds on its sub-problem. As the sub-problem is explored, these bounds are refined until eventually, the lower bound and upper bound become equal. At that point, the sub-problem is optimally solved [12].

In order to avoid thrashing through redundant assignment replacing, *ADOPT* uses a “threshold splitting” mechanism. Our implementation uses the same heuristic for *threshold splitting* used in the open code implementation (the “*splitThresholdOneChild*” heuristic). The construction of the *pseudo tree* is generated also according to the original implementation, using the well known *DFS* algorithm.

To help reduce the number of messages, we improved *ADOPT*'s implementation, having each agent read its entire mailbox, process all awaiting messages and only then send the messages needed. A similar improvement was done for the *ABT* algorithm [17, 19, 1]. In our experimental evaluation, we considered the processing of all these messages as a single computational step.

Synchronous Branch and Bound (*SBB*) is a simple algorithm, that simulates centralized Branch & Bound in a distributed environment [17]. A single *CPA* which carries the search state, and is passed between agents is all that is needed.

Figure 3 presents the average run-time in number of computation steps, of the three algorithms *AFB*, *ADOPT* and *SBB* on *Max-DisCSPs* with $n = 10$ agents, domain size $k = 10$, and a constraint density of $p_1 = 0.4$. The value of p_2 was varied between 0.4 and

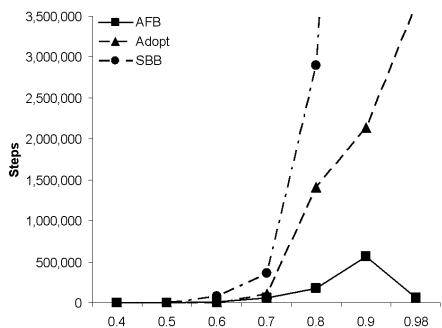

Figure 3. Total Non-concurrent computational steps by AFB, ADOPT and SBB on Max-DisCSP.

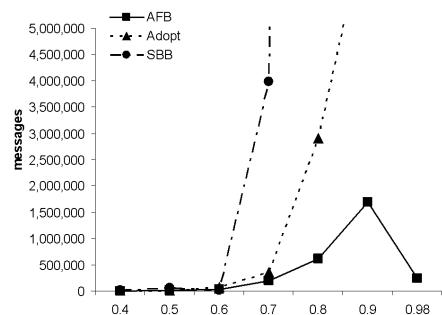

Figure 4. Total number of messages sent by AFB, ADOPT and SBB.

0.98, to cover all ranges of problem difficulty [15].

It is clear in Figure 3 that as the tightness becomes larger and the problem harder, *AFB* outperforms *ADOPT* which outperforms *SBB*. For tightness values that are higher than 0.9 *AFB* demonstrates a phase transition, while *ADOPT*'s and *SBB*'s run-time keeps growing. The behavior of *AFB* is very similar to that of lookahead algorithms on centralized *Max-CSPs* [3, 4, 6]. The run time of *ADOPT* ad *SBB* increases exponentially fast, so that on the very extreme values of p_2 it simply did not terminate in a reasonable time and their execution was terminated. Figure 4 shows the total number of messages sent by the three algorithms. *AFB* clearly outperforms *ADOPT* which outperforms *SBB* in this measure.

6 Conclusion

The present paper proposes a *DisCOP* algorithm that performs Forward-Bounding asynchronously. Extended consistency maintenance procedures are performed concurrently. The results presented in Section 5 demonstrate the importance of consistency maintenance for distributed search. The concurrent form of extended lookahead (forward bounding) prevents an exponential growth in run-time for the tighter problem instances. This is similar to the centralized case of *Max-CSPs* [3, 6]. The run-time performance of *AFB* is far better than *ADOPT* on tight distributed *Max-DisCSPs*. The advantage of *AFB* over *ADOPT* in overall network load is even more pronounced (Figure 4).

Recent studies of centralized constraints optimization problems have shown that the use of extended consistency maintenance procedures improves the performance of simple Branch and Bound [4, 6]. In particular, the hardest problem instances (with high p_2 value) show a phase transition, in which run-time decreases [3, 4, 5, 6].

Previous studies of distributed *COPs* have shown many advantages of the *ADOPT* algorithm over *SBB*, which is the naive algo-

rithm for solving these problems [12]. Previous experimental evaluations of *ADOPT* measured its scalability, by increasing the number of variables/agents ([12, 9, 8]). The behavior of *ADOPT* on the hardest (tightest) *Max-DisCSP* instances was not explored. The experiments in the present study measure the algorithm's performance over varying problem difficulty levels. The exponential growth of concurrent run-time of *ADOPT* for very hard and tight problem instances is therefore, only apparent in the present study.

Distributed Log-based Reconciliation

Yek Loong Chong¹ and Youssef Hamadi²

Abstract. Computer Supported Cooperative Work (CSCW) defines software tools and technology to support groups of people working together on a project, often at different sites [5]. In this work, we present four distributed algorithms for log-based reconciliation, an important NP-hard problem occurring in CSCW. Our methods remove the classical drawbacks of centralized systems like single point of failure, performance bottleneck and loss of autonomy. The problem is formalized using the Distributed Constraint Satisfaction paradigm (DisCSP). In the worst case, the message passing complexity of our methods range from $O(p^2)$ to $O(2^p)$ in a system of p nodes. Experimental results confirm our theoretical analysis and allow us to establish quality and efficiency trade-off for each method.

Keywords: Distributed Constraint Satisfaction

1 INTRODUCTION

Optimistic replication is a technology of choice for Computer Supported Cooperative Work (CSCW) where users collaborate asynchronously to achieve a common goal. The major assumption in optimistic replication systems is that conflicting operations are exceptional [10] and can be resolved through a process called reconciliation. In these systems, users share a set of common data objects through replication and update their local replicas independently. These isolated updates can introduce divergence in the states of the shared objects which are occasionally repaired through reconciliation. In *log-based* reconciliation, local updates are recorded in logs containing the isolated operations. These logs represent the input of the reconciliation process. The output or *schedule*, which is an ordered collection of non-conflicting operations, is computed by combining the isolated operations in some order. The schedule when executed against a previously consistent state results in a new consistent state. However, a set of isolated updates may contain conflicting operations and combining these operations may violate some invariant. One way of preserving correctness is to exclude conflicting operations from the schedule. An efficient reconciliation algorithm minimizes these exclusions.

A major criticism of current optimistic systems is that reconciliation is centralized, which exhibits classical drawbacks like single point of failure, performance bottleneck and loss of autonomy. Drawbacks aside, due to various factors like organizational boundaries and security/privacy, centralization may indeed be impossible or undesirable. What is needed is a method for making decision locally and incrementally, without having to accumulate all information at one site. In this work, we present a set of distributed algorithms for log-based reconciliation that avoid the previous drawbacks and preserve privacy.

As demonstrated in [9], the semantic of several CSCW systems can be represented using constraints. These systems can be modelled and solved in the Constraints formalism [7]. In this work, we provide the first distributed algorithms for distributed log-based reconciliation. These algorithms are defined in the Distributed Constraint Satisfaction Problem paradigm (DisCSP) [12].

This paper is organised as follows. We first provide a high level overview of the different domains in section 2. Section 3 presents the modelling of log-based reconciliation as a distributed constraint satisfaction problem. Our algorithms are presented in section 4 and their theoretical analysis is given in section 5. Before the general conclusion provided in the last section, section 6 presents detailed experimental results.

2 BACKGROUND

2.1 Constraint-based Optimistic Replication

In order to maintain consistency in a log-based reconciliation system, different updates to the same object must be executed in the same sequence at every replica. This can be complicated due to the varying latencies involved in accessing replicas that are distributed across a wide-area network. This problem is further exacerbated in mobile computing where the availability of replicas is also variable. Many optimistic systems like Bayou [2] and IceCube [9], circumvent this problem by using a centralised commit protocol (also known as the primary-based commit). In these systems, a distinguished site or *primary* is elected by the system for committing tentative operations. The order in which tentative operations are committed at the primary is deemed to be the authoritative order. Tentative operations must be executed at all replicas in the order specified by the authoritative sequence. IceCube is an optimistic replication system that supports multiple applications and data types using a concept called constraints between operations. The input is made by a set of logs coming from p users or sites $\{(a_{i1}, \dots, a_{ij}) | 1 \leq i \leq p\}$ where a_{ij} represents the j^{th} action for user i . These logs are individually consistent i.e., operations recorded in a log do not violate any correctness criterion at the originating site. The schedule is an ordered collection of non-conflicting operations (a_1, \dots, a_k) which represents the largest subset of users' operations consistent with the following conditions :

1. *before* or *temporal* constraint : for any a_i, a_j in the schedule, a_i comes before a_j (not necessarily immediately before) : $a_i \rightarrow a_j$
2. *must have* or *dependency* constraint : for any a_i in the schedule, a_j must also be in the schedule : $a_i \triangleright a_j$

Operations which are not part of the final schedule are deemed conflicting and aborted by the system. The semantics of a large set of applications can be represented through the combination of these low level constraints. For instance, the fact that a method f_m of a software object o needs to start with the call to an initialisation method f_i can be encoded into, $o.f_i \rightarrow o.f_m, o.f_m \triangleright o.f_i$.

² Microsoft Research Ltd., 7 J J Thomson Avenue, Cambridge CB3 0FB, United Kingdom, youssef@microsoft.com

A consistent schedule must respect any dependency relation and avoid oriented cycles of temporal constraints. The previous problem restricted to *before* constraints can be reduced to the search of the largest acyclic network of actions which is NP-hard.

2.2 Distributed Constraint Satisfaction

DisCSP is a general paradigm usually deployed in multi-agent applications where the global outcome depends on the joint decisions of autonomous agents. Examples of such applications are distributed planning and distributed sensor networks management [3]. Informally, a DisCSP is represented by a set of variables, each of which is associated with a domain of values, and a set of constraints that restrict combinations of values between variables. The variables are partitioned amongst a set of agents, such that each agent owns a proper subset of the variables. The task is for each agent to assign a value to each variable it owns without violating the constraints.

Solving a DisCSP is equivalent to finding an assignment of values to variables such that all the constraints are satisfied.

3 MODELLING THE DISTRIBUTED LOG-BASED RECONCILIATION PROBLEM

Efficiently solving the log-based reconciliation problem involves the finding of the largest set of non conflicting actions. This optimisation problem could theoretically be solved with a distributed optimisation procedure like [11]. This algorithm can find an optimal solution or a solution within a user-specified distance from the optimal. Unfortunately, it is too space intensive for our purpose and does not scale beyond a few dozens of variables. Therefore, we decided to apply a pragmatic strategy which computes locally optimal solutions (optimal within the scope of each agent) and globally combines them into a consistent distributed solution. The drawback of this approach comes from the loss of global optimality, but the benefit is efficiency. Moreover, final schedules are reasonably good since local decision making can take into account peers decisions. We now detail our full DisCSP model in the following.

Assuming that there are n tentative operations from p sites or agents, we use two constrained variables x_i and s_i to represent each tentative operation a_i . Therefore, a distributed reconciliation problem formulated as a DisCSP is a quadruplet (X, D, C, A) where :

1. X is a set of $2n$ variables $x_1, \dots, x_n, s_1, \dots, s_n$.
2. D is the set of domains $D_{x_1}, \dots, D_{x_n}, D_{s_1}, \dots, D_{s_n}$ of possible values for the variables $x_1, \dots, x_n, s_1, \dots, s_n$ respectively, where:
 - $D_{x_i} = [0..1]$, the value 1 is set when the action (or operation) a_i is selected for inclusion in the schedule.
 - $D_{s_i} = [-n^2 .. n^2]$, each value represents a possible position for action a_i in the schedule³.
3. C is the set of predicates defining the constraints (see section 2.1) between the operations:
 - (a) $(x_i == 1) \implies (s_i < s_j)$ to express any $a_i \rightarrow a_j$ relation.
 - (b) $x_j \geq x_i$ to express any $a_i \triangleright a_j$ relation.
4. A is a partitioning of X amongst the set of p autonomous agents P_1, \dots, P_p defined by $f : X \rightarrow A$ such that $f(x_i) = P_k \Leftrightarrow f(s_i) = P_k$.

³ Intuitively, n discrete values would be adequate to represent the positions of n operations. However, this is not the case with our distributed algorithms (see sec. 4).

Finally, each P_k uses a local branch-and-bound search which maximizes, $\sum_{a_i \in P_k} x_i$. It represents the maximizing of the size of the local schedule. Search is performed over the x_i with bound consistency on the s_i . At the end of the distributed exploration, any selected operation a_i (s.t., $x_i = 1$) can use the lower bound of the associated s_i as a valid ordering position in the schedule.

4 DISTRIBUTED ALGORITHMS FOR LOG-BASED RECONCILIATION

4.1 Distributed ordering of the agents

Our solution synthesis algorithms are totally asynchronous. However, they require an ordering $>_o$ between related agents (two agents are related if they share some constraint). We decided to use a general method, Distributed Agent Ordering (DisAO) which is classically used to order a network of agents [8]. DisAO computes a distributed acyclic graph of agents where related agents are always strictly ordered by $>_o$. It can use any domain-dependent heuristic to guide its reasoning.

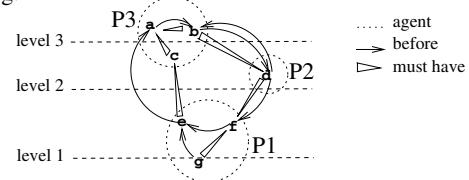

Figure 1. Distributed Ordering of the agents

Figure 1 presents a small reconciliation problem ordered with DisAO. Each agent is presented with internal actions and constraints. It shows that $P_3 >_o P_2 >_o P_1$. Agent P_3 has two *Children*, P_1 and P_2 . P_2 has one parent and one child while at the bottom, P_1 has two parents. These *Parents* and *Children* sets represent primaries with higher (resp. lower) priorities.

4.2 Distributed Reconciliation Algorithm

Our first procedure is presented in Algorithm 1. It represents a powerful problem-specific extension of ABT [12]. For each agent, the input is made by the previously defined *Parents* and *Children* sets. The output is a locally optimal schedule consistent with both intra- and inter-constraints. Solution synthesis begins with the simultaneous initialisation of the nodes. *localView* the data structure representing parents' solutions is initialized and a search for s , a locally optimal solution is performed. The method *maximize* runs a local branch-and-bound which maximizes the size of the local schedule. Before this first call to the local solver [6], the domains D_{s_i} are updated thanks to a first call to *resolveDomain*. This method sets the domain of each local variable s_i to $D_{s_i} = [0..n_k - 1]$, where n_k represents the number of local actions. This represents the initial basis or referential of each agent knowing that n_k values are enough to schedule n_k local operations at that stage. Afterwards, s is propagated to the *Children* acquaintances through *infoVal* messages. Interactions can then start through an event loop. First, agents check for termination. Such messages are addressed by some entity able to detect global stabilization of the system (see [1]). Next, *infoVal* messages are processed. If the current solution s appears to be compatible with the new information, the processing stops. Note that the current solution may be compatible but suboptimal w.r.t. incoming information.

Now, if some inconsistency is detected, a new locally optimal solution must be found. This process starts with a *rewriting* of the incoming solution and a computation of the new ranges of the s_i variables. Intuitively, we only require n_k discrete values to represent the

position of n_k local operations. However, agent P_k searching for a new local solution must consider its *Parents* solutions. Clearly, some local operation a_i could be scheduled between, before or after ancestors' operations. The rewriting of the incoming solution allows the scheduling of local operations between ancestor ones. This process is presented in algorithm 2. It takes an ordered incoming solution S_{in} and rewrites it into S'_{in} , the same solution where actions are shifted to allow the potential scheduling of n_k local actions in between. Finally, to authorize the scheduling of the local operations before or after ancestors ones, the local s_i variables are set to $D_{s_i} = [\min(\{s_i | s_i \in \text{localView}\}) - n_k .. \max(\{s_i | s_i \in \text{localView}\}) + n_k]$. The call to the *resolveDomain* function sets the previous bounds.

Algorithm 1: Distributed Reconciliation

Input: Parents, Children sets;
Output: A local schedule consistent with intra- and inter-constraints;
begin

```

localView:=∅; resolveDomains(localView);
s:=maximize(local problem); send('infoVal', s, Children);
end:=false;
while (!end) do
  msg:=getMsg();
  if (msg.type = "terminate") then
    end:=true;
  if (msg.type = "infoVal") then
    if (!localView.compatible(s)) then
      msg.content := rewriteSolution(msg.content);
      localView.add(msg.content);
      resolveDomains(localView);
      s:=maximize(local problem);
      if (s) then
        send('infoVal', s, Children);
      else
        conflicts:=∅;
        ng:=computeNogoods(conflicts);
        send('backtrack',ng,conflicts);
        localView.remove(msg.content);
        s:=maximize(local problem);
        send('infoVal', s, Children);

    if (msg.type = "backtrack") then
      storeNogoods(msg.content);
      s:=maximize(local problem);
      if (s) then
        send('infoVal', s, Children);
      else
        conflicts:=∅;
        ng:=computeNogoods(conflicts);
        send('backtrack',ng,conflicts);

  end

```

Algorithm 2: rewriteSolution

Input: $S_{in} = \{(x_0, s_0), \dots, (x_k, s_k)\}$, sorted on s_i ;
Output: $S'_{in} = \{(x_0, s'_0), \dots, (x_k, s'_k)\}$;
begin

```

s'_0 := s_0; i:=1;
while (i ≤ k) do
  s'_i := s'_{i-1} + s_i - s_{i-1} + n_k + 1;
  i++;

```

If a new solution exists, it is propagated to related children. If such a solution cannot be found, a backtrack step is started. This implies first the detection of the parents involved in the conflict, second the detection of the external actions causing the conflict. A call to *computeNogoods* returns these two sets. Then, a *backtrack* message is addressed to related parents. At that point, the agent can remove

the current content from the local view and look for a new satisfying solution. Looking for a new solution instead of waiting for the consequence of the *backtrack* message has a positive impact on robustness in case of transient failures. Then, an agent considers any backtracking request. First, the incoming nogoods are stored. Subsequent searches will have to respect these new constraints. The agent looks for a new locally optimal solution s compatible with local constraints, local view and stored nogoods. If a consistent solution is found, it is propagated. If not, a new backtrack is initiated as before. Since, in log-based reconciliation, an empty schedule is perceived as consistent, termination can only happen when agents are waiting for incoming messages and when no such messages transit in the communication network. In this situation each agent has a local solution consistent with its *Parents*.

4.3 Example

Figure 2 shows from left to right a step by step execution of the algorithm on the small reconciliation example of figure 1. Each snapshot includes the local state of each action a_i in the form (x_i, s_i) .

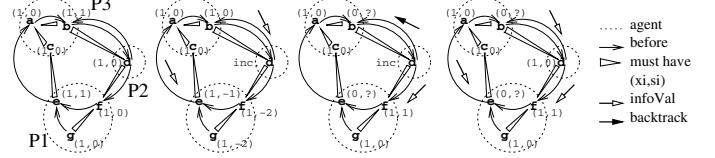

Figure 2. A complete example of distributed reconciliation

Processing starts at top left with the concurrent computation of a locally optimal solution for each sub-problem. At that step, all the actions are included in the schedule with respect to intra-constraints. Then in the second snapshot, we assume that P_2 and P_1 are processing incoming *infoVal* messages upcoming from P_3 . P_1 finds a new local solution consistent with P_3 , while P_2 detects an inconsistency. This inconsistency comes from the cycle of *before* constraints between actions b and d combined to the dependency constraints $b \triangleright d$. Indeed, removing action d in order to avoid the inconsistency upcoming from the cycle is not compatible with the dependency constraint. In the third snapshot, the nogood ($x_b \neq 1$) is addressed to P_3 in a *backtrack* message. At the same time, P_1 processes the *infoVal* message upcoming from P_2 . It finds a new local solution excluding e but compatible with both P_3 and P_2 . In the last snapshot, P_3 finds a new solution which respects its recorded nogood and propagates it towards P_1 and P_2 . Then P_2 can find for the first time a local solution compatible with P_3 . It addresses it towards P_1 . Finally P_1 successively processes two *infoval* messages and finds them compatible with its current local solution. At that stage termination is detected. The final quality of the distributed schedule is 5 (actions) while a globally optimal solution would have a quality of 6 (excluding action b). The overall message cost is 7.

4.4 Backtrack-free Distributed Reconciliation

The previous example shows that our algorithm can easily handle inconsistencies upcoming from distributed cycles of *before*. More generally,

Property 4.1 *Distributed cycles of temporal constraints can always be broken by an agent of lowest priority.*

The proof is direct if we consider that DisAO totally orders related agents. Therefore, there is always a unique agent of lowest priority for each distributed cycle of *before* which can always break

the cycle by excluding some local action. For example, in figure 2, (a, b, d, f, e) can always be broken in P_1 by removing either f or e .

Property 4.2 *Distributed backtracking is the result of the scheduling of some operation a which depends on some external operation b ($a \triangleright b$) managed by an agent of lower priority.*

From 4.1, we know that inter-temporal constraints cannot force a system to backtrack. Therefore, backtracking comes from inter-dependency constraints. Indeed, if b cannot be scheduled in the child, a has to be withdrawn. This is performed thanks to a distributed backtracking message, e.g., actions b and d in figure 2.

We can easily specialize Algorithm 1 into a new backtrack-free method. In the new procedure, a node proactively excludes actions whose scheduling depends on some child's decision. From property 4.2, the new method is backtrack-free.

When we apply this algorithm to the problem of figure 2, P_3 and P_2 proactively remove b and d . At the end of the resolution, the overall quality is 5 (P_1 can keep three actions) while the message passing cost is just 3.

4.5 Optimal Orderings

The backtrack-free algorithm proactively excludes actions which rely on children decisions. Therefore, an immediate objective is to avoid these costly situations by prioritizing the agents in a way which circumvents these *badly oriented* dependencies. In a general case, this is not always possible since a system can contain distributed cycles of dependencies. However, these cycles may intersect, and breaking as many of them at their intersection minimizes the number of badly oriented constraints and consequently, the number of forced exclusions. Ideally, we would do this by computing a minimal cycle-cut set in the oriented dual graph of dependency constraints.

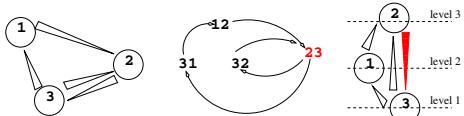

Figure 3. Distributed cycles of dependencies, dual graph and optimal ordering

Figure 3 illustrates this. On the left part we have a system with three agents linked through two cycles of dependencies. An optimal ordering will decide $P_2 >_o P_3$. Indeed, this decision breaks the two cycles in the dual graph of dependencies. The final ordering, $P_2 >_o P_1 >_o P_3$, has just one badly oriented constraint, which is coloured in red. It is presented on the right. In the middle, the dual graph is presented with its cut set coloured in red. Unfortunately, the problem of finding a minimal cycle-cut set is NP-hard [4] and we can just find ways to approximate its solution. We do this with DisAO (see sec. 4.1) which takes as input the following new heuristic function:

1. Compute locally inconsistent orderings, $P_j >_o P_i >_o P_k$ (where $P_j \triangleright P_i \triangleright P_k$).
2. Propagate these orderings in the neighbourhood.
3. Collect inconsistent orderings, prune local combinations of orderings by using collected information.

The first step detects situations where some action in P_j relies on some action managed by P_i while at the same time some possibly different action in P_i relies on some action managed by P_k . These situations must be avoided. The last step assumes that a node manages all the possible local orderings involving itself and its neighbours. It uses incoming inconsistencies to filter these local orderings. When it receives some inconsistency $P_j \triangleright P_i \triangleright P_k$, it prunes all

the orderings assuming $P_j \triangleright P_i$ or $P_i \triangleright P_k$. The message passing complexity of this calculation is $O(p^2)$, see [8].

The application of the previous heuristic to our main example, gives the optimal ordering presented in figure 4. We can observe that, action e relies on action c , which means that the top priority agent depends on the decision of a child. With this ordering, our distributed reconciliation algorithm uses 4 messages and find an optimal solution which schedules 6 actions (b 's removal breaks the two distributed cycles of *before*). The backtrack-free method requires 4 messages and schedules 5 actions.

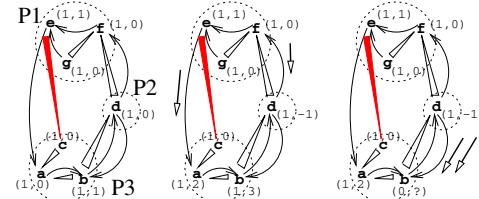

Figure 4. An optimal ordering

If we include the previous pre-processing step which minimizes dependencies towards children decisions, we finally have four methods for distributed log-based reconciliation:

1. The general distributed reconciliation : *backtracking*.
2. The backtrack-free algorithm : *backtrack-free*.
3. The general distributed reconciliation which uses the previous pre-processing : *pre-proc+backtracking*.
4. The backtrack-free algorithm which uses the previous pre-processing : *pre-proc+backtrack-free*.

5 THEORETICAL ANALYSIS

5.1 Distributed Reconciliation

To demonstrate *correctness*, we must first show that rewritten solutions are equivalent to original ones. Because of space considerations, we do not detail the proof, which involves the demonstration that dependency constraints are not affected by the rewriting; that original inter-space is preserved and, that added inter-space does not go against the original consistency of S_{in} . Second, we must show that the dynamic narrowing of the local domains D_{s_i} is correct. By definition, algorithm 2 adds at least n_k scheduling positions between scheduled actions upcoming from parents. Therefore, it gives enough space to schedule the n_k local actions between any pair of external actions. Finally, n_k values are reserved before (resp. after) the lowest (resp. highest) scheduling position in the local view (call to *resolve-Domain*). Therefore, enough space is provided to schedule local operations before, between or after parents' ones. Third, we must show that when the system stops, computed solutions are consistent. The proof is related to the correctness of [1] which is used to detect situations where, 1.) the communication network is empty and 2.) agents are waiting for incoming messages. To show *completeness*, we need to show that if there is a solution, our algorithm can reach it and that the algorithm eventually *terminates*. Here, because of space considerations, we refer readers to [12].

Computationally, the worst case is made of a fully connected network of p agents individually managing a single action. Therefore, any DisAO ordering uses p levels. Insolubility is proven after an exhaustive exploration of the distributed search space. Since this exploration is done on the x_i variables, the search space size is 2^p . Hence, in the worst case, time and message passing complexities are $O(2^p)$.

5.2 Backtrack-free Distributed Reconciliation

Completeness (w.r.t., pessimistic decision making), correctness and termination are obvious with this algorithm. However, the complexity must be detailed. As, with the previous worst case, each agent proactively removes its local action to avoid incoming backtracks. The top level agent sends $p - 1$ *infoVal* messages while the others send a number of messages related to their position in the distributed ordering. Since this ordering has p levels, time and message passing complexities are $O(p^2)$.

6 EXPERIMENTAL RESULTS

Experiments were conducted over a set of randomly generated inputs. We simulated a system of $p = 10$ agents with a total number of $n = 100$ actions. Each agent P_k was allocated exactly $n_k = 10$ actions. Two tightness parameters p_b and p_{mh} were used to define respectively the number of *before* and *must have* constraints. Each parameter represents a percentage over the set of all possible constraints. Since hard internal sub-problems impact the overall quality but do not raise high interaction levels, we decided to restrict the hardness of each sub-problem to respectively 9 *before* and 5 *must have* constraints. The amount of inter-constraints was defined as, $tightness \times (\sum_{k=1}^p n_k \times (n - n_k))$ with both tightness parameters ranging from 0.1% to 1.5%. These values range over the space of realistic log-based reconciliation problems which appear to be under-constrained [9]. Indeed when the previous parameters are pushed they rapidly meet overconstrained regions with empty solutions (see [7] for full landscape analysis). Each system had from 18 to 270 inter-constraints either *before* or *must have*. Overall, our experiments used 200 variables and a maximum of 410 constraints. They represent the largest experiments in DisCSPs as far as our knowledge goes. For each combination of parameters we present average values over 20 random instances.

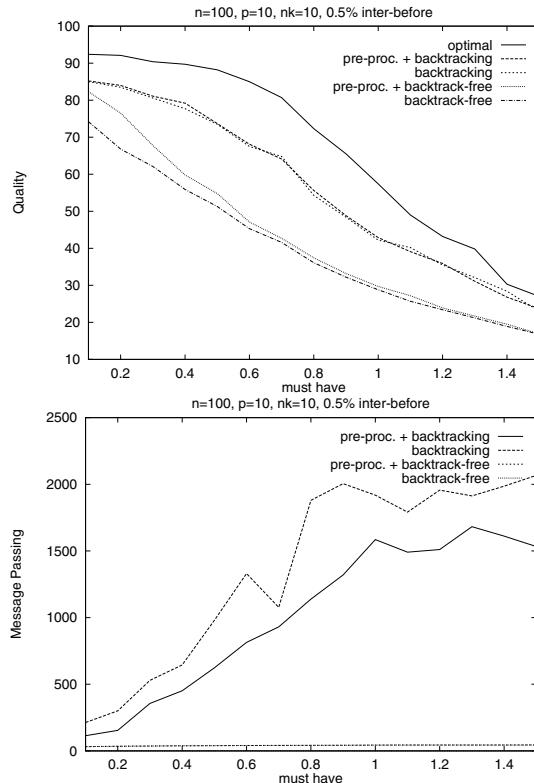

Figure 5. Quality and message passing results

Figure 5 present quality and message passing results at $p_b = 0.5\%$, i.e., 45 inter-*before* constraints. When we consider the quality, we can see that *backtracking* and *pre-proc backtracking* are very close. Note that optimal quality is provided (top curve). On the other-hand, the *backtrack-free* method really benefits from the pre-processing. It organizes the system in a way which reduces the number of pessimistic choices. The biggest win appears at $p_{mh} = 0.2$ with an improvement of 14.5%. Message passing presents a different dynamic. The pre-processing clearly improves the *backtracking* algorithm; up to 48% of the messages are saved at $p_{mh} = 0.2$. As expected, it has no impact on the message cost of the *backtrack-free* algorithm.

7 CONCLUSION

We have proposed a set of distributed algorithms which perform distributed log-based reconciliation, an important problem in CSCW. Our first method iteratively corrects locally optimal solutions through distributed backtracking. Its worst case time and message passing complexities are $O(2^p)$. Our second method is backtrack-free. It applies a pessimistic decision making which is built on a fine analysis of backtrack prone situations. Its worst case time and message passing complexities are bounded by $O(p^2)$. Moreover, we showed that in a general case, distributed cycles prohibit the complete suppression of badly oriented dependencies, i.e., a non-pessimistic procedure cannot be backtrack-free. Furthermore, we showed that it was possible to reduce backtrack prone situations; a perfect reduction being equivalent to the NP-hard computation of a minimal cycle-cut set in the dual graph of inter-dependency constraints. To approximate a perfect reduction, we have also presented a specific agent ordering heuristic. It was experimentally shown that by using this heuristic, 1) the backtrack-free procedure improves the overall quality of its solutions (up to 14.5%), 2) the general backtracking algorithm decreases its message passing consumption (up to 48%).

Extracting MUCs from Constraint Networks

Fred Hemery and Christophe Lecoutre and Lakhdar Sais and Frédéric Boussemart¹

Abstract. We address the problem of extracting Minimal Unsatisfiable Cores (MUCs) from constraint networks. This computationally hard problem has a practical interest in many application domains such as configuration, planning, diagnosis, etc. Indeed, identifying one or several disjoint MUCs can help circumscribe different sources of inconsistency in order to repair a system. In this paper, we propose an original approach that involves performing successive runs of a complete backtracking search, using constraint weighting, in order to surround an inconsistent part of a network, before identifying all *transition* constraints belonging to a MUC using a dichotomic process. We show the effectiveness of this approach, both theoretically and experimentally.

1 Introduction

A constraint network is said to be minimal unsatisfiable if and only if it is unsatisfiable and deleting an arbitrary constraint makes it satisfiable. Deciding whether a set of constraints is minimal unsatisfiable is well known to be DP-Complete [20]. It can be reduced to the SAT-UNSAT problem: given two CNF formulas ϕ and ψ , is ϕ satisfiable and ψ unsatisfiable? DP corresponds to the second level of the Boolean hierarchy. A problem in this class can be considered as the difference between two NP-problems.

On the practical side, when inconsistency is encountered, circumscribing the conflicting parts of a system can help the user understand, explain, diagnose and restore consistency. To illustrate the importance of the problem addressed in this paper, one can mention the well-known Radio Link Frequency Assignment Problem (RLFAP) which is often used as a benchmark in the CSP (Constraint Satisfaction Problem) community. This problem involves assigning frequencies to a set of radio links defined between pairs of transmitters in order to avoid interferences. To this end, one looks for a solution that minimizes the number of used frequencies. Circumscribing the unfeasible subnetwork areas (of minimal size) can help find new positions of the transmitters.

In the case of Boolean constraints (formula in Conjunctive Normal Form), finding minimal unsatisfiable sub-formula is an active research area. Tractable classes have been exhibited. Most of them are based on the deficiency of the formula (i.e. difference between the number of clauses and variables) [4, 7]. Also, recent advances in satisfiability checking has allowed successful extensions of SAT solvers for handling such a hard computational problem [3, 23, 15, 19].

In the context of constraint satisfaction, there is a significant amount of work dealing with the identification of conflict sets of constraints. Such sets, which can be built by recording explanations during search, are usually used to perform different forms of intelligent backtracking (e.g. [22, 8, 13]). However, there are only a few works

really dedicated to the extraction of MUCs from constraint networks. An approach for the diagnosis of over-constrained networks has been proposed in [1] and a method to find all MUCs from a given set of constraints is presented in [9, 5]. This method corresponds to an exhaustive exploration of a so-called CS-tree, but is limited by the combinatorial explosion in the number of subsets of constraints. Finally, a divide and conquer approach has been proposed in [12] in order to extract from an over-constrained problem an explanation (or relaxation) using preferences given by the user.

In this paper, we propose an original approach to extract a MUC from a given constraint network. This approach consists of two stages. The first one exploits the conflict-directed variable ordering heuristic *dom/wdeg* [2] in order to surround (and then extract) an unsatisfiable core by performing successive complete runs of a backtracking search algorithm. Search is restarted, while preserving constraint weighting from one run to the next one, until the size of the proved unsatisfiable core cannot be made smaller. Then, using a total order on the constraints based on their current weights, and following the principle introduced in [6], the second stage allows iteratively identifying the constraints of a MUC. Compared to *constructive* [6] and *destructive* [1] approaches which are respectively $O(e.k_e)$ and $\theta(e)$, the *dichotomic* approach that we propose is $O(\log(e).k_e)$. Here, the complexity corresponds to the worst-case number of calls to the backtracking search algorithm, e denotes the number of constraints of the given constraint network and k_e denotes the number of constraints of the extracted MUC. We also relate this complexity with the one obtained by Junker [12].

The paper is organized as follows. First, we introduce some technical background. Then, we present the two stages of our approach: extracting an unsatisfiable core by exploiting constraint weighting and extracting a minimal core by identifying so-called *transition* constraints. Next, related work is discussed. Finally, before concluding, we present the results of an experimentation that we have conducted.

2 Technical Background

A Constraint Network (CN) P is a pair $(\mathcal{X}, \mathcal{C})$ where \mathcal{X} is a finite set of n variables and \mathcal{C} a finite set of e constraints. Each variable $X \in \mathcal{X}$ has an associated domain, denoted $dom(X)$, which contains the set of values allowed for X . Each constraint $C \in \mathcal{C}$ involves a subset of variables of \mathcal{X} , called scope, and has an associated relation, denoted $rel(C)$, which contains the set of tuples allowed for the variables of its scope. For any subset $S \subseteq \mathcal{C}$ of constraints of P , $P^{\uparrow S}$ will denote the constraint network obtained from P by removing all constraints of S and $P_{\downarrow S}$ will be equivalent to $P^{\uparrow(\mathcal{C}-S)}$.

A solution to a CN is an assignment of values to all the variables such that all the constraints are satisfied. A CN is said to be satisfiable iff it admits at least one solution. The Constraint Satisfaction Problem (CSP) is the NP-complete task of determining whether a given

¹ CRIL-CNRS FRE 2499, rue de l'université, SP 16, 62307 Lens cedex, France. email: {hemery, lecoutre, sais, boussemart}@cril.univ-artois.fr

CN is satisfiable. A CSP instance is then defined by a CN, and solving it involves either finding one (or more) solution or determining its unsatisfiability. To solve a CSP instance, a depth-first search algorithm with backtracking can be applied, where at each step of the search, a variable assignment is performed followed by a filtering process called constraint propagation. Usually, constraint propagation algorithms, which are based on some constraint network properties such as arc consistency, remove some values which can not occur in any solution. The algorithm that maintains arc consistency during search is called MAC. An unsatisfiable core corresponds to an unsatisfiable subnetwork of a CN.

Definition 1. Let $P = (\mathcal{X}, \mathcal{C})$, $P' = (\mathcal{X}', \mathcal{C}')$ be two CNs. P' is an unsatisfiable core of P iff P' is unsatisfiable, $\mathcal{X}' \subseteq \mathcal{X} \wedge \mathcal{C}' \subseteq \mathcal{C}$.

Different unsatisfiable cores of a given CN may exist. Those which do not contain any proper unsatisfiable core are said to be minimal.

Definition 2. Let $P = (\mathcal{X}, \mathcal{C})$ be a CN and $P' = (\mathcal{X}', \mathcal{C}')$ an unsatisfiable core of P . P' is a Minimal Unsatisfiable Core (MUC) of P iff it does not exist any unsatisfiable core P'' of P' s.t. $P'' \neq P'$.

To show the minimality of an unsatisfiable core, one can just check the satisfiability of any CN obtained when removing one constraint.

3 Extracting Unsatisfiable Cores

First, following the idea given in [1], we introduce an approach that allows removing some constraints (while preserving unsatisfiability). Then, we refine this approach by exploiting constraint weighting and (complete) restarts.

3.1 A Proof-based Approach

When the unsatisfiability of a CSP instance is proved by a filtering search algorithm, one can automatically extract a core that is guaranteed to be unsatisfiable. Indeed, it suffices to keep track of all the constraints that have been involved in the proof of unsatisfiability, that is to say, any constraint that has been used during search to remove, by propagation, at least one value in the domain of a variable. This principle was mentioned in [1] and can be related to the concept of implication graph used in SAT (e.g. see [17, 23]).

Let us examine how it works with MAC which maintains arc consistency by exploiting, for instance, an algorithm such as AC3 [16]. It involves successive revisions of arcs (pairs composed of a constraint and of a variable) in order to remove the values that are no more consistent with the current state. At the heart of the solver is then the function depicted in Algorithm 1. All values of the domain of the given variable that are not currently supported by the given constraint are removed (lines 2 to 4).

By introducing a data structure, denoted *active*, that allows associating a Boolean with each constraint, we are then in a position to extract an unsatisfiable core. The function *pcore* depicted in Algorithm 2 allows such an extraction. Initially, all Booleans are set to *false* (line 1). Then, the MAC solver is called (line 2), what involves successive revisions. Hence, whenever a revision is effective, the Boolean associated with the constraint is set to *true* (line 5 of Algorithm 1). Finally, the function returns (line 3) the CN obtained from P by removing any constraint C such that $active[C]$ is *false*. It is important to remark that the network returned by *pcore* is guaranteed to be unsatisfiable but not necessarily minimal.

Algorithm 1 *revise*(C : Constraint, X : Variable) : Boolean

```

1: domainSize  $\leftarrow |dom(X)|$ 
2: for each  $a \in dom(X)$  do
3:   if seekSupport( $C, X, a$ ) = false then
4:     remove  $a$  from dom( $X$ )
5:     active[ $C$ ]  $\leftarrow true$ 
6: if dom( $X$ ) =  $\emptyset$  then
7:   wght[ $C$ ]  $\leftarrow wght[C] + 1$  // used by some heuristics
8: return domainSize  $\neq |dom(X)|$ 
```

Algorithm 2 *pcore*($P = (\mathcal{V}, \mathcal{C})$: CN) : CN

```

1: active[ $C$ ]  $\leftarrow false$ ,  $\forall C \in \mathcal{C}$ 
2: MAC( $P$ )
3: return  $P^{\uparrow \{C \in \mathcal{C} | active[C] = false\}}$ 
```

3.2 A Conflict-based Approach

Even if the proof-based approach is an elegant approach, we have no idea about its practical efficiency. In other words, we cannot predict the size of the unsatisfiable core extracted by *pcore*. It is clear that the smallest the size is, the most efficient the approach is. Actually, as illustrated below, exploiting a conflict-directed variable ordering heuristic in order to push up an unsatisfiable core by performing successive runs makes the proof-based approach quite effective.

Heuristic *dom/wdeg* In [2], it is proposed to associate a counter, denoted *wght*[C], with any constraint C of the problem. These counters are used as constraint weighting. Whenever a constraint is shown to be unsatisfied (during the constraint propagation process), its weight is incremented by 1 (see line 7 of Algorithm 1). The weighted degree of a variable X is then defined as the sum of the weights of the constraints involving X and at least another uninstantiated variable. The conflict-directed heuristic *dom/wdeg* [2] involves selecting first the variable with the smallest ratio current domain size to current weighted degree. As search progresses, the weight of hard constraints become more and more important and this particularly helps the heuristic to select variables appearing in the hard part of the network. This heuristic has been shown to be quite efficient [2, 14, 10].

Illustrative Example Using *dom/wdeg* allows efficiently proving the unsatisfiability of many instances. However, in order to obtain a proof of unsatisfiability of moderate size, one has to be aware that it is important to perform successive runs by restarting search several times. As an illustration, let us consider the problem of putting some queens and some knights on a chessboard as described in [2]. The instance with 6 queens and 3 knights involves 9 variables and 36 constraints and is unsatisfiable. In fact, we know that the subproblem corresponding to the 3 knights, and involving 3 variables and 3 constraints, is unsatisfiable. In a first phase, solving this instance with MAC-*dom/wdeg* (i.e. MAC combined with the *dom/wdeg* variable ordering heuristic) yields a proof of unsatisfiability integrating all constraints of the instance (that is to say, all Boolean *active* have been set to *true*). However, solving again the same instance, using current weighting of the constraints as obtained after the first run, yields a new proof of unsatisfiability integrating only 9 constraints. An additional run furnishes the same result.

Figure 1 illustrates the evolution of such proofs of unsatisfiability. CNs are represented by constraint graphs where vertices correspond to variables and edges to binary constraints. Note that constraints ir-

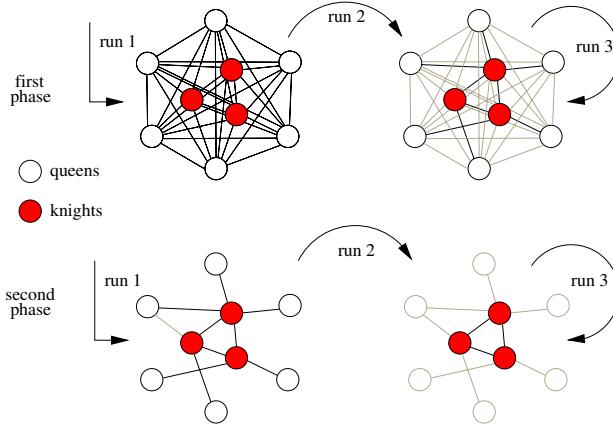

Figure 1. Evolution of the proof of unsatisfiability

relevant to unsatisfiability after one run are represented by dashed edges. Then, it is possible to refine the extraction after removing all the constraints which are not involved in the detected core, i.e., proof of unsatisfiability. Indeed, in a second phase, we obtain an unsatisfiable core that corresponds to the knights subproblem.

Exploiting Conflict-directed Heuristics As illustrated above, performing several runs of a MAC solver may be useful to surround an unsatisfiable core provided that a conflict-directed heuristic such as *dom/wdeg* is used. This approach is depicted by Algorithm 3. Initially (line 1), the weight of all constraints is set to 1. Then, iteratively, MAC-*dom/wdeg* is run (line 6) and the number of constraints found in the unsatisfiable core detected by the current run is counted (line 7). The iteration stops when the size of the current unsatisfiable core is greater than or equal to the size of the previous one. Remember that from one run to the next one, the *wght* counters are preserved, which allows potentially concentrating the search to a smaller and smaller unsatisfiable core. Note that we can easily generalize this algorithm in order to perform several phases as mentioned in the illustration.

Algorithm 3 $wcore(P = (\mathcal{V}, \mathcal{C}) : CN) : CN$

```

1:  $wght[C] \leftarrow 1, \forall C \in \mathcal{C}$ 
2:  $cnt_{aft} \leftarrow +\infty$ 
3: repeat
4:    $active[C] \leftarrow false \forall C \in \mathcal{C}$ 
5:    $cnt_{bef} \leftarrow cnt_{aft}$ 
6:   MAC-dom/wdeg( $P$ )
7:    $cnt_{aft} \leftarrow |\{C \in \mathcal{C} | active[C]\}|$ 
8: until  $cnt_{aft} \geq cnt_{bef}$ 
9: return  $P \upharpoonright \{C \in \mathcal{C} | active[C] = false\}$ 

```

4 Extracting Minimal Unsatisfiable Cores

It is clear that the unsatisfiable core that can be extracted by using the function *wcore* is not guaranteed to be minimal. In order to find a minimal core, it is necessary to iteratively identify the constraints that are involved in it. More precisely, we know that, given an unsatisfiable CN P and a total ordering of the constraints (to simplify, we shall consider the natural lexicographic order C_1, C_2, \dots, C_e of the constraints), there exists a constraint C_i such that $P \upharpoonright \{C_1, \dots, C_{i-1}\}$ is satisfiable and $P \upharpoonright \{C_1, \dots, C_i\}$ is unsatisfiable². This constraint which

² We shall assume that no constraint C exists in P such that $\text{rel}(C) = \emptyset$.

clearly belongs to a minimal core of P will be called the *transition constraint* of P (according to the given ordering). Note also that any constraint C_j with $j > i$ can be safely removed.

4.1 Identifying the Transition Constraint

It is possible to identify the *transition constraint* of an unsatisfiable CN P by using a constructive approach, a destructive approach or a dichotomic one. Below, $\text{MAC}(P)$ returns *SAT* (reps. *UNSAT*) iff P is satisfiable (resp. unsatisfiable), and the parameter $k (< |\mathcal{C}|)$ indicates the number of transition constraints previously identified (the first k constraints of the current network). It will be meaningful later, but initially, just consider $k = 0$.

Constructive Approach The principle is to successively add the constraints of the given network until the current network becomes unsatisfiable. This approach is analog to the one introduced in [6] and is depicted by Algorithm 4.

Algorithm 4 $csTransition(P = (\mathcal{V}, \mathcal{C}) : CN, k : int) : Constraint$

```

1: for  $i$  increasingly varying from  $k + 1$  to  $|\mathcal{C}|$  do
2:   if  $\text{MAC}(P \upharpoonright \{C_1, \dots, C_i\}) = \text{UNSAT}$  then return  $C_i$ 

```

Destructive Approach The principle is to successively remove the constraints of the given network until the current network becomes satisfiable (note² that i can never reach 1). This approach has been introduced in [1] and is depicted by Algorithm 5.

Algorithm 5 $dsTransition(P = (\mathcal{V}, \mathcal{C}) : CN, k : int) : Constraint$

```

1: for  $i$  decreasingly varying from  $|\mathcal{C}|$  to  $k + 1$  do
2:   if  $\text{MAC}(P \upharpoonright \{C_1, \dots, C_{i-1}\}) = \text{SAT}$  then return  $C_i$ 

```

Dichotomic Approach Finally, it is possible to use a dichotomic search in order to find the transition constraint. This approach is depicted by Algorithm 6. At each step of the search, we know that the transition constraint of P belongs to $\{C_{min}, \dots, C_{max}\}$.

Algorithm 6 $dcTransition(P = (\mathcal{V}, \mathcal{C}) : CN, k : int) : Constraint$

```

1:  $min \leftarrow k + 1 ; max \leftarrow |\mathcal{C}|$ 
2: while  $min \neq max$  do
3:    $center \leftarrow (min + max)/2$ 
4:   if  $\text{MAC}(P \upharpoonright \{C_1, \dots, C_{center}\}) = \text{SAT}$  then  $min \leftarrow center + 1$ 
5:   else  $max \leftarrow center$ 
6: return  $C_{min}$ 

```

4.2 Extracting the Minimal Core

Using one of the functions described above allows finding the transition constraint C_i of an unsatisfiable network P , that is to say one element that belongs to a minimal core of P . To get a second element, we apply the same function on a new CN P' which is obtained from P by removing all constraints C_j such that $j > i$ (since unsatisfiability is preserved) and considering a new order of the constraints such that C_i is considered as the smallest element (a natural order can be preserved by simply renaming constraints). This process can be repeated until all constraints of the current network correspond to transition constraints that have been successively found. The principle of this iterative process has been described in [6, 11, 21]. It is

depicted by Algorithm 7 which returns a MUC from the given network (just consider one of the tree approaches by replacing xx with cs, ds or dc). Note that we have to determine if the last constraint belongs to the MUC (lines 7 and 8).

Algorithm 7 $xxMUC(P = (\mathcal{V}, \mathcal{C}) : CN) : CN$

```

1:  $P' \leftarrow P ; k \leftarrow 0$ 
2: while  $k < |\mathcal{C}'| - 1$  do
3:    $C_i \leftarrow xxTransition(P', k)$ 
4:    $k \leftarrow k + 1$ 
5:    $P' \leftarrow P'^{\uparrow\{C_j | j > i\}}$ 
6:   in  $P'$ ,  $tmp \leftarrow C_i$ ,  $C_{j+1} \leftarrow C_j$  for  $1 \leq j < i$ ,  $C_1 \leftarrow tmp$ 
7: if  $MAC(P'^{\uparrow\{C_{|\mathcal{C}'|}\}}) = UNSAT$  then return  $P'^{\uparrow\{C_{|\mathcal{C}'|}\}}$ 
8: else return  $P'$ 

```

The following proposition (whose proof is omitted) suggests that the dichotomic approach should be more efficient than the two other ones.

Proposition 1. *Let $P = (\mathcal{X}, \mathcal{C})$ be an unsatisfiable CN. The worst-case number of calls to MAC is $O(e \cdot k_e)$ for csMUC(P), $\theta(e)$ for dsMUC(P) and $O(\log(e) \cdot k_e)$ for dcMUC(P). Here, $e = |\mathcal{C}|$ and k_e is the number of constraints of the extracted MUC.*

To be more precise, we obtain a worst-case number of calls to MAC by dcMUC bounded by $\log_2(e) \cdot (k_e + 1)$ (+1 since we have to prove that the k_e transition constraints form a MUC). It can be compared with QuickXplain whose worst-case complexity is $2k_e \cdot \log_2(e/k_e) + 2k_e$ [12]. In the worst-case, dcMUC is better than QuickXplain when $(\log_2(k_e) - 1) \cdot 2k_e / (k_e - 1) < \log_2(e)$, that is to say, when the size of the extracted core is rather small. This condition holds for all the instances that have been tested in our experimentation. Also, considering the illustration given in [12] with $e = 2^{20}$ and $k_e = 2^3$, we obtain 288 calls with QuickXplain against 180 calls with dcMUC.

Finally, for efficiency reasons, it is really important to use, in practice, a conflict-based approach (function *wcore*) before extracting a MUC (function *xxMUC*). This will be shown in Section 6. The methods that we consider are then (given a constraint network P):

- CS which corresponds to call csMUC(*wcore*(P))
- DS which corresponds to call dsMUC(*wcore*(P))
- DC which corresponds to call dcMUC(*wcore*(P))

Even if it does not explicitly appear above, we will consider that all constraints are renamed, before calling xxMUC, in such a way that the lexicographic order corresponds to the decreasing order of the current weights of the constraints. It allows to improve the methods by limiting the number of runs performed. Note also that we can arbitrarily bound the number of calls to MAC by *wcore* in order to have Proposition 1 hold for CS, DS and DC. In practice, we have observed that the number of calls to MAC by *wcore* is always low.

5 Related Work

On the one hand, research in extraction of unsatisfiable cores of constraint networks is rather limited. Bakker et al. [1] have proposed a method to extract a MUC (in the context of Model-Based Diagnosis). This method essentially corresponds to call dsMUC(*pcore*(P)). Our approach can then be seen as a refinement³ of theirs since we propose

³ It is also important to note that weights introduced in [1] correspond to static preferences given by the user.

a dichotomic approach (dcMUC) and a conflict-based preliminary stage (*wcore*) whose practical importance will be shown in Section 6. Some other works [11, 21] concern the identification of minimal II conflict-sets where II denotes a propagation operator. Roughly speaking, while extracting a MUC is an activity which is global to the network, extracting a II conflict-set is an activity limited to a branch of the search tree. As a consequence, in order to keep some incrementality of the propagation process, the proposed algorithms in [11, 21] involves (at least, partially) a constructive schema. The (new) method QuickXplain [12] exploits a divide and conquer approach (which exploits a dichotomic process) and whose complexity has been discussed in Section 4.2. A similar approach, called XC1, has been proposed in [18] in a more general context.

On the other hand, research in unsatisfiable cores for propositional satisfiability (SAT) is quite active. Bruni and Sassano [3] have proposed an “adaptive core search” to recover a small unsatisfiable sub-formula. Clause hardness are evaluated thanks to an history search analysis. By selecting a fixed percentage of hard clauses, the current unsatisfiable core is expended or contracted until the core becomes unsatisfiable. In [23], using a resolution proof based approach, the Zchaff solver is extended for approximating an unsatisfiable core (i.e. the returned unsatisfiable core is not guaranteed to be minimal). Finally, Lynce and Marques-Silva [15] have proposed a model that computes a *minimum* unsatisfiable core (i.e. the smallest unsatisfiable core in the number of clauses).

6 Experiments

In order to show the practical interest of the approach described in this paper, we have conducted an experimentation, using for each run MAC-dom/wdeg, on a PC Pentium IV 2.4GHz 512Mo under Linux. Performances have been measured in terms of the number of runs (#runs) and the cpu time in seconds (cpu). We also indicate the number of constraints (#C) (and, sometimes, of variables (#V)) of instances and extracted cores.

Our experimentation has been performed wrt some random and real-world instances. The random instances correspond to the unsatisfiable instances of two sets, denoted *ehi-85-297* and *ehi-90-315*, containing 100 easy random instances embedding a small unsatisfiable part. The real-world instances correspond to the two archives RLFAP and FAPP. The selected unsatisfiable instances of the Radio Link Frequency Assignment Problem (RLFAP) came from the CELAR (Centre electronique de l’armement) while the instances of the Frequency Assignment with Polarization Problem (FAPP) came from the ROADEF’2001 challenge. Most of these instances were used as benchmarks⁴ for the first CSP solver competition.

Instance	<i>pcore</i>		<i>wcore</i>	
	cpu	#C	cpu	#C
<i>qk-25-25-5-mul</i> (#C = 435)	100.1	427	107.7	32
<i>ehi-85-297-0</i> (#C = 4, 094)	2.93	3, 734	3.01	226
<i>graph-14-f28</i> (#C = 4, 638)	4.23	3, 412	4.69	503

Table 1. Cost (cpu) and Size (#C) of cores extracted by *pcore* and *wcore*

First, we have studied the practical interest of calling *wcore* instead of *pcore*. Table 1 indicates the size of the cores extracted by both methods wrt some instances. One can observe that it is really worth using *wcore* since the size of the extracted core can be very small and the additional cost of performing successive runs is not penalizing (the cost for *wcore* is given for all performed runs). It is

⁴ <http://cpai.ucc.ie/05/Benchmarks.html>

illustrated with one queens-knights instance, one random 3-SAT instance and one RLFAP instance. Note that, for some other instances, the gap between the two methods is negligible.

Then, we have compared DC with CS and DS. On random EHI instances (mean costs are given in the first part of Table 2), the difference between DS and DC is not very important. It can be explained by the fact that the extracted core returned by *wdeg* is already small (it has been observed on all EHI instances but not on all tested real-world instances). However, on RLFAP and FAPP instances (see second and third parts of Table 2), DC clearly outperforms CS and DS. Both, in terms of cpu and number of runs, DC is about 10 times more efficient than CS and DS. We have obtained this kind of results on about half the RLFAP and FAPP instances that we have tested.

Instance	Method	cpu	#runs	MUC	
				#V	#C

#C = 6071	DC	119	46	4	4

Table 2. Extracting a MUC from EHI, RLFAP and FAPP instances

Finally, we have used the three methods in order to iteratively remove, until satisfiability is reached, disjoint MUCs (i.e. MUCs that do not share any constraint) from two RLFAP instances. It takes about 5 minutes to reach this goal with DC. Remark that there are about 40 and 130 constraints involved in the set of disjoint MUCs extracted from *graph05* and *scen11-f10*, respectively. It represents about 3.5% of the set of constraints of each instance.

Instance	Method	cpu	#runs	#MUCs
<i>graph05</i>	CS	5,175	8,825	5
#V = 200	DS	1,996	2,010	5
#C = 1134	DC	330	526	5
<i>scen11-f10</i>	CS	1,491	3,840	5
#V = 680	DS	3,040	2,452	5
#C = 4103	DC	263	562	5

Table 3. Extracting successive MUCS from RLFAP instances

7 Conclusion

In this paper, we have presented a new approach, denoted DC, that allows extracting MUCs from constraint networks. The originality of this approach is that it exploits the recent heuristic *dom/wdeg* in order to surround an unsatisfiable core by performing successive complete runs of MAC, and a dichotomic search in order to identify the successive transition constraints belonging to a MUC. We have introduced both theoretical and practical arguments to support our

approach. In particular, the worst-case number of calls to MAC of DC is bounded by $\log_2(e) \cdot (k_e + 1)$, and DC has appeared to be quite efficient with respect to real-world instances taken from the RLFAP and FAPP archives. Indeed, a MUC has been extracted from most of these instances in less than 1 minute. In comparison, it is worth mentioning that most of the instances that have been experimented in this paper can not be solved, in a reasonable amount of time, when using standard variable ordering heuristics (see [2, 14]).

Preference-based Inconsistency Proving: When the Failure of the Best Is Sufficient

Ulrich Junker¹

Abstract. Inconsistency proving of CSPs is typically achieved by a combination of systematic search and arc consistency, which can both be characterized as resolution. However, it is well-known that there are cases where resolution produces exponential contradiction proofs, although proofs of polynomial size exist. For this reason, we will use optimization methods to reduce the proof size globally by 1. decomposing the original unsatisfiability problem into a conjunction of satisfiable subproblems and by 2. finding an ordering that separates the solution spaces of the subproblems. This principle allows Operation Research methods to prove the inconsistency of overconstrained linear programs even if domains are infinite. We exploit the principle for testing the satisfiability of global user requirements in product configuration problems.

1 Introduction

Many applications of constraint programming combine a generic constraint model with specific user requirements, which easily leads to overconstrained constraint satisfaction problems (CSP). For example, scheduling problems have no solution if due dates are too tight. And it may not be possible to configure a product that satisfies all user wishes, while respecting a limited budget.

The inconsistency of such a problem can be proved by a solver that maintains arc consistency (MAC) during a systematic and exhaustive tree search. MAC eliminates locally inconsistent variable-value assignments in each search node. Search then picks a still undecided variable-value assignment and makes it true in one child node and false in the other one. If all possible values of a variable have been eliminated in a search node, then the problem of this search node is arc inconsistent. The inconsistency is proved if each leave of the search tree is arc inconsistent. We can characterize the inconsistency proof by labelling each node of the search tree by the sequence of variable-value eliminations that have been effectuated in this node. The size of the proof (i.e. the number of all eliminations summed over the whole tree) is a good measure for the effectiveness of the MAC-based prover and allows us to identify problematic cases:

1. *Polynomial proof size*: arc consistency is a complete method for proving the inconsistency of tree-like constraint graphs. Although arc consistency is polynomial, it can lead to too much overhead if the variable domains and the relations of the constraints are large. This can happen in configuration problems when the complete product catalogue of a database is mapped to a CSP.
2. *Exponential proof size*: the well-known resolution principle has an exponential proof complexity as demonstrated by examples such as the pigeon-hole problem. MAC limited to binary constraints is a form of resolution and cannot do better.

3. *Infinite proof size*: the Tarski-like fixpoint definition of arc consistency can be generalized for constraints on variables with infinite domains. In this case, arc consistency as well as bound consistency can lead to an infinite number of value removals. As example, consider two integer variables x and y that are greater than 1 and the constraints $x \geq 2 \cdot y$ and $y \geq 2 \cdot x$.

Can we obtain shorter proofs if we use other proof principles? Indeed, many customized constraint propagation algorithms internally exploit dominance principles and solve optimization subproblems to test satisfiability. This applies to numerical constraints such as $x + y \leq z$. We determine the smallest value for z under $x, y \in [40, 80]$ when checking the consistency of the upper bound of $z \in [20, 60]$. The smallest value 80 for z is obtained for $x = 40$ and $y = 40$. Since it exceeds the upper bound of 60, any other value for x and y will also lead to a value for z that exceeds 60. We can thus reduce the proof size by checking only the smallest values for x and y .

Linear programming solvers proceed in a similar way when proving the unsatisfiability of overconstrained linear programs. They relax some of the constraints and replace them by an optimization objective. They use this objective to determine a best solution of the remaining constraints. If this best solution violates a relaxed constraint, then no solution exists. This approach works even if domains are infinite. Even global constraints such as constraints of all-difference of n variables solve a maximal flow optimization subproblem to find inconsistency proofs of polynomial size for pigeonhole-like problems.

In contrast to arc consistency (AC), those methods do not inspect each possible domain value. Indeed they decompose the original problem into a conjunction of two satisfiable subproblems and they determine an ordering on the possible assignments that permits a separation of the solution spaces of the two subproblems. It is then sufficient to show that the best value of one problem is worse than the worst value of the other problem. Usually one order is determined by exploiting some monotonicity property of some of the constraints.

In this paper, we give a general formulation of this separation principle based on arbitrary partial orders (Sections 3 and 4). We no longer require that the order can be expressed in form of a ranking or utility function. We thus gain in terms of flexibility for relaxing constraints. For example, we can use Pareto-dominance for relaxing bound constraints on multiple criteria. We can use CP-nets [2] to relax conditional constraints. In Section 5, we apply this theoretical framework to a practical case, namely the configuration of multiple product components under global resource constraints (such as the sum of the prices of all devices of my home cinema must not exceed my budget). Although AC is sufficient in this case, it leads to a high overhead. PrefAC [1] uses preferences to reduce this effort for arc consistent CSPs, but will converge with AC on arc inconsistent CSPs. However, we can generate preferences from global resource

¹ ILOG S.A., France, email: ujunker@ilog.fr

constraints and reduce the effort to those solutions of the remaining constraints that are the best ones w.r.t. those preferences. Thus we can significantly reduce the size of inconsistency proofs (in particular if there is a single best solution). The approach also promises an effective incorporation of databases into CSPs, in particular if the subproblem consists of a single, but large table constraint that models a product catalogue. Recent work on preference databases fits in neatly and allows the calculation of the Pareto-frontier of such a catalogue (cf. e.g. [4]). The separation principle can also be used to generate comprehensive explanations of failure for those kind of problems since the results of the optimization subproblems provide useful information for understanding the nature of the failure.

2 Constraints and Preferences

Throughout this paper, we consider a finite set of variables \mathcal{X} where each variable $x \in \mathcal{X}$ has a domain $D(x)$ (e.g. the set of integers between 0 and 1000). Each value $v \in D(x)$ defines a possible value assignment $x = v$ to x . A set that contains exactly one of those value assignments for each variable in \mathcal{X} and that contains no other elements is called an *assignment* to \mathcal{X} . The set of all assignments to \mathcal{X} is called the *problem space* of \mathcal{X} and we denote it by $\mathcal{S}(\mathcal{X})$. Given an assignment σ to \mathcal{X} we can project it to a subset Y of the variables be defining $\sigma[Y] := \{(x = v) \in \sigma \mid x \in Y\}$.

We can restrict the problem space of \mathcal{X} by defining constraints on variables in \mathcal{X} . A constraint c has a scope $X_c \subseteq \mathcal{X}$ and a ‘relation’ which we express by a set R_c of assignments to the scope X_c . This set can be specified explicitly in form of a table where each column corresponds to a variable in X_c , each row corresponds to an assignment in R_c , and the value v from a value assignment $(x = v) \in \sigma$ is put in the cell for column x and row σ . The relation R_c can also be specified by a logical formula that involves the variables from X_c and the operations from a given mathematical structure over the variable domains. A *constraint satisfaction problem* CSP for \mathcal{X} is given by a finite set of constraints \mathcal{C} the scopes of which are all subsets of \mathcal{X} . A CSP is finite if all its domains and relations are finite. A constraint c is satisfied by an assignment σ to \mathcal{X} iff $\sigma[X_c]$ is an element of R_c . An assignment σ is a *solution* of \mathcal{C} iff it satisfies all constraints of \mathcal{C} . If a CSP has no solution then it is called inconsistent. It is often convenient to replace a CSP \mathcal{C} by the conjunction $\bigwedge_{c \in \mathcal{C}} c$ of its constraints. Hence all definitions and propositions referring to constraints C_1, C_2 can also be applied to CSPs.

We now define preference orderings on a problem space. In decision theory, preferences can be modelled in form of a complete preorder \succsim that can be decomposed into a strict part \succ and indifference \sim . In this paper, we are only interested in strict preferences and we suppose that these preferences can be specified in an incomplete way, which allows us to refine them. The absence of a strict preference between two alternatives thus can either signify indifference or incompleteness. Hence, we specify preferences in form of a strict partial order \succ on the assignments to \mathcal{X} . We write $\sigma_1 \succeq \sigma_2$ as a short-hand for $\sigma_1 \succ \sigma_2$ or $\sigma_1 = \sigma_2$. We also consider the inverse order \prec . We have $\sigma_1 \prec \sigma_2$ iff $\sigma_2 \succ \sigma_1$. We say a solution σ of C is a \succ -best (\succ -worst or \prec -best) solution of C iff there is no other solution σ^* of C s.t. $\sigma^* \succ \sigma$ ($\sigma^* \prec \sigma$).

Although a strict partial order \succ on the assignments to \mathcal{X} has an exponential size in general, there are interesting cases allowing a polynomial representation, in particular if a subset X of variables is preferentially independent from its complement. In this case, $A \cup C \succ B \cup C$ is equivalent to $A \cup D \succ B \cup D$ for all assignments A, B to X and all assignments C, D to $\mathcal{X} - X$. The projection $\succ_{[X]}$

of the partial order \succ on the variables X is well-defined in this case. We simply define $A \succ_{[X]} B$ iff there exists C s.t. $A \cup C \succ B \cup C$.

Pareto-dominance naturally meets this independence condition. Given two strict partial orders \succ_1, \succ_2 on two disjoint sets of variables X_1, X_2 , we say that an assignment σ_1 to $X_1 \cup X_2$ dominates an assignment σ_2 to $X_1 \cup X_2$ in the Pareto-sense iff 1. σ_1 is different from σ_2 and 2. σ_1 is better than or equal to σ_2 on X_1 (i.e. $\sigma_1[X_1] \succeq_1 \sigma_2[X_1]$) and σ_1 is better than or equal to σ_2 on X_2 (i.e. $\sigma_1[X_2] \succeq_2 \sigma_2[X_2]$). We can apply this combination in an inductive manner to n strict partial orders, namely one for each variable in \mathcal{X} .

We also consider the case where the strict partial order is the strict part of a complete preorder. It is called a *ranked order* in this case, which is a strict partial order satisfying the following property for all assignments $\sigma_1, \sigma_2, \sigma_3$: if $\sigma_1 \succ \sigma_2$ then either $\sigma_3 \succ \sigma_2$ or $\sigma_1 \succ \sigma_3$. Ranked orders can be represented by utility functions u that map assignments to a numerical value s.t. $u(\sigma_1) > u(\sigma_2)$ iff $\sigma_1 \succ \sigma_2$.

3 Preference-based Separation

Given a set of constraints \mathcal{C} , we either want to prove that \mathcal{C} has no solution or find a solution of \mathcal{C} . Systematic search methods solve this problem by exploring alternative ways to tighten it, e.g. by choosing a variable x and by adding the constraint $x = v$ for different values v to \mathcal{C} . An alternative way is to relax certain constraints by using some preference order \succ . For example, if we want to book a hotel for each guest, but the cheapest hotel exceeds the budget of the richest guest, then there is no solution to the problem. Here, we relax some of the constraints in a way such that we consider only the \succ -best solutions of those constraints and we relax other constraints such that we consider only the \succ -worst solutions of those constraints. To formalize this, we use a preference order \succ to define a relaxation of a constraint C , i.e. a constraint C' such that $R_C \subseteq R_{C'}$:

Definition 1 Let \succ be a strict partial order and C a constraint. We define the \succ -relaxation C^\succ as the set of all assignments that are equal or worse (w.r.t. the order \succ) than a solution of C .

We can uniquely characterize a \succ -relaxation as follows:

Proposition 1 The \succ -relaxation of C is the greatest relaxation of C that has the same \succ -best solutions as C .

We now consider two constraints C_1 and C_2 and want to determine whether they have a common solution. Given an order \succ , we perform this test for the \succ -relaxation of C_1 and the \prec -relaxation of C_2 . Hence, the same order is used to determine a relaxation of C_1 and of C_2 . Figure 1 illustrates these relaxations for a Pareto-order obtained by combining the increasing order on x with the increasing order on y . We show the Pareto-frontier which is spanned by the \succ -best solutions of C_1 and the Pareto-frontier which is spanned by the \prec -best solutions of C_2 . Both relaxations have a common solution iff the Pareto-frontiers intersect:

Proposition 2 (Separation principle) Let \succ be a strict partial order and C_1, C_2 two constraints. $C_1^\succ \wedge C_2^\prec$ is consistent if and only if there is a \succ -best solution σ_1 of C_1^\succ and a \succ -worst solution σ_2 of C_2^\prec such that $\sigma_1 \succeq \sigma_2$.

Proof: (\Rightarrow) If σ is a solution of $C_1^\succ \wedge C_2^\prec$ then it is \succ -worse than or equal to a \succ -best solution σ_1 of C_1^\succ and \succ -better than or equal to a \succ -worst solution σ_2 of C_2^\prec . Hence, we get $\sigma_1 \succeq \sigma \succeq \sigma_2$. (\Leftarrow) Since σ_1 is a best solution of the \succ -relaxation C_1^\succ and σ_2 is \succ -worse than σ_1 , the solution σ_2 of C_2^\prec satisfies C_1^\succ as well, meaning that the conjunction of both constraints is consistent. \square

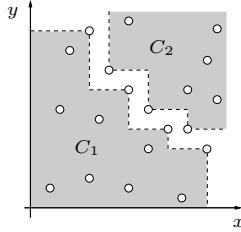

Figure 1. Pareto-dominance as a separating order.

As a corollary, we can state that if no \succ -best solution σ_1 of C_1 and no \succ -worst solution σ_2 of C_2 satisfy $\sigma_1 \succeq \sigma_2$, then $C_1 \wedge C_2$ is inconsistent. This gives a sufficient condition for inconsistency, but not a necessary one. If an order \succ satisfies this sufficient condition, then we call it a *separating order* for C_1 and C_2 . For ranked orders we can limit the test for separating orders to a single solution:

Proposition 3 *Let \succ be a ranked order. If a \succ -best solution of C_1 is strictly worse than a \succ -worst solution of C_2 then all \succ -best solutions of C_1 are strictly worse than all \succ -worst solutions of C_2 .*

As an example for a ranked separating order, consider two constraints $x = 2 \cdot y + 7$ and $x = 2 \cdot y + 4$ on integer variables x, y . Let $\sigma_1 \succ \sigma_2$ iff σ_1 assigns an even value to x and σ_2 assigns an odd value to x .

It is easy to show that a separating order for C_1 and C_2 exists whenever $C_1 \wedge C_2$ is inconsistent. We can, for example, label the solutions of C_1 by 1 and the solutions of C_2 by -1 and use this label as ranking function. Those labels provide a proof why no solution exists. For establishing this proof, we still need to compute each solution of C_1 and each solution of C_2 . Hence, we do not gain much for inconsistency proving if the separating order is defined in terms of both C_1 and C_2 and depends on the combination of both constraints. In the next section, we explore cases where a separating order can be defined in terms of only one of the constraints.

4 The Best-Fail Principle

In many cases, the solution space of a constraint satisfies some global properties. If an assignment $\{x = v, y = w\}$ satisfies the constraint $x \geq y$ then we know that all other assignments $\{x = v', y = w'\}$ with $v' \geq v$ and $w \geq w'$ satisfy the constraint as well. Those dependencies can be characterized in form of a preference order on the problem space. We prefer assignments that satisfy the constraint to assignments that violate it. In other words, if an assignment satisfies a constraint then all better assignments need to satisfy it.

Definition 2 *A strict partial order \succ is a preference order for a constraint C iff all assignments σ_1, σ_2 satisfy the following property: if $\sigma_1 \succ \sigma_2$ and σ_2 satisfies C then σ_1 satisfies C .*

Hence, the truth function of a constraint is anti-monotonic w.r.t. its preference order. Preference orders capture dominance phenomena and classical styles of relaxations such as Lagrangian relaxation.

The constraint $e(x) \leq b$ has the preference order \succ_e that prefers smaller values of the expression $e(x)$. Hence, $\sigma_1 \succ_e \sigma_2$ holds iff $(x = v_1) \in \sigma_1, (x = v_2) \in \sigma_2$, and $e(v_1) < e(v_2)$. This case covers linear and non-linear inequalities. Multiple inequalities of the form $\bigwedge_i e_i(x) \leq b_i$ have the Pareto combination of $\succ_{e_1}, \dots, \succ_{e_n}$ as a preference order, but the order \succ_e obtained from an additive sum $e(x) := \sum_i \lambda_i \cdot e_i(x)$ is not a preference order for this conjunction.

Conditional expressions such as $\text{if } c(y) \text{ then } e_1(x) \text{ else } e_2(x)$ can be handled by context-dependent preferences as expressible in CP-nets. We can combine preference orders for boolean expressions:

Proposition 4 *If \succ is a preference order for constraint C then \prec is a preference order for $\neg C$. If \succ_1 is a preference order for constraint C_1 and \succ_2 is a preference order for constraint C_2 , then $\succ_1 \cap \succ_2$ is a preference order for $C_1 \wedge C_2$ and for $C_1 \vee C_2$.*

We also obtain a second characterization of \succ -relaxations.

Proposition 5 *A constraint C is equal to its \prec -relaxation C^\prec iff \succ is a preference order of C .*

Hence, preference orders can directly be used as separating orders. Interestingly, a preference order \succ of C_2 is a separating order for C_1 and C_2 and this is independent of the properties of C_1 . Furthermore, we can simplify the separation principle for preference orders. It is sufficient to check whether the best solutions of C_1 satisfy C_2 .

Proposition 6 (Best-fail principle) *Let \succ be a preference order for C_2 . $C_1 \wedge C_2$ is consistent if and only if there is a \succ -best solution σ^* of C_1 that satisfies C_2 .*

Proof: (\Rightarrow) Let σ be a solution of $C_1 \wedge C_2$. There exists a \succ -best solution σ^* of C_1 such that $\sigma^* \succeq \sigma$. We show that σ^* satisfies C_2 by distinguishing two cases: 1. If σ^* is equal to σ then σ^* satisfies C_2 since σ does so. 2. If σ^* is different from σ then $\sigma^* \succ \sigma$. Since \succ is a preference order for C_2 and σ satisfies C_2 , σ^* must satisfy C_2 . (\Leftarrow) since σ^* satisfies both C_1 and C_2 the conjunction $C_1 \wedge C_2$ is consistent. \square

For ranked orders, it is sufficient to check a single solution.

Proposition 7 *Let \succ be a ranked preference order for C_2 . $C_1 \wedge C_2$ is inconsistent iff there is a \succ -best solution of C_1 that violates C_2 .*

Hence, to prove the inconsistency of $C_1 \wedge C_2$ it is sufficient to show that all \succ -best solutions of C_1 violate C_2 . We thus reduce the unsatisfiability problem to an optimization problem. An inconsistency proof can be represented by the set of \succ -best solutions of C_1 (or a single best solution for ranked orders).

The best-fail principle can immediately be applied to scheduling and configuration problems that are inconsistent due to tight bound constraints. For example, job-shop scheduling problems are guaranteed to have solutions if all due date constraints are relaxed. Similarly, it is a natural assumption that product configuration problems without user requests have solutions and user requests have the form of bound constraints on global criteria in many interesting cases.

The best-fail principle also generalizes the way in which LP solvers prove the unsatisfiability of overconstrained linear programs. The solver does not solve the original problem, but a dual problem where all constraints are relaxed and the objective consists in maximizing the satisfaction of the constraints. We can generalize this dual solving by the following sequential process. Initially, we relax all of the given n constraints c_1, \dots, c_n . We will step by step add constraints to a pool C_i and maintain a solution σ_i of the pool C_i . We start with the empty pool $C_0 = \emptyset$ and an arbitrary assignment σ_0 . In the i -th step, we try to add the constraint c_i if it is consistent w.r.t. the pool C_{i-1} . To test this, we generate a preference order \succ_i for c_i and determine the \succ_i -best solutions of C_{i-1} . If they all violate c_i then we have proved that the constraints c_1, \dots, c_n are inconsistent. If one of the optimal solution satisfies c_i , then we add c_i to the pool by doing $C_i := C_{i-1} \cup \{c_i\}$ and we set σ_i to this solution.

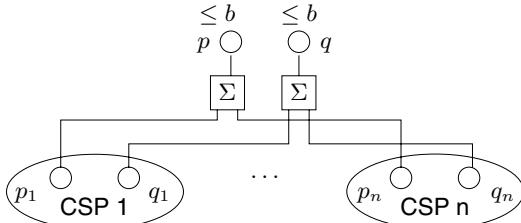

Figure 2. Configuration problem with resource constraints

When solving the optimization subproblem, we can profit from the fact that σ_{i-1} is a solution of C_{i-1} . We can use this as a starting point for the optimization. Indeed, the problem consists in finding one (or all) solutions of C_{i-1} that improve a solution σ w.r.t. the preferences \succ_i . This is a kind of generalized pivot operation and the problem can be solved efficiently for linear constraints (and other constraints having a convex shape). Hence, the best-fail principle provides an effective generalization of the ‘dual’ constraint solving iff all constraints have suitable preference ordering and the optimization subproblem can efficiently be solved for those preferences.

5 Best-Fail for Global Resource Constraints

As optimization problems are often solved by a sequence of satisfiability problems, it is not evident to ensure that the optimization problem C_1 can be solved faster than solving the original satisfiability problem $C_1 \wedge C_2$. A significant speed-up can be obtained for the optimization problem iff this problem breaks down into several independent subproblems. This is the case for an important class of configuration problems.

Many configuration problems (e.g. simple shopping baskets) involve the configuration of multiple key components. For example, my audio/video system may consist of a TV, DVD player, a tuner, and so on. Those key components are designed in a way such that we can choose them from different product catalogues and combine them without facing technical incompatibilities. Each key component may have a huge number of possible configurations and we would like to configure each of these components independent of the other ones in order to obtain an additive complexity. However, there are non-technical constraints that need to be respected by the whole system. These are the user requirements on global properties such as the total price and the total quality of the system.

We illustrate the difficulties of these configuration problems by using a fictive travel planning example. It corresponds to an extreme case which is nevertheless instructive and its pattern can occur in more complex scenarios: *Space voyager LJ will visit the planets 1 and 2 of the All-Value-Galaxy and seeks a Hotel close to a sea resort on both planets. Hotels in the All-Value-Galaxy try to distinguish themselves by different prices, qualities, beach distances and so on. Due to the huge number of hotels, we can find a hotel for nearly every value of each criterion as long as this value is within a given range. And moreover, we can find all price/beach-distance combinations within a given region in the problem space except for some exceptions. Figure 3 shows those regions for the planets 1 and 2. The forbidden combinations are crossed out. LJ has a total budget of $b := 1200$ Star dollars and wants to keep the total sum of beach distances smaller than 1200 m. According to Figure 3, planet 1 has hotels for 300 dollars and planet 2 has hotels for 200 dollars. Hence the global budget constraint can be met if we ignore the beach-distance*

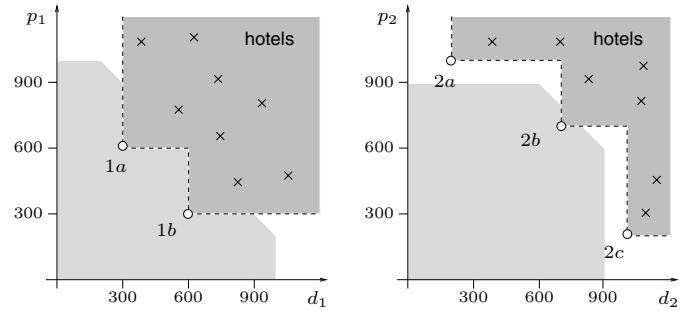

Figure 3. Price-distance constraint for planet 1 (left) and planet 2 (right).

requirement. Similarly, we can meet the beach distance requirement if we forget about the budget. But can we meet both requirements?

To answer this question, we set up a CSP. Since the only dependencies between the different hotel choices are the global resource constraints we obtain a structured CSP as depicted in Figure 2. It consists of n sub-CSPs, namely one for each key component. In the general case, the sub-CSP can involve multiple variables and constraints. In our simple example, the i -th sub-CSP consists of a single constraint representing the hotel catalogue of the i -th planet. It has variables such as product identifier, price, quality, and so on. The prices of the different components are summed up to compute the total price which is submitted to user requirements (e.g. an upper bound on the total price). We obtain a similar resource constraint for the total distance.

A naive method to solve the problem will determine the set of all configurations for each component and then tries to combine them in a way to meet the global resource constraints. In our example, the configurations for a single component are already provided by the t catalog entries. The number t is close to b^2 in the considered example. We then obtain a multiplicative complexity of $O(t^n)$ in order to solve the entire problem which includes the global resource constraints. Our purpose is to achieve a complexity of $O(n \cdot t)$ which is additive for the subproblems.

If there is a single global resource constraint, such an additive approach is easy to figure out. Suppose that there is only one global requirement $\sum_j x_j \leq b$, say on the price. Then the CSP is inconsistent if and only if the sum of the cheapest solutions of each sub-CSP exceeds the given maximum price. Hence, it is sufficient to determine the cheapest entry of each product catalogue, which is linear in the number t of catalogue entries (or even faster if the product catalogue is available in form of a data-base with suitable indexing structure). In this case, we have mapped the unsatisfiability problem into n optimization subproblems by relaxing the maximum price constraint. Each optimization subproblem can be solved in $O(t)$ which leads to the desired additive complexity.

Multiple requirements of the form $y_i \leq b_i$ where $y_i = \sum_j x_{i,j}$ lead to multiple criteria y_i each of which need to be minimized. There are different ways to combine these criteria to a preference order on assignments. We are not satisfied by an arbitrary aggregation of the individual preferences, but want to establish a preference order for the sum-constraint as required by definition 2.

A popular method is the Lagrangian relaxation, which seeks a positive weight λ_i for each criterion and uses the additive utility function $\sum_i \lambda_i \cdot y_i$ to define the global order. However, this leads to a large relaxation which may indeed intersect with the non-relaxed constraints although no solution exists. We can also look at the convex hull of

the relaxed constraints, but it is not easy to define the corresponding order. Indeed, we first need to compute the convex hull and then define the order. Again, this relaxation may be too large as demonstrated by the example. First, we determine the convex hull of the hotels on planet 1. We are then interested in the region of all points $(b - v, b - w)$ which is left over if any hotel (v, w) from this convex hull is chosen. It is clear that a hotel from planet 2 needs to fall into this second region to guarantee the existence of a solution. The right part of Figure 3 shows this region in light Grey. It contains the hotel $2b$, meaning that there might be a solution. Hence, the convex hull is not sufficient to prove the unsatisfiability of our example.

The Pareto-order does not have these problems since it is a preference order of a conjunction of inequalities of the form $y_i \leq b_i$. Hence, it leads to a relaxation that is equal to the solution space of this conjunction. As for the classical relaxations based on a single criterion, there is no solution if the solution space of the relaxed constraints does not intersect with the non-relaxed constraints. In contrast to the Lagrangian relaxation, the other direction holds as well: *if there is no solution then there is no intersection*.

Pareto-dominance thus allows us to apply the best-fail principle if we want to relax multiple resource constraints. In the example, we relax both the price and distance requirements simultaneously. We then need to determine all combinations of component configurations which are Pareto-optimal w.r.t. the minimization of the four variables p_1, p_2, d_1, d_2 . Since the global constraints are all relaxed, the non-relaxed constraints split into n independent subproblems based on the following result:

Proposition 8 *Let \mathcal{X} be a set of variables. Let C_1, \dots, C_n be constraints on variables from \mathcal{X} such that C_i and C_j have disjoint variables for $i \neq j$. Suppose that \succ is a strict partial order such that $X(C_i)$ is preferentially independent from $\mathcal{X} - X(C_i)$ for all i . Then σ is a \succ -preferred solution of $\bigwedge_i C_i$ iff $\sigma[C_i]$ is a $\succ_{[X(C_j)]}$ -preferred solution of C_i for all $i = 1, \dots, n$.*

Hence, the decomposition is possible since the n subproblems do not have any variable in common and since the Pareto-dominance ensures that the price and distance variables of each subproblem are preferentially independent from the price and distance variables of the other subproblems.

The first subproblem consists in finding all hotels of planet 1 with minimal price and with minimal beach distance. All Pareto-optimal solutions with respect to both criteria need to be found. A similar task need to be solved for planet 2. For planet 1, we find two Pareto-optimal solutions, namely $(600, 300)$ and $(300, 600)$. For planet 2, we find three Pareto-optimal solutions, namely $(200, 1000)$, $(700, 700)$, and $(1000, 200)$. Any combination of those Pareto-optimal solutions leads to a Pareto-optimal solution for the conjunction of the sub-CSP1 and sub-CSP2 and the other direction works as well. Hence, the best solutions of the non-relaxed problem are given by:

$$\left(\begin{array}{l} (p_1 = 600 \wedge d_1 = 300) \vee \\ (p_1 = 300 \wedge d_1 = 600) \end{array} \right) \wedge \left(\begin{array}{l} (p_2 = 200 \wedge d_2 = 1000) \vee \\ (p_2 = 700 \wedge d_2 = 700) \vee \\ (p_2 = 1000 \wedge d_2 = 200) \end{array} \right)$$

It is easy to see that this is inconsistent w.r.t. $p_1 + p_2 \leq 1000$ and $d_1 + d_2 \leq 1000$. Hence, if the number of Pareto-optimal solutions of each subproblem is small, the problem breaks down. We still need to test all combinations of Pareto-optimal solutions (six in our example), but we can, for example, exploit arc consistency to filter the Pareto-optimal solutions of the subproblems. The following theorem applies the best-fail principle to decomposable problems and thus summarizes the approach of this section:

Theorem 1 *Let \mathcal{X} be a set of variables. Let C, C_1, \dots, C_n be constraints on variables from \mathcal{X} such that C_i and C_j have disjoint variables for $i \neq j$. Suppose that \succ is a preference order for C for which $X(C_i)$ is preferentially independent from $\mathcal{X} - X(C_i)$ for all i . The conjunction $C \wedge \bigwedge_i C_i$ is inconsistent iff there are no $\succ_{[X(C_j)]}$ -preferred solutions σ_i of C_i s.t. $\bigcup_i \sigma_i$ satisfies C .*

We also explain the cost for finding the Pareto-optimal solutions. In our example, we have two criteria and can thus use the algorithm from [6] (generalized to multiple criteria in [3]). It can be applied as follows: first we seek the best price p_1 starting from 1. If there is no support for the current price we increase it. Once we found the best price, we seek the best distance among the supports for this price. The result of this gives the first Pareto-optimal solution. We then check whether an increase of the price can reduce the distance. We repeat this procedure until no further increase of the price brings a reduction of the distance. We thus need to scan once over all possible values of the price and over all possible supports of each price. Hence, the complexity for computing the Pareto-frontier of one constraint is bounded by $O(b + t)$.

6 Conclusion

We have addressed an important limitation of classical relaxation techniques from Operations Research. Although those techniques are very effective in proving the unsatisfiability of overconstrained problems by relaxing some of the constraints and by replacing them by an optimization objective, they impose unnecessary restrictions on the form of the relaxation. In this paper, we profit from recent work on preferences in AI and in databases and develop a relaxation technique based on general partial orders. Based on this, we are able to use Pareto-frontiers to test the satisfiability of global resource constraints for product configuration problems. Proof complexity is rather reduced compared to pure AC-based methods and more comprehensive explanations for unsatisfiability are obtained. There is room to improve the approach and to reduce the Pareto-frontier in size, for example by further relaxing the constraints or by using indifference among values to tighten the preference orders of the constraints [5]. Furthermore, our preference-based relaxation framework also promises to produce relaxations for other forms of constraints such as conditional expressions.

Return of the JTMS: Preferences Orchestrate Conflict Learning and Solution Synthesis

Ulrich Junker and Olivier Lhomme¹

Abstract. We use a lexicographical preference order on the problem space to combine solution synthesis with conflict learning. Given two preferred solutions of two subproblems, we can either combine them to a solution of the whole problem or learn a ‘fat’ conflict which cuts off a whole subtree. The approach makes conflict learning more pervasive for Constraint Programming as it well exploits efficient support finding and compact representations of Craig interpolants.

1 Introduction

A justification-based truth maintenance system (JTMS) [6] allows a problem solver to record logical dependencies between deductions. A JTMS supports the retraction of constraints and provides explanations for the recorded deductions. The JTMS also introduced a technique which is now called conflict learning [10, 20]. Conflicts permit a search procedure to backtrack to the causes of a failure, while keeping choices in independent subproblems unchanged. As a consequence, we obtain an additive complexity instead of a multiplicative complexity for independent subproblems [9]. Although independent subproblems are frequent in configuration and design problems, they are rare in popular applications of Constraint Programming (CP) such as scheduling and resource allocation. Hence, conflict learning was seldom used in CP, although recent efforts are promising [14].

However, conflict learning proved to be essential for the recent success of SAT solvers [10, 20]. It can be observed that conflict learning reduces the complexity of a problem even if subproblems are not independent, but have some variables in common. Suppose a problem solver first determines a solution S_1 of subproblem $A(x, y)$ and then solves the subproblem $B(y, z)$ under the restrictions that S_1 imposes on the common variables y . If this restricted version of B has no solution, the problem solver backtracks and seeks a new solution S_2 of the subproblem A . It then solves subproblem B under the restrictions S_2 imposes on y . Hence, the subproblem B is solved several times and this for different solutions S_i of the subproblem A . Although these solutions are all different, their projection on the common variables y can be the same, meaning that the same restricted version of the subproblem B is solved again and again. This thrashing behaviour will in particular be very cumbersome if the whole problem has no solution and the whole solution space of A needs to be traversed. Conflict learning permits the problem solver to avoid this thrashing behaviour. If a subproblem B fails for a restriction C on the common variables y , the conflict $\neg C$ is incorporated into the problem A and avoids that solutions with restriction C on variables y are generated again. If the whole problem is inconsistent, then the set of learned conflicts is a Craig interpolant [4, 16]. Conflict learning thus permits a factorization of the problem solving. We can also

show that conflict learning behaves like a lazy version of bucket elimination [5] if the buckets are chosen as subproblems. Hence, conflict learning is exponential in the induced width [5, 8] in the worst-case.

JTMS thus well supports factorization of problems provided it uses a static preference ordering between variables as proposed in [17] when choosing the culprits to be retracted. Moreover, JTMS can be used to maintain a lexicographically preferred solution. As described in [6], non-monotonic justifications can be used to encode preferences between the different values of a variable, which leads to an ordered disjunction [3]. This mechanism always activates the best assignment for a variable that is not defeated by a recorded conflict. If this best assignment occurs in a new conflict, JTMS can retract this assignment and activate the next one. This procedure will finally result in a lexicographically preferred solution, which will be updated if new constraints are added (e.g. new conflicts learned from interactions with other problems). However, if variable domains are large, then this procedure may try out many value assignments. An activated value assignment $y = w$ will only be abandoned if it occurs in a conflict. When seeking a support for an assignment $x = v$ on the constraint $C(x, y)$, d such assignments $y = w_i$ may be tried out, meaning that d conflicts have to be learned.

Modern algorithms that maintain arc consistency (MAC) [19] directly seek supports (i.e. solutions of a single constraint) without needing to learn so many conflicts. Moreover, the preferences between values can be used to activate preferred supports [2]. Provided with an assignment $x = v$, the constraint $C(xy)$ can thus determine the preferred support (v, w) for $x = v$ and activate the assignment $y = w$ without trying out all better value for y . An even further idea is to synthesize the preferred supports from different constraints into a lexicographically preferred solution. PrefAC [2] has this behaviour for tree-like CSPs if parent variables are preferred to child variables. However, the activation of preferred supports gets blocked for cyclic constraint networks when different preferred supports activate different values for the same variable.

It is possible to learn a conflict in those situations. In this paper, we show how to combine solution synthesis and conflict learning. Consider again the two subproblems $A(xy)$ and $B(yz)$. We first determine a preferred solution S_1 for A . We then determine a preferred solution S_2 for B under the restriction that it must not be better than S_1 on the common variables y . If both solutions assign the same values to the common variables y , then we can synthesize them to a solution of the whole problem. Otherwise, we learn a ‘fat’ conflict that cuts off a whole subtree in the search space of y . All assignments between S_1 (projected to y) and S_2 (projected to y) are infeasible. Hence, less solutions of A need to be generated in turn and conflict learning becomes effective for CSPs even if domains are large. By introducing fat conflicts, we enable a return of the JTMS to CP.

¹ ILOG S.A., France, email: {ujunker, olhomme}@ilog.fr

The paper is organized as follows: Firstly, we introduce solution synthesis and conflict learning based on a lexicographical order and show how they can be used to decompose a problem into two subproblems. Secondly, we apply this decomposition recursively until we obtain buckets, i.e. constraints having a variable in common. We show how to solve the buckets by reducing lexicographical bounds.

2 Preference-based Interpolation

2.1 Constraints and Preferences

Throughout this paper, we consider combinatorial problems that are modelled by a set of constraints C formulated over a set of variables X having the domain \mathcal{D} . A variable x from X can be interpreted by any value v from the domain \mathcal{D} and we describe such a variable-value assignment by the constraint $x = v$. An *assignment* to X is a set that contains exactly one value assignment for each variable in X . The set of all assignments to X is called the *problem space* of X , and we denote it by $\mathcal{S}(X)$. We project an assignment σ to a set Y by defining $\sigma[Y] := \{(x = v) \in \sigma \mid x \in Y\}$. If the assignment σ contains $x = v$, we denote the value v of x by $\sigma(x)$. Furthermore, we define $\sigma(x_1, \dots, x_n)$ as the vector $(\sigma(x_1), \dots, \sigma(x_n))$.

A constraint c is specified by an n -ary set of variables X_c , called scope, and an n -ary ‘relation’ R_c , which is described by a subset of $\mathcal{S}(X_c)$. The relation can be specified by a predicate, a numerical or logical expression, a set of allowed tuples, or a set of forbidden tuples. An assignment σ to X is a *solution* of the constraint c iff $\sigma[X_c] \in R_c$ holds.

The set of variables of a set of constraints C is denoted by $X_C := \bigcup_{c \in C} X_c$. An assignment σ (to X) is a *solution* of the constraints C iff it is a solution of all constraints $c \in C$. It is often convenient to replace a constraint set C by the conjunction $\bigwedge_{c \in C} c$. Similarly, we can replace a conjunction $\bigwedge_{i=1}^k c_i$ be the set of its conjuncts $\{c_1, \dots, c_k\}$. All statements about the constraints C_1, C_2 can thus be applied to CSPs and vice versa. Two constraints C_1 and C_2 with same scope are equivalent iff they have the same solutions.

Throughout this paper, we assume that the user can express preferences between the possible values of a variable x_i and we consider some linearization $>_i$ of those preferences as indicated in [13]. Furthermore, we suppose that the user can express an importance ordering between the variables and we consider a linearization $>$ of this importance ordering (cf. [13]). The ordering $>$ can be used to sort a set of variables. Let $X^>$ denote the sorted vector $(x_{\pi_1}, \dots, x_{\pi_n})$ where X is equal to $\{x_1, \dots, x_n\}$ and π is the permutation of $1, \dots, n$ that satisfies $x_{\pi_1} > \dots > x_{\pi_n}$. We define the lexicographical ordering $>_{lex}$ between two vectors of values $v := (v_{\pi_1}, \dots, v_{\pi_n})$ and $w := (w_{\pi_1}, \dots, w_{\pi_n})$: $v >_{lex} w$ holds iff there exists an i among $1, \dots, n$ such that $v_{\pi_j} = w_{\pi_j}$ for $j = 1, \dots, i-1$ and $v_{\pi_i} >_{\pi_i} w_{\pi_i}$. A solution σ of C is called *preferred solution* of C iff there is no other solution σ^* s.t. $\sigma^*(X^>) >_{lex} \sigma(X^>)$. As in [13], we use an optimization operator $\text{Lex}(X^>)$ to describe the set of preferred solutions. The operator maps the constraint C to a new constraint $\text{Lex}(X^>)(C)$ that is satisfied by exactly the preferred solution of C . This notation allows us to reason about optimization results inside the constraint language.

The lexicographical ordering can be used to formulate a constraint in the constraint language. Let x be a sorted vector of variables and v be a sorted vector of values. The constraint $x >_{lex} v$ is equivalent to

$$\bigvee_{i=1}^n \left(\bigwedge_{j=1}^{i-1} x_{\pi_j} = v_{\pi_j} \wedge x_{\pi_i} >_{\pi_i} v_{\pi_i} \right) \quad (1)$$

We obtain similar constraints for \geq_{lex} , $<_{lex}$, and \leq_{lex} . The lexicographical constraint allows us to express a property which is fundamental for this paper. If σ^* is a solution of $\text{Lex}(X^>)(C)$ then C implies $X^> \leq_{lex} \sigma^*(X^>)$.

2.2 Solution Synthesis and Fat Conflicts

We now consider two sets of constraints C_1 and C_2 . Each set represents a subproblem. We will show how the whole problem $C_1 \cup C_2$ can be solved by solving the two subproblems independently. The only information that we exchange between the two subproblems are supplementary constraints that are formulated on the common variables of C_1 and C_2 , i.e. $X_{C_1} \cap X_{C_2}$. If the whole problem $C_1 \cup C_2$ is inconsistent, then it is well-known that there is a constraint C' that contains only the common variables, that is implied by C_2 , and that is inconsistent w.r.t. C_1 . The constraint C' is called a *Craig interpolant* [4, 16]. In this section, we will show that we can either synthesize two solutions of the subproblems into a solution of the whole problem or compute a Craig interpolant by generating a sequence of conflicts. We use the lexicographical preference ordering to determine which solutions and conflicts may be generated in each step.

We can only synthesize two solutions of the subproblems if the importance ordering $>$ on the variables ensures that the variables added by C_2 are less important than the variables in C_1 . We first lift the ordering on variables to sets of variables: $X_1 \succ X_2$ iff $x_i > x_j$ for all $x_i \in X_1, x_j \in X_2$. We then extend it to constraints:

Definition 1 A constraint C_1 is more important than a constraint C_2 in the ordering $>$, written $C_1 \succ C_2$, iff $X_{C_1} \succ X_{C_2} - X_{C_1}$.

An example is given be the two constraints in table 1. The domain is $\mathcal{D} := \{1, 2, 3\}$. Greater values are preferred for all variables and the variables are ordered as follows: $x_1 > x_2 > x_3 > x_4$.

From now on, we suppose that C_1 is more important than C_2 . In section 3.1, we will show that we can always find subproblems that meet this condition. In the sequel, we write X_1 for the ordered tuple of variables $X_{C_1}^>$ of C_1 , X_2 for the ordered tuple of variables $X_{C_2}^>$ of C_2 , Δ for the ordered tuple of variables $(X_{C_1} \cap X_{C_2})^>$ occurring in both subproblems, and Ω for the ordered tuple of variables $(X_{C_1} \cup X_{C_2})^>$ occurring in the whole problem.

We start the whole solving process by seeking a preferred solution for the first subproblem C_1 . If this problem is inconsistent, then $C_1 \cup C_2$ is inconsistent as well. Hence, the failure of the first subproblem leads to a global failure and we can stop in this case.

If the first subproblem has the preferred solution σ_1 , then we project it on the common variables by taking $\sigma_1(\Delta)$. If we want to find a solution σ_2 of the second subproblem that is compatible with σ_1 , then this other solution cannot be lexicographically better than σ_1 on the common variables Δ . Indeed, if $\sigma_2(\Delta) >_{lex} \sigma_1(\Delta)$ holds, then the two solutions cannot be synthesized. We therefore temporarily add a lexicographical constraint $\Delta \leq_{lex} \sigma_1(\Delta)$ to C_2 when determining a preferred solution of the second subproblem. Please note that this constraint involves only variables that are shared by both subproblems. If the enforced version of the second subproblem has no solution, then the added constraint cannot be true and we can add its negation to the first subproblem. We thus obtain a first part of an interpolant:

Proposition 1 Let C_1, C_2 be two constraint sets and X_1, Δ as defined above. Let σ_1 be a solution of $\text{Lex}(X_1)(C_1)$. If $C_2 \cup \{\Delta \leq_{lex} \sigma_1(\Delta)\}$ is inconsistent, then

$$C_1^* := C_1 \cup \{\Delta >_{lex} \sigma_1(\Delta)\}$$

Table 1. Two constraints $C_1(x_1, x_2, x_3)$ and $C_2(x_2, x_3, x_4)$

x_1	x_2	x_3		x_2	x_3	x_4	
3	2	2	(1. σ_1)	3	3	2	
3	1	3		3	1	3	(4. σ'_2)
1	3	2	(3. σ'_1)	2	3	3	
1	2	2		2	3	1	
1	2	1		1	2	3	(2. σ_2)
1	1	3		1	1	2	

is a constraint that is not satisfied by σ_1 and $C_1^* \cup C_2$ is equivalent to $C_1 \cup C_2$. Furthermore, $C_1^* \succ C_2$ if $C_1 \succ C_2$.

If the enforced version of the second subproblem has the preferred solution σ_2 , then we need to check whether σ_1 and σ_2 coincide on the common variables Δ . If they do, then we can synthesize the two solutions. Moreover, we also know that the result is a preferred solution as C_2 only adds less important variables. This property is important if we use the whole procedure recursively. However, if the solutions do not coincide on the common variables, then we can remove all assignments to Δ which are between $\sigma_1(\Delta)$ and $\sigma_2(\Delta)$ with respect to the lexicographical ordering. Whereas standard conflict learning only removes a branch in a subproblem, we remove a whole subtree. Hence, we learn ‘fat’ conflicts:

Proposition 2 Let C_1, C_2 be two constraint sets and X_1, X_2, Δ, Ω as defined above. Let σ_1 be a solution of $\text{Lex}(X_1)(C_1)$ and σ_2 be a solution of $\text{Lex}(X_2)(C_2 \cup \{\Delta \leq_{\text{lex}} \sigma_1(\Delta)\})$.

1. If $\sigma_1(\Delta) = \sigma_2(\Delta)$ and $C_1 \succ C_2$ then $\sigma_1 \cup \sigma_2$ is a solution of $\text{Lex}(\Omega)(C_1 \cup C_2)$.
2. If $\sigma_1(\Delta) \neq \sigma_2(\Delta)$ then

$$C_1^* := C_1 \cup \{\Delta \leq_{\text{lex}} \sigma_2(\Delta) \vee \Delta >_{\text{lex}} \sigma_1(\Delta)\}$$

is a constraint that is not satisfied by σ_1 and $C_1^* \cup C_2$ is equivalent to $C_1 \cup C_2$. Furthermore, $C_1^* \succ C_2$ if $C_1 \succ C_2$.

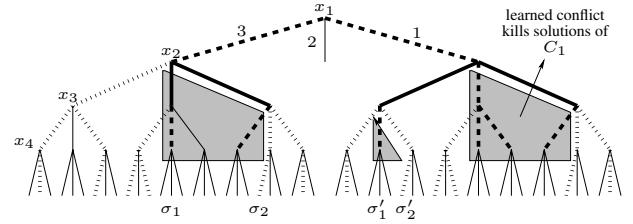

This proposition summarizes the approach of this paper. The first case corresponds to solution synthesis. The second case corresponds to conflict learning. Both are coordinated by the global preference ordering.

Compared to MAC [19], the constraints do not communicate conjunctions of domain constraints (such as $x_i \neq v_i$) to each other, but lexicographical constraints between a subset of variables and a vector of values. The result of this communication is either solution synthesis or a ‘fat’ conflict. As an effect, the number of iterations for eliminating inconsistent values can be reduced. In the example of table 1, the inconsistency of the problem is proved in the third iteration.

2.3 Lex-based Interpolation

We now develop an interpolation algorithm based on the principles developed in the last section. It basically iterates those principles until a preferred solution of the whole problem has been found or a Craig interpolant has been added to the first subproblem, thus making it inconsistent.

The algorithm LEXINTERPOLATE is shown in figure 2. In each loop iteration, it first solves the first subproblem which consists of C_1 and of an initially empty set I containing the learned conflicts. If the first subproblem has no solution, then the whole problem is inconsistent and the algorithm stops. Otherwise, it takes the preferred

**Figure 1.** Effect of conflict learning on the search tree of C_1 .

solution σ_1 of the first subproblem and formulates a lexicographical upper bound constraint on the common variables Δ and adds it temporarily to the second subproblem. If the second subproblem produces a preferred solution σ_2 that matches σ_1 then both solutions are combined into a preferred solution of the whole problem and the algorithm stops. In all other cases, a new conflict is learned and added to the interpolant. This conflict invalidates the previous solution σ_1 of the first subproblem, meaning that this solution will be revised in the next iteration. Hence, each iteration eliminates at least one assignment in the problem space of Δ meaning that the algorithm terminates for finite domains.

Theorem 1 Suppose that $C_1 \succ C_2$. The algorithm LEXINTERPOLATE(C_1, C_2) terminates after at most $O(d^{|\Delta|})$ steps. If $C_1 \cup C_2$ is consistent, then it returns a solution of $\text{Lex}(\Omega)(C_1 \cup C_2)$. Otherwise, it returns an inconsistency and the set I of the learned conflicts is a Craig interpolant for C_2, C_1 .

The Craig interpolant in the example of table 1 is as follows:

$$\begin{aligned} & ((x_2 \leq 1) \vee (x_2 = 1 \wedge x_3 \leq 2)) \vee ((x_2 > 2) \vee (x_2 = 2 \wedge x_3 > 2)), \\ & ((x_2 \leq 3) \vee (x_2 = 3 \wedge x_3 \leq 1)) \vee ((x_2 > 3) \vee (x_2 = 3 \wedge x_3 > 2)) \end{aligned}$$

Figure 1 shows how these conflicts are learned. The upper three levels of the figure show the search tree for C_1 . The lower three levels show two copies of the search tree of C_2 which are superposed with the one of C_1 . Solutions of C_1 are displayed by dashed branches and solutions of C_2 are displayed by dotted branches (straight lines are obtained when both overlap). The shadowed areas show the conflicts. The first conflict is learned in the first copy of C_2 ’s search tree. As a consequence, it also appears in the right copy. As it has been added to C_1 , it now kills several solutions of C_1 .

There are several ways to improve the algorithm. For example, we can add a constraint $X_1 \leq_{\text{lex}} \sigma_1(X_1)$ to C_1 recording the fact that there is no better solution than σ_1 . When the first problem is resolved again in later iterations, then the search can immediately start from σ_1 and the part of the search space that is lexicographically greater than σ_1 need not be searched again. Furthermore, the first subproblem may consist of several independent parts and the addition of the conflict may concern only one of those parts. We need to keep a lexicographical upper bound constraints on each independent part in order to ensure that solving complexity is additive for the independent parts and not multiplicative [9].

Another issue are functional constraints such as $x_1 + x_2 = x_3$, in particular if this constraint belongs to the second subproblem and all variables belong to Δ . When we learn a conflict for Δ , the value of x_3 depends on those of x_1 and x_2 , meaning that we can simplify the conflict by suppressing x_3 . It is therefore worth to keep track of functional dependencies between variables and to detect a subset of Δ by a conflict analysis similar to [6, 10, 20]. The elaboration of this algorithm is a topic of future work.

3 Solution Synthesis by Support Activation

3.1 The Activation Process

We now apply the algorithm LEXINTERPOLATE to an arbitrary constraint network C and to an arbitrary total ordering $>$ of the variables of C . The idea is to recursively decompose the constraints C into subproblems. We observe that decomposition only makes sense if the second subproblem has a variable that is not contained in the first subproblem. As a consequence, we stop decomposition if all the constraints in a subproblem share the last variable of the subproblem. In [5], this is called a *bucket*. There are different ways to decompose a problem into buckets. In this paper, we visit the variables of C in the ordering $X^> = (x_{\pi_1}, \dots, x_{\pi_n})$ that is produced by $>$. For each variable x_{π_i} , we define the two subproblems $C_1^{(i)}$ and $C_2^{(i)}$:

1. $C_1^{(i)}$ is the set of all constraints from C that contain only variables from $x_{\pi_1}, \dots, x_{\pi_{i-1}}$
2. $C_2^{(i)}$ is the set of all constraints from C that contain only variables from $x_{\pi_1}, \dots, x_{\pi_i}$ and that contain the variable x_{π_i} .

The two sets are disjoint. The first subproblem for the first variable $C_1^{(1)}$ is equal to the empty set. We consider the whole problem of a variable x_{π_i} , which is the union $C_1^{(i)} \cup C_2^{(i)}$ of the two subproblems. This whole problem is equal to $C_1^{(i+1)}$ if $i < n$. The whole problem of the last variable is equal to C . The second subproblem $C_2^{(i)}$ is the bucket for the variable x_{π_i} as all of its constraints contain x_{π_i} as their last variable. The first subproblem of a variable is more important than its second subproblem, i.e. $C_1^{(i)} \succ C_2^{(i)}$ for $i = 1, \dots, n$.

Each decomposition thus meets the requirements of algorithm LEXINTERPOLATE and can be solved by it. Hence, we apply LEXINTERPOLATE in a sequence, activating one variable after the other. When we activate a variable x_{π_i} for $i > 1$, we already have a solution for its first subproblem as it is equal to the whole problem of the previous variable. We just need to find a solution for the bucket of the variable while taking into account the lexicographical constraint $\Delta \leq_{lex} \sigma_1(\Delta)$ that is formulated on all variables of the bucket except for x_{π_i} . If the second subproblem alone (i.e. without lexicographical constraint) is inconsistent, then this inconsistency will only be detected after the first subproblem is solved. If the second subproblem is smaller in size than the first subproblem, we will check the consistency of the second subproblem before solving the first one.

The whole process has some similarities to bucket elimination (BE). BE processes the variables from the last one to the first one. It eliminates a variable x_{π_i} from its bucket by deriving a new constraint between the remaining variables of the bucket. This constraint is a Craig interpolant for $C_1^{(i)}$ and $C_2^{(i)}$ if the problem is inconsistent and thus corresponds to the set of conflicts learned by LEXINTERPOLATE. Otherwise, LEXINTERPOLATE learns only a part of those constraints and thus behaves like a lazy form of bucket elimination.

3.2 Heavy Supports

We now discuss how to determine a solution for the bucket $B := C_2^{(i)}$ of variable $y := x_{\pi_i}$. When searching this solution, we have already determined a preferred solution σ_1 for the problem $C_1^{(i)}$. This solution assigns a value to each variable of the bucket except for y . Let Δ be the ordered vector of all those variables, i.e. $\Delta := (X_B - \{y\})^>$. As explained in section 2.2, we add a lexicographical upper bound constraint $\Delta \leq_{lex} \sigma_1(\Delta)$ when seeking a preferred solution of the bucket. This constraint can easily be extended to an equivalent

Algorithm LEXINTERPOLATE(C_1, C_2)

```

1.    $I := \emptyset;$ 
2.   while true do
3.      $\sigma_1 := Lex(X_1)(C_1 \cup I);$ 
4.     if  $\sigma_1$  is an inconsistency then return  $\perp$ ;
5.      $\sigma_2 := Lex(X_2)(C_2 \cup \{\Delta \leq_{lex} \sigma_1(\Delta)\});$ 
6.     if  $\sigma_2$  is an inconsistency then
7.        $I := I \cup \{\Delta >_{lex} \sigma_1(\Delta)\};$ 
8.     else if  $\sigma_1(\Delta) = \sigma_2(\Delta)$  then
9.       return  $\sigma_1 \cup \sigma_2;$ 
10.    else  $I := I \cup \{\Delta \leq_{lex} \sigma_2(\Delta) \vee \Delta >_{lex} \sigma_1(\Delta)\};$ 

```

Figure 2. Algorithm for lexicographic interpolation.

constraint that covers the variable y as well. We simply add to σ the assignment of the variable y to its best value v^* , thus obtaining $\sigma := \sigma_1 \cup \{y = v^*\}$. The best value of y is simply the value in the domain of y that is maximal w.r.t. the ordering $>_{\pi_i}$. Let Y be the ordered vector of the variables in the bucket, i.e. $Y := X_B^>$. Our problem then consists in finding a preferred solution of the bucket B and the lexicographical constraint $Y \leq_{lex} \sigma(Y)$.

If the bucket contained only a single constraint, then the problem would reduce to that of finding a support of the constraint that is worse than or equal to $\sigma(Y)$. We first test whether $\sigma(Y)$ satisfies the constraint. If not, we seek the next best tuple according to the lexicographical order. If the bucket contains multiple constraints, all defined on the same variables Y , then we can iterate this approach. Each time, we invoke a constraint with a given lexicographical upper bound σ , it will reduce this to a new upper bound. We iterate this approach until the given upper bound satisfies all the constraints or until we encounter a constraint that cannot be satisfied under the reduced bound. The solution obtained in the first case combines the supports of all the constraints of variable y . We therefore call it a *heavy support*. Whereas classic supports indicate that a single variable-value assignment is consistent w.r.t. a constraint, a heavy support indicates that a bucket has a solution under a given lexicographical bound.

A bucket can contain multiple constraints which have some variables in common, but not all. An example is

$$\begin{aligned} c_1 &:= (x_1 = 2 \wedge x_3 = 2 \wedge y = 1) \vee (x_1 = 2 \wedge x_3 = 1 \wedge y = 2) \\ c_2 &:= (x_1 = 2 \wedge x_2 = 2 \wedge y = 2) \vee (x_1 = 1 \wedge x_2 = 1 \wedge y = 1) \end{aligned}$$

Suppose that higher values are preferred for all variables and that the variables are ordered as follows: $x_1 > x_2 > x_3 > y$. If the initial bound is $\{x_1 = 2, x_2 = 2, x_3 = 2, y = 2\}$, we first invoke c_1 , which reduces this bound to $\{x_1 = 2, x_2 = 2, x_3 = 2, y = 1\}$. If the constraint c_2 ignores the variable x_3 , then it will return $\{x_1 = 1, x_2 = 1, y = 1\}$ as best support under $\{x_1 = 2, x_2 = 2, y = 1\}$. However, if x_3 is taken into account, then new bound should be $\{x_1 = 2, x_2 = 2, x_3 = 1, y = 2\}$. It is obtained by reducing the value for x_3 and by choosing the tuple $\{x_1 = 2, x_2 = 2, y = 2\}$ of c_2 . Hence, a constraint can modify the bound on a variable even if it does not contain it. We capture this by the following definition:

Definition 2 Let σ be an assignment to X and c be a constraint s.t. $X_c \subseteq X$. An assignment σ' to X is a support for c under σ iff (1) $\sigma' \leq_{lex} \sigma$ and (2) σ' satisfies c , i.e. $\sigma'[X_c] \in R_c$. An assignment σ' is a preferred support for c under σ iff σ' is a support for c under σ and there is no other support σ^* for c under σ s.t. $\sigma' <_{lex} \sigma^*$.

A preferred support for c under σ can be found by a generic algorithm. Customized algorithms for certain types of constraints (tables with forbidden tuples; lex constraints; numerical constraints) can speed up support finding and are a topic of future work.

Algorithm HEAVYSUPPORT(B, σ)

```

1.  $Q := \{c \in B \mid \sigma[X_c] \notin R_c\};$ 
2. while  $Q \neq \emptyset$  do
3.   choose best  $c$  from  $Q$ ;
4.   if  $c$  has a support under  $\sigma$  then
5.     let  $\sigma'$  be the preferred support of  $c$  under  $\sigma$ ;
6.     set  $\sigma$  to  $\sigma'$ ;
7.   else return  $\perp$ .
8.    $Q := \{c \in B \mid \sigma[X_c] \notin R_c\};$ 
9. return  $\sigma$ .

```

Figure 3. Algorithm for finding heavy supports.

An algorithm for finding a heavy support is described in figure 3. In each step, the algorithm determines the set of constraints that are not satisfied by the lexicographical bound. It selects such a constraint c , determines a preferred support for c , and uses it to reduce the lexicographical bound. Constraints having more important variables should be processed first as they can result in higher decreases of the bound. When reducing the bound, some variables are changing their value and all constraints containing those variables need to be rechecked. If they are not satisfied by the new bound, they are added to the queue Q . The process is repeated until the current bound satisfies all the constraints or there is a constraint that has no support under the given bound.

Theorem 2 *The algorithm HEAVYSUPPORT(B, σ) terminates after at most $O(d^{|Y|})$ iterations. If $B \cup \{Y \leq_{lex} \sigma(Y)\}$ is consistent, then it returns a solution of $\text{Lex}(Y)(B \cup \{Y \leq_{lex} \sigma(Y)\})$. Otherwise, it returns an inconsistency.*

It is important to understand the ‘backtracking’ behaviour of the algorithm. When seeking for a preferred support, the algorithm will first reduce the bound on the last variable. If this fails, it backtracks to the previous variable and will reduce its bound. By doing this, it can hit a ‘hole’, i.e. a variable that does not belong to the constraint. After reducing the bound on the ‘hole’, the algorithm can choose any value for the succeeding variables, return a support, and hand over control to a constraint having a variable covering the hole. However, it can also happen that there is no support given the values of the variables preceding the hole. In that case, the algorithm backjumps over the hole and changes a value of a variable that precedes the hole.

4 Conclusion

In [15], David McAllester has predicted that MAC-based solvers will outperform constraint engines based on truth maintenance. For more than one decade, this had been true. The recent success of conflict analysis and conflict learning in SAT solvers has changed the picture again. It became an intensive research topic to extend SAT by specific theories such as linear constraints, uninterpreted functions, and others, and to make conflict learning work for those problems. In this paper, we showed that conflict learning can profit from the structure of general CSPs as well. It reacts to the failure of synthesizing supports and the learned conflicts cut off whole subtrees and not just partial assignments. We thus obtain a smooth adaption of JTMS ideas from [6] to CSPs, while generalizing the form of conflicts and allowing compact representations of Craig interpolants in form of lexicographical constraints. The approach makes conflict learning more pervasive for CP and permits a return of the JTMS to CP. However, the approach may also be interesting for other applications of Craig interpolants [1, 16].

Our work has the same relation to BE as PrefAC [2] has to AC as it focuses effort to preferred values. We get the behaviour of PrefAC for problems with an induced width of 1. As LEXINTERPOLATE keeps results of subproblems that are solved again and again, it promises a better behaviour for proving inconsistencies as required by overconstrained configuration problems [11] and by certain software verification problems (such as the detection of tests that are always false). It also appears that we exchanged the roles of search and inference. Each constraint has a customized support finding algorithm, which is indeed a local backjumping [18] search algorithm. And LEXINTERPOLATE provides a generic algorithm that infers ‘fat’ conflicts based on the result of the local searches. It is important to note that this is only possible if the different subproblems share the same preference orders. We thus identified another case where preferences play an important role for problem solving [7].

Experimental evaluation for specific software verification problems is in progress. Future work will be devoted to incorporate the best-fail principle from [12] to deal with infinite domains as they occur in software verification problems.

Multi-Objective Propagation in Constraint Programming

Emma Rollon and Javier Larrosa¹

Abstract. *Bounding constraints* are used to bound the tolerance of solutions under certain undesirable features. Standard solvers propagate them one by one. Often times, it is easy to satisfy them independently, but difficult to satisfy them simultaneously. Therefore, the standard propagation methods fail. In this paper we propose a novel approach inspired in multi-objective optimization. We compute a *multi-objective lower bound set* that, if large enough, can be used to detect the inconsistency of the problem. Our experiments on two domains inspired in real-world problems show that propagation of additive bounding constraints using our approach is clearly superior than previous approaches.

1 Introduction

A *constraint satisfaction problem* (CSP) requires the assignment of a set of variables in such a way that a set of constraints is satisfied. Many problems have constraints that refer to different objectives. Consider the scheduling of a major football league. A good schedule should be *fair* (no team should feel that is treated *much* worse than any other,...), *exciting* (e.g., hot games should be scheduled in accordance to TV requests, several hot games should not take place the same day, ...), *safe* (e.g., rival teams should not play simultaneously in close stadiums, teams with violent followers should not play late in the evening or near a play-ground in the afternoon), etc. One way to deal with different criteria is to establish *tolerance bounds* for each one, and find satisfying assignments with respect to all of them. Often, these constraints are in conflict, meaning that assignments that are good with respect one constraint are likely to be bad with respect another. Typically, it is easy to satisfy each constraint independently, but it is hard to satisfy all of them simultaneously. Hence, the difficulty lays on the conjunction.

CSPs are usually solved by searching on the tree of possible assignments. After each assignment a *propagation* process takes place. Its goal is to detect if the current assignment can be extended to a solution. Most propagation algorithms detect and discard domain values that are inconsistent with the current assignment. If some variable loses all its values, the algorithm backtracks. Typically, each constraint is propagated independently. Namely, a value is removed if it is shown to be inconsistent with respect one of the constraints. The only *communication* between constraints is through *value pruning* (pruning one value due to one constraint, may produce the pruning of another value due to another constraint, yielding a cascade effect). This solving approach may not be strong enough for problems with conflicting bounding constraints. Consider the following two con-

straints over 0-1 variables:

$$x_1x_2 + x_2x_3 + x_3x_4 \geq 1; \quad \sum_{i=1}^4 x_i \leq 1$$

Note that every value is consistent with respect each constraint, because every value can be extended to satisfy it. However, it is clear that no value is consistent with respect the two simultaneously. This is a simple example that many solvers would deal efficiently with. However, we will show in Section 4 that, if constraints are more intricate, standard solvers may perform poorly.

We propose a more appropriate propagation method. Essentially, our approach consists on considering CSP subproblems as multi-objective minimization problems. The set of tolerance bounds plays the role of a multi-objective upper bound. Then, we compute a multi-objective lower bound that, if large enough, allows backtracking. More precisely, we use *multi-objective mini-bucket elimination* (MO-MBE) [10] as a general parameterizable multi-objective lower bound algorithm. Our experiments on two domains inspired on real world problems show the suitability of our approach.

2 Preliminaries

2.1 CSPs, Bounding Constraints, and MBE

A *constraint satisfaction problem* (CSP) is a triplet $\mathcal{P} = (\mathcal{X}, \mathcal{D}, \mathcal{R})$ where \mathcal{X} is an ordered set of *variables*. Each variable $x_i \in \mathcal{X}$ takes values on a finite *domain* $D_i \in \mathcal{D}$. \mathcal{R} is a set of *constraints*. For convenience, we will consider that a constraint $c \in \mathcal{R}$ is a boolean function over a subset of the variables $var(c) \subseteq \mathcal{X}$ called its *scope*. A tuple t is a (possibly partial) assignment over a subset of the variables $var(t) \subseteq \mathcal{X}$. A singleton tuple is noted $(x_i \leftarrow a)$ and the join of two tuples is noted $t \cdot t'$. If $var(t) = var(c)$, then $c(t)$ tells whether the assignment is allowed by the constraint. We allow partial assignments of functions. Thus, if $var(t) \subset var(c)$, then $c(t)$ is a new constraint in which variables of $var(t)$ have been *fixed* as indicated by t , and its new scope is $var(c) - var(t)$. If $var(t) \not\subseteq var(c)$, then $c(t)$ is the partial assignment of c with respect to $var(t) \cap var(c)$. A *solution* of a CSP is a complete assignment that satisfies all the constraints. Solving a CSP is in general NP-complete.

An *additive bounding constraint* is a pair (\mathcal{F}, \top) , where $f \in \mathcal{F}$ are cost functions and $\top \in \mathbb{N}$ is the maximum acceptable cost. For convenience, we define the sum of costs as $u \oplus v = \min\{u + v, \top\}$. Tuple t satisfies the constraint iff,

$$\sum_{f \in \mathcal{F}} f(t) < \top$$

In this paper we will consider CSPs with $p > 1$ additive bounding constraints. Note that we do not make any assumption over cost functions $f \in \mathcal{F}$, which makes the concept of additive bounding

constraint extremely general. Besides, the ideas that we will introduce directly apply to more general bounding constraints such as *semiring-based* [2].

In recent years, many propagation algorithms for additive bounding constraints have been proposed. For instance, all *weighted CSP* local consistencies [9, 3] can be used for this purpose. Another alternative is *mini-bucket elimination* MBE [6], which is the basis of our work. The main advantage of MBE over local consistencies is its control parameter z that allows to trade resources for accuracy. For our purposes in this paper, MBE has the additional advantage of being extendible to multi-objective optimization. The main disadvantages are that MBE cannot be easily used for filtering [5] and that its implementation inside a solver is not incremental. MBE uses the following two operations over cost functions.

- Let f and g be two cost functions. Their sum, denoted $f + g$, is a new function with scope $\text{var}(f) \cup \text{var}(g)$ defined as,

$$(f + g)(t) = f(t) \oplus g(t)$$

- Let f be a cost function. The elimination of x_i , $f \downarrow x_i$, is a new function with scope $\text{var}(f) - \{x_i\}$ defined as,

$$f \downarrow x_i(t) = \min_{a \in D_i} \{f(t \cdot (x_i \leftarrow a))\}$$

Figure 1 shows MBE. It receives an additive bounding constraint (\mathcal{F}, \top) and returns a lower bound of the best assignment. MBE can be used as a propagation procedure inside search, because if the lower bound equals \top , the constraint cannot be satisfied and the current line of search can be abandoned. MBE processes variables in decreasing order. For each variable x_i , it computes \mathcal{B}_i the set of cost functions having x_i in the domain. \mathcal{B}_i is partitioned into subsets such that the join scope has size at most $z+1$. The functions of each subset are summed and variable x_i is eliminated. After the last elimination, a zero-arity (namely, a constant) contains the result. MBE is time and space exponential on parameter z .

2.2 Multi-Objective Minimization

Let us consider problems with p objectives. Let \vec{v} and \vec{u} be two distinct p -vectors. We say that \vec{v} dominates \vec{u} (noted $\vec{v} < \vec{u}$) if $\forall j, v_j \leq u_j$. A *multiobjective weighted constraint satisfaction problem* (MO-WCSP) is defined as $\mathcal{P} = (\mathcal{X}, \mathcal{D}, \{\mathcal{F}_j, \top_j\}_{j=1}^p)$, where \mathcal{X} and \mathcal{D} are variables and domains. \mathcal{F}_j defines the j -th objective, $F_j(X) = \sum_{f \in \mathcal{F}_j} f(X)$. The multi-objective function is $F(X) = (F_1(X), \dots, F_p(X))$. Given a complete assignment X ,

we say that $F(X)$ is *consistent* iff $\forall j, F_j(X) < \top_j$. A *solution* is a consistent complete assignment. A solution X is *efficient* or *Pareto optimal* if there is no better solution (i.e., $\forall X', F(X') \not< F(X)$). \mathcal{X}_E is the set of efficient solutions and \mathcal{EF} is the corresponding *efficient frontier*. The task in a MO-WCSP is to compute \mathcal{EF} (and, possibly, one or all efficient solutions for each of its elements).

Multi-objective MBE (MO-MBE) [10] extends MBE to the multi-objective context. Let $\vec{\top} = (\top_1, \dots, \top_p)$. The sum of p -vectors is defined as,

$$\vec{v} + \vec{u} = \begin{cases} \vec{\top} & \exists j, v_j \oplus u_j = \top_j \\ (v_1 \oplus u_1, \dots, v_p \oplus u_p) & \text{otherwise.} \end{cases}$$

The non-domination closure of a set of p -vectors S is defined as $\langle S \rangle = \{v \in S \mid \forall u \in S, u \not< v\}$. MO-MBE works with p -functions which, instead of scalar costs, return sets of non-dominated p -vectors. For that purpose, original cost functions $f \in \mathcal{F}_j$ need to be reformulated from $f(t) = u$ to $f(t) = \{(0, \dots, 0, u, 0, \dots, 0)\}$ (where the u component is at the j -th position). Operations on functions are accordingly extended,

- Let f and g be p -functions. Their sum $h = f + g$ is defined as,

$$h(t) = \langle \{ \vec{v} \mid t = t' \cdot t'', \vec{v} = \vec{v}' + \vec{v}'', \vec{v}' \in f(t'), \vec{v}'' \in g(t'') \} \rangle$$
- Eliminating of x_i from a p -function f , $h = f \downarrow x_i$, is defined as,

$$h(t) = \langle \{ \vec{v} \mid \forall a \in D_i, \vec{v} \in f(t \cdot (x_i \leftarrow a)) \} \rangle$$

Note that, if $p = 1$, these definitions reduce to the classical ones.

Consider as an example the 2-functions f and g in Figure 2 with $\vec{\top} = (15, 18)$ under domains $\{a, b\}$. The sum $f + g$ is a 2-function $(f + g)(x_1, x_2, x_3)$. Note that in $(f + g)(a, b, a)$, the sum of the 2-vectors $(4, 10)$ and $(11, 1)$ is $\vec{\top}$. As $\vec{\top}$ is dominated by $(10, 12)$, it has been removed. The elimination of variable x_3 from $f + g$ is a 2-function $(f + g) \downarrow x_3(x_1, x_2)$. Note that in $(f + g) \downarrow x_3(a, a)$, the 2-vector $(4, 9)$ has been removed as a consequence of the non-domination closure. Moreover, $\vec{\top}$ has also been removed from $(f + g) \downarrow x_3(a, b)$ for the same reason.

The code of MO-MBE is the same as MBE in Figure 1. The only difference is that costs are now p -vectors, and cost functions are now p -functions. Given a MO-WCSP, MO-MBE returns a set S of non-dominated p -vectors which forms a *lower bound set* of its efficient frontier \mathcal{EF} (namely, $\forall \vec{v} \in \mathcal{EF}, \exists \vec{v}' \in S$ such that either $v = v'$ or $v' < v$). If MO-MBE returns $\vec{\top}$, the MO-WCSP does not have any solution. The time complexity of MO-MBE is $O(e \times \prod_{j=1}^{p-1} \top_j^2 \times d^z)$, where e is the number of p -functions and d is the largest domain size.

3 Propagating Additive Constraints using Multi-Objective Techniques

Let $\mathcal{P} = (\mathcal{X}, \mathcal{D}, \mathcal{R})$ be a CSP such that its set of constraints can be divided into two sets: \mathcal{H} is a set of arbitrary hard constraints, and $\{(\mathcal{F}_j, \top_j)\}_{j=1}^p$ are p additive bounding constraints. The problem is solved with a usual systematic search procedure. Consider an arbitrary search state with its associated partial assignment, which can be seen as if some of the domains have become singletons. Let $\mathcal{P}' = (\mathcal{X}', \mathcal{D}', \mathcal{R})$ be the associated subproblem. At this point, standard solvers would propagate the current assignment using general or specific algorithms for each type of constraint. Since we consider MBE as the propagation algorithm of bounding constraints and it does not prune unfeasible values, it makes sense to propagate in two

$f:$	$x_1 \quad x_2$	$\begin{array}{ c c c } \hline a & a & \{(3, 2), (2, 8)\} \\ a & b & \{(4, 10)\} \\ b & a & \{\top\} \\ b & b & \{\top\} \\ \hline \end{array}$	$f + g:$	$x_1 \quad x_2 \quad x_3$	$\begin{array}{ c c c c } \hline a & a & a & \{(4, 4), (3, 10)\} \\ a & a & b & \{(5, 3), (4, 9)\} \\ a & b & a & \{(10, 12)\} \\ a & b & b & \{\top\} \\ b & a & a & \{\top\} \\ b & a & b & \{\top\} \\ b & b & a & \{\top\} \\ b & b & b & \{\top\} \\ \hline \end{array}$	$(f + g) \downarrow x_3:$	$x_1 \quad x_2$	$\begin{array}{ c c c } \hline a & a & \{(4, 4), (3, 10), (5, 3)\} \\ a & b & \{(10, 12)\} \\ b & a & \{\top\} \\ b & b & \{\top\} \\ \hline \end{array}$
$g:$	$x_2 \quad x_3$	$\begin{array}{ c c c } \hline a & a & \{(1, 2)\} \\ a & b & \{(2, 1)\} \\ b & a & \{(6, 2), (11, 1)\} \\ b & b & \{\top\} \\ \hline \end{array}$						

Figure 2. Sum and projection over 2-functions. $\vec{T} = (15, 18)$.

steps: first the set \mathcal{H} , and second a sequence of MBE executions, one for each bounding constraint. The practical effectiveness of MBE can be greatly improved if each \mathcal{F}_j is augmented with the set of hard constraints \mathcal{H} ,

$$F_j(X) = \sum_{f \in \mathcal{F}_j \cup \mathcal{H}} f(X) < \top_j$$

For this purpose, boolean functions $c \in \mathcal{H}$ must be redefined in terms of costs (namely, $c(t) \in \{\top_j, 0\}$). Formally, we can see the propagation process as,

$$\text{Propagate}(\mathcal{H}) \wedge \bigwedge_{j=1}^p (\text{MBE}(z, \mathcal{F}_j \cup \mathcal{H}, \top_j) < \top_j)$$

If the previous expression returns *false* the search procedure should backtrack.

We propose the use of multi-objective mini-buckets instead of mono-objective mini-buckets. It requires the replacement of the sequence of calls to MBE by a single call to MO-MBE,

$$\text{Propagate}(\mathcal{H}) \wedge (\text{MO-MBE}(z, \{\mathcal{F}_j \cup \mathcal{H}, \top_j\}_{j=1}^p) < \vec{T})$$

The previous change may seem a minor modification. However, the subjacent algorithm is completely different and the kind of inference performed is much more powerful, as can be seen in the following example.

Consider a CSP $\mathcal{P} = (\mathcal{X}, \mathcal{D}, \mathcal{R})$ with three 0/1 variables and two bounding constraints: $(F_1, 12)$ with $F_1 = \{f_1(x_1) = 10x_1, f_2(x_2) = 10x_2, f_3(x_3) = 2x_3\}$, and $(F_2, 10)$ with $F_2 = \{h_1(x_1) = 3(1 - x_1), h_2(x_2) = 4(1 - x_2), h_3(x_3) = 8(1 - x_3)\}$. There are two additional constraints $x_1 \neq x_2$ and $x_2 \vee x_3$. If we propagate with MBE($z = 2$) each bounding constraint (augmented with hard constraints) we obtain lower bounds 10 and 3, respectively. Find below the trace of each execution (note that in this example, there is no need to break buckets into mini-buckets),

1st bounding constr.	domain	value	g_3	g_2	$g_1()$
	1		0	2	10
2nd bounding constr.	0		2	10	
	1		0	4	3
	0		0	0	

The propagation indicates that the problem *may have* solution. Note that each lower bound is the optimum assignment of one bounding constraint discarding the other, so MBE is doing a perfect estimation with the information that it receives. Its problem is that it only *knows* part of the information. If we propagate with MO-MBE($z = 2$) the two bounding constraints simultaneously (augmented with hard constraints) we obtain a lower bound set of $\{\top\}$

which indicates that the problem *does not have* any solution. Find below the trace of the execution,

domain	value	g_3	g_2	$g_1()$
1		$\{(2, 0), (0, 8)\}$	$\{(2, 4)\}$	$\{\top\}$
0		$\{(2, 0)\}$	$\{(10, 8)\}$	

The key is that in each execution of MBE, it searches for one different valid assignment. Each one satisfies one bounding constraint separately, but not simultaneously. However, MO-MBE searches for a unique assignment that satisfies both bounding constraints simultaneously and cannot find it.

4 Computational Experiments

We tested our propagation mechanism in two different domains: *combinatorial auctions* and *satellite scheduling*. In both cases the problem contains two additive bounding constraints with unary cost functions plus a set of small arity hard constraints. We compare the performance of four algorithms based on depth-first search. The first is IlogSolver 6.1 with default parameters. Bounding constraints are encoded with the IloPack global constraint. The second algorithm enforces FDAC [9] with each bounding constraint augmented with the hard constraints. The third one enforces arc-consistency in the set of hard constraints and then executes MBE ($z = 2$) with the bounding constraints (namely, the first approach described in Section 3). The fourth one is like the third, but the two calls to MBE are replaced to one call to MO-MBE (namely, the second approach described in Section 3). For comparison, we always report cpu time. We run all the experiments on a Pentium IV at 3GHz with 2 GB of memory, running Linux.

4.1 Combinatorial Auctions

Combinatorial auctions (CA) allow bidders to bid for indivisible subsets of goods. In risk-conscious auctions, the bid-taker wants to control the risk of bid withdrawal following winner determination, because it may cause large losses in revenue [7]. Consider a set of goods $\{1, 2, \dots, n\}$ that go on auction. There are m bids. Bid i is defined by the subset of requested goods $X_i \subseteq \{1, 2, \dots, n\}$, the money offer b_i and the probability of payment failure r_i . The bid-taker must decide which bids are to be accepted. We consider a decision version of the problem in which the bid-taker provides two constants (P, R) indicating that she does not want to miss more than P over the maximum possible revenue ($\sum_{i \leq m} b_i$) and probability of bid withdrawal lower than R . Both constraints can be expressed as additive (the second one requires a probabilistic independence assumption and a logarithmic transformation).

We have generated mono-objective CA using the PATH model of the CATS generator [8] and randomly added payment failure probabilities to the bids in the range 0.0 to 0.3. We experiment on instances with 20 and 50 goods, varying the number of bids from 80 to 200. For each parameter configuration, we generate samples of size 25 and set the time limit to 300 seconds. For each instance, we established the values of (P, R) in such a way that *i*) the instance admits a solution and *ii*) a small decrease of either one renders the problem unsolvable. Consequently, the instances are difficult with respect to the two constraints.

Figure 3 reports the results for instances with 20 and 50 goods, respectively. It can be observed that problems become harder as the number of bids increases. Regarding the algorithms, it is clear that MO-MBE propagation always outperforms the other three approaches. For instances with 20 goods, it is about 6 times faster than its competitors. With 50 goods the gain is still larger (up to 10 times faster).

4.2 Earth observation satellite scheduling

An earth observation satellite, such as the Spot5 [1], orbits the earth while taking photographs requested by different customers. It is impossible to fulfill all the requests. Thus, the problem is to select the subset that the satellite will actually take and decide which camera will be used for each one. We experiment with Spot5 instances that have binary and ternary hard constraints and variables with domains of size 2 and 4. We consider instances with 2 bounding constraints. The first one comes from the on-board storage limit. The second one comes from the importance of photographs (each photograph has an associated penalty for not taking it). We consider the decision problem in which two constants (S, P) are given: the available on-board memory has size S and cannot be surpassed, and the maximum acceptable aggregated penalty is P . Since we could not solve complete instances, we considered subinstances as follows: $X_{\geq k}$ denotes instance X where photographs whose penalty is less than k have been eliminated.

Figure 4 reports the results for instance $1506_{\geq 1000}$. Since we observed that the behavior of other subinstances (i.e., $1401_{\geq 1000}$, $1403_{\geq 1000}$, $1405_{\geq 1000}$, and $1407_{\geq 1000}$) was very similar, we do not report their results. Each plot reports results for a fixed value of P and varying the value of S . We established a time limit of 600 seconds. Note the logarithmic scale. We observed that IlogSolver always performs very poorly and only solves instances with $S \leq 4$. Thus, we omit it from the plot.

Considering MBE and MO-MBE, we observe the following pattern that is best exemplified in the $P = 450000$ plot (Figure 4 top left). For high values of S , MBE is more efficient than MO-MBE. The reason is that the memory constraint is very easy to satisfy, which makes it practically irrelevant. MBE already captures the difficulty of the problem, which is mono-objective in nature. Thus, the higher overhead of MO-MBE is wasted. As the value of S decreases, the situation changes. Both bounding constraints become difficult to satisfy simultaneously. Propagating with mono-objective MBE fails in detecting inconsistency because it is easy to satisfy each constraint if the other one is disregarded, but it is difficult to satisfy the two of them simultaneously. Only the bi-objective nature of MO-MBE can capture such difficulty. As a result, MBE cannot solve the problems, while MO-MBE solves them in a few seconds. If S decreases even further, the memory constraint becomes clearly unsatisfiable in conjunction with the penalty constraint. MO-MBE propagation detects it easily but MBE propagation does not. Only for the lowest val-

ues of S , when the constraint is unsatisfiable independently of other constraints, MBE detects it efficiently. The algorithm that enforces FDAC behaves similarly to MBE because it also considers the two bounding constraints separately. However, it provides a much better average performance.

Observing the plots in decreasing order of P , we observe that problems become harder as the penalty bounding constraint becomes tighter and harder to satisfy. As before, there is a range of S for which the instances are most difficult. This difficulty peak shifts towards the right as P decreases. For MO-MBE propagation, the range is narrower than for MBE and FDAC, but it also fails to solve some instances within the time limit of 600 seconds.

The $P = 250000$ case requires further discussion: the plot only shows the left-hand side of the difficulty peak, where the tight memory constraint *helps* MO-MBE to prove unsatisfiability almost instantly whilst MBE and FDAC cannot. For large values of S the constraint becomes trivial and irrelevant. Then the problem difficulty is given only by the penalty constraint and the three algorithms fail in solving it.

5 Related Work

The idea of using the conjunction of two or more constraints during propagation, rather than using them one-by-one, is not new. For instance, path-consistency, path-inverse consistency and neighborhood inverse consistency [4] use this idea at different levels of sophistication. However, all these works assume binary problems and cannot be efficiently extended to higher arity constraints such as bounding constraints. The work of [12] is also related to ours. However, it is restricted to problems with so-called *knapsack constraints*, which are a special case of pairs of additive bounding constraints that share unary cost functions (namely, linear constraints of the form $L \leq AX \leq U$). A little bit more general is the work of [11], which applies to pairs of constraints of the form,

$$\sum_{i=1}^n w_i x_i \leq U \quad \wedge \quad \sum_{i=1}^n p_i x_i > U$$

Our notion of additive bounding constraint includes these and many other cases and allow us to take into account any number of bounding constraints. Besides, it can be easily extended to more sophisticated bounding constraints expressible in terms of semirings [2]. Moreover, our algorithmic approach using multi-objective optimization techniques is radically different.

6 Conclusions and Future Work

Additive bounding constraints, $\sum_{f \in \mathcal{F}} f(X) < \top$, are used to bound the tolerance under certain undesirable feature in problem solutions. The propagation in problems involving conflicting bounding constraints is a difficult task for standard solvers. Typically, they propagate constraints one by one. When it is easy to satisfy bounding constraints independently, but difficult to satisfy them simultaneously, this approach clearly fails. In this paper we have proposed a novel approach inspired in multi-objective optimization. We propagate the additive bounding constraints simultaneously with multi-objective mini-bucket elimination MO-MBE [10]. The output is a multi-objective lower bound set that can be used to detect the inconsistency of the problem. Our experiments on two domains inspired in real-world problems show that propagation of additive bounding constraints using MO-MBE is clearly superior than previous approaches.

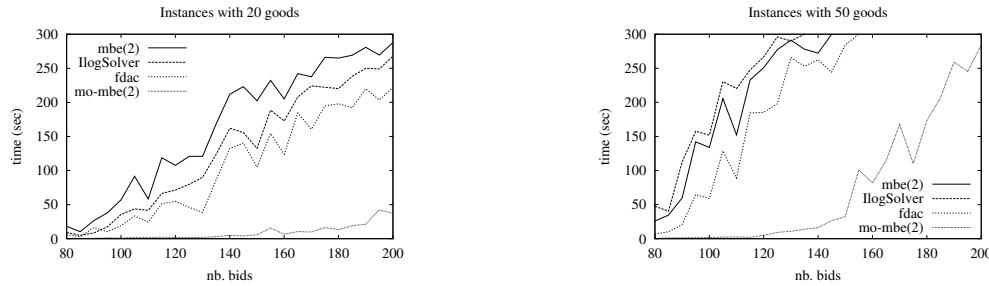

Figure 3. Experimental results on CA for 20 and 50 goods, respectively. Risk probabilities ranging from 0.0 to 0.3. Average time on 25 instances for each parameter configuration. Time limit 300 sec.

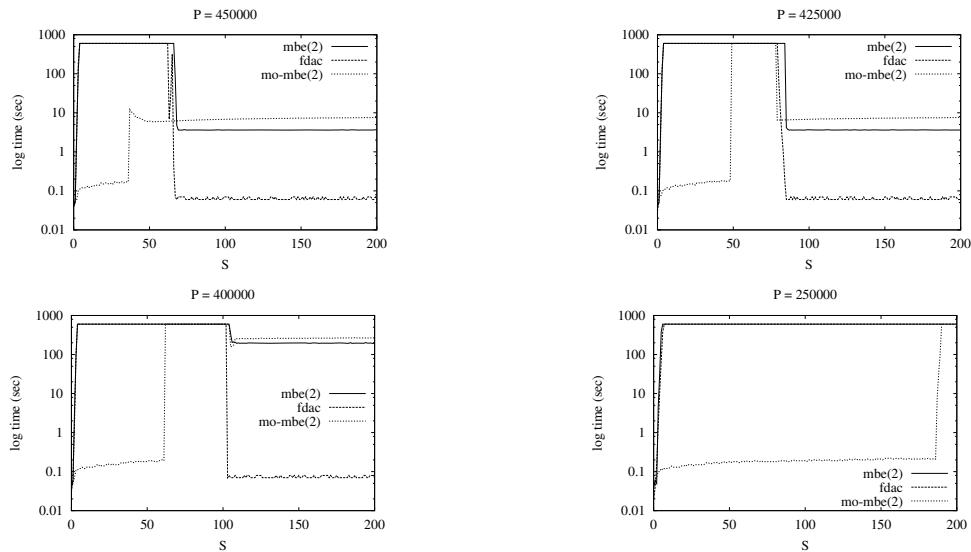

Figure 4. Experimental results on $1506_{\geq 1000}$ spot5 instance. Time limit 600 sec. Note the logarithmic scale.

The high overhead of multi-objective propagation may render it useless in problems with many bounding constraints. In that case, it may be useful to detect automatically pairs of conflicting constraints and apply MO-MBE to these pairs independently. Moreover, the experiments indicated that loose bounding constraints cause overhead but are of no use to our approach, so they should be detected and discarded in the propagation process. The development of this idea is part of our future work. A major drawback of MO-MBE propagation is that it cannot detect and prune unfeasible values. We want to overcome this problem using the ideas of [5].

Last Conflict based Reasoning

Christophe Lecoutre and Lakhdar Sais and Sébastien Tabary and Vincent Vidal¹

Abstract. In this paper, we propose an approach to guide search to sources of conflicts. The principle is the following: the last variable involved in the last conflict is selected in priority, as long as the constraint network can not be made consistent, in order to find the (most recent) culprit variable, following the current partial instantiation from the leaf to the root of the search tree. In other words, the variable ordering heuristic is violated, until a backtrack to the culprit variable occurs and a singleton consistent value is found. Consequently, this way of reasoning can easily be grafted to many search algorithms and represents an original way to avoid thrashing. Experiments over a wide range of benchmarks demonstrate the effectiveness of this approach.

1 Introduction

For solving instances of the Constraint Satisfaction Problem (CSP), tree search algorithms are commonly used. To limit their combinatorial explosion, various improvements have been proposed. Such improvements mainly concern ordering heuristics, filtering techniques and conflict analysis, and can be conveniently classified as look-ahead and look-back schemes [8]. *Look-ahead* schemes are used when the current partial solution has to be extended and *Look-back* schemes are designed to manage encountered dead-ends.

Early in the 90's, the look-ahead Forward-Checking (FC) algorithm [12] combined with the look-back Conflict-directed Back-Jumping (CBJ) technique [20] was considered as the most efficient approach to solve CSP instances. However, some years later, the look-ahead MAC algorithm, which maintains arc-consistency during search, was shown to be more efficient than FC-CBJ [21, 2].

Then, it became unclear if both paradigms were orthogonal, i.e. counterproductive one to the other, or not. Indeed, while it is confirmed by theoretical results [6] that the more advanced the forward phase is, the less useful the backward phase is, some experiments on hard, structured problems show that adding CBJ to M(G)AC can still present significant improvements. Further, refining the look-back scheme [11, 1, 16] by associating a so-called eliminating explanation (or conflict) with any value rather than with any variable gives to the search algorithm a more powerful backjumping ability. The empirical results in [1, 16] show that MAC can be outperformed by algorithms embedding such look-back techniques.

More recently, look-ahead techniques have taken an advantage with the introduction of conflict-directed variable ordering heuristics [4]. The idea is to associate a weight with any constraint C and to increment the weight of C whenever C is violated during search. As search progresses, the weight of hard constraints become more and more important, and this particularly helps the heuristic to select variables appearing in the hard part of the network. It does respect the

fail-first principle : "To succeed, try first where you are most likely to fail" [12]. The new conflict-directed heuristic $dom/wdeg$ is a very simple way to prevent thrashing [4, 13] and is an efficient alternative to backjump-based techniques [18].

Even if an advanced look-ahead technique is used, one can be interested by looking for the reason of an encountered dead-end as finding the ideal ordering of variables is intractable in practice. A dead-end corresponds to a conflict between a subset of decisions (variable assignments) performed so far. In fact, it is relevant (to prevent thrashing) to identify the most recent decision (let us call it the culprit one) that participates to the conflict. Indeed, once the culprit has been identified, we know that it is possible to safely backtrack up to it – this is the role of look-back techniques such as CBJ and DBT (Dynamic Backtracking) [11].

In this paper, we propose an original approach to (indirectly) backtrack to the culprit of the last encountered dead-end. To achieve it, the leaf conflict variable becomes in priority the next variable to be selected as long as the successive assignments that involves it render the network arc inconsistent. It then corresponds to checking the singleton consistency of this variable from the leaf toward the root of the search tree until a singleton value is found. In other words, the variable ordering heuristic is violated, until a backtrack to the culprit variable occurs and a singleton value is found.

In summary, the approach that we propose aims at guiding search to dynamically detect the conflict reason of the last encountered dead-end. It is important to remark that, contrary to sophisticated backjump techniques, our approach can be grafted in a very simple way to a tree search algorithm without any additional data structure.

2 Technical background

A Constraint Network (CN) P is a pair $(\mathcal{X}, \mathcal{C})$ where \mathcal{X} is a finite set of n variables and \mathcal{C} a finite set of e constraints. Each variable $X \in \mathcal{X}$ has an associated domain, denoted $dom(X)$, which contains the set of values allowed for X . Each constraint $C \in \mathcal{C}$ involves a subset of variables of \mathcal{X} , called scope and denoted $vars(C)$, and has an associated relation, denoted $rel(C)$, which contains the set of tuples allowed for its variables. A solution to a CN is an assignment of values to all the variables such that all the constraints are satisfied. A CN is said to be satisfiable iff it admits at least one solution. The Constraint Satisfaction Problem (CSP) is the NP-complete task of determining whether a given CN is satisfiable. A CSP instance is then defined by a CN, and solving it involves either finding one (or more) solution or determining its unsatisfiability. To solve a CSP instance, one can modify the CN by using inference or search methods [8]. Usually, domains of variables are reduced by removing inconsistent values, i.e. values that cannot occur in any solution. Indeed, it is possible to filter domains by considering some properties of constraint networks. Arc Consistency (AC) remains the central one.

¹ CRIL-CNRS FRE 2499, rue de l'université, SP 16, 62307 Lens cedex, France. email: {lecoutre,sais,tabary,vidal}@cril.univ-artois.fr

Definition 1 Let $P = (\mathcal{X}, \mathcal{C})$ be a CN. A pair (X, v) , with $X \in \mathcal{X}$ and $v \in \text{dom}(X)$, is arc consistent iff $\forall C \in \mathcal{C} \mid X \in \text{vars}(C)$, there exists a support of (X, v) in C , i.e., a tuple $t \in \text{rel}(C)$ such that $t[X] = v$ and $t[Y] \in \text{dom}(Y) \forall Y \in \text{vars}(C)$. P is arc consistent iff $\forall X \in \mathcal{X}$, $\text{dom}(X) \neq \emptyset$ and $\forall v \in \text{dom}(X)$, (X, v) is arc consistent.

Singleton Arc Consistency (SAC) [7] is a stronger consistency than AC, i.e. SAC can identify more inconsistent values than AC can. SAC guarantees that enforcing arc consistency after performing any variable assignment does not show unsatisfiability, i.e., does not entail a domain wipe-out.

Backtracking Search Algorithms The backtracking algorithm (BT) is a central algorithm for solving CSP instances. It employs a depth-first search in order to instantiate variables and a backtrack mechanism when dead-ends occur. Many works have been devoted to improve its forward and backward phases by introducing look-ahead and look-back schemes [8].

MAC [21] is the look-ahead algorithm which is considered as the most efficient generic approach to solve CSP instances. It simply maintains (re-establishes) arc consistency after each variable assignment. A dead-end is encountered if the network becomes arc inconsistent (because a domain is wiped out, i.e. becomes empty). When mentioning MAC, it is important to indicate which branching scheme is employed. Indeed, it is possible to consider binary (2-way) branching or non binary (d -way) branching. These two schemes are not equivalent as it has been shown that binary branching is more powerful (to refute unsatisfiable instances) than non-binary branching [14]. With binary branching, at each step of the search, a pair (X, v) is selected where X is an unassigned variable and v a value in $\text{dom}(X)$, and two cases are considered: the assignment $X = v$ and the refutation $X \neq v$. The MAC algorithm (using binary branching) can then be seen as building a binary tree. During search (i.e. when the tree is being built), we can make the difference between an opened node, for which only one case has been considered, and a closed node, for which both cases have been considered. Classically, MAC always starts by assigning variables before refuting values.

On the other hand, three representative look-back algorithms are SBT (Standard Backtracking), CBJ (Conflict Directed Backjumping) [20] and DBT (Dynamic Backtracking) [11]. The principle of these look-back algorithms is to jump back to a variable assignment that must be reconsidered as it is suspected to be the most recent culprit of the dead-end. SBT simply backtracks to the previously assigned variable whereas CBJ and DBT can identify a meaningful culprit decision by exploiting eliminating explanations.

Search Heuristics The order in which variables are assigned by a backtracking search algorithm has been recognized as a key issue for a long time. Using different variable ordering heuristics to solve a CSP instance can lead to drastically different results in terms of efficiency. In this paper, we will focus on the following representative variable ordering heuristics: dom , bz , dom/ddeg and dom/wdeg . The well-known dynamic heuristic dom [12] selects, at each step of the search, one variable with the smallest domain size. To break ties (which correspond to sets of variables that are considered as equivalent by the heuristic), one can use the current (also called dynamic) degree of the variable. This is the heuristic called bz [5]. By directly combining domain sizes and dynamic variable degrees, one obtains dom/ddeg [2] which can substantially improve the performance of the search on some problems. Finally, in [4], the heuristic

dom/wdeg has been introduced. The principle is to associate with any constraint of the problem a counter which is incremented whenever the constraint is involved in a dead-end. Hence, wdeg that refers to the weighted degree of a variable corresponds to the sum of the weights of the constraints involving this variable (and at least another unassigned variable).

3 Reasoning from conflicts

In this section, we show that it is possible to identify a nogood from a sequence of decisions leading to a conflict, and to exploit this nogood during search. We then discuss the impact of such a reasoning on thrashing prevention.

3.1 Nogood identification

Definition 2 Let $P = (\mathcal{X}, \mathcal{C})$ be a CN and (X, v) be a pair such that $X \in \mathcal{X}$ and $v \in \text{dom}(X)$. The assignment $X = v$ is called a positive decision whereas the refutation $X \neq v$ is called a negative decision. $\neg(X = v)$ denotes $X \neq v$ and $\neg(X \neq v)$ denotes $X = v$.

From now on, we will consider an inference operator ϕ assumed to satisfy some usual properties. This operator can be employed at any step of a tree search, denoted ϕ -search, using a binary branching scheme. For example, MAC corresponds to the ϕ_{AC} -search algorithm where ϕ_{AC} is the operator that establishes AC.

Definition 3 Let P be a CN and Δ be a set of decisions. $P|_{\Delta}$ is the CN obtained from P such that, for any positive decision $(X = v) \in \Delta$, $\text{dom}(X)$ is restricted to $\{v\}$, and, for any negative decision $(X \neq v) \in \Delta$, v is removed from $\text{dom}(X)$. $\phi(P)$ is the CN obtained after applying the inference operator ϕ on P .

If there exists a variable with an empty domain in $\phi(P)$ then P is clearly unsatisfiable, denoted $\phi(P) = \perp$.

Definition 4 Let P be a CN and Δ be a set of decisions. Δ is a nogood of P iff $P|_{\Delta}$ is unsatisfiable. Δ is a ϕ -nogood of P iff $\phi(P|_{\Delta}) = \perp$. Δ is a minimal ϕ -nogood of P iff $\nexists \Delta' \subset \Delta$ such that $\phi(P|_{\Delta'}) = \perp$.

Obviously, ϕ -nogoods are nogoods, but the opposite is not necessarily true. Our definition includes both positive and negative decisions as in [9, 17]. Note that we can consider a ϕ -nogood Δ as deduced from a sequence of decisions $\langle \delta_1, \dots, \delta_i \rangle$ such that $\Delta = \{\delta_1, \dots, \delta_i\}$. Such a sequence can correspond to the decisions taken along a branch in a search tree leading to a dead-end.

Definition 5 Let P be a CN and $\Sigma = \langle \delta_1, \dots, \delta_i \rangle$ be a sequence of decisions such that $\{\delta_1, \dots, \delta_i\}$ is a ϕ -nogood of P . A decision $\delta_j \in \Sigma$ is said to be culprit iff $\exists v \in \text{dom}(X_i) \mid \phi(P|_{\{\delta_1, \dots, \delta_{j-1}, \neg \delta_j, X_i=v\}}) \neq \perp$ where X_i is the variable involved in δ_i . We define the culprit subsequence of Σ to be either the empty sequence if no culprit decision exists, or the sequence $\langle \delta_1, \dots, \delta_j \rangle$ where δ_j is the latest culprit decision in Σ .

In other words, the culprit subsequence of a sequence of decisions Σ leading to an inconsistency ends in the most recent decision such that, when negated, there exists a value that can be assigned, without yielding an inconsistency with ϕ , to the variable involved in the last decision of Σ . We can show that it corresponds to a nogood.

Proposition 1 Let P be a CN and $\Sigma = \langle \delta_1, \dots, \delta_i \rangle$ be a sequence of decisions s.t. $\{\delta_1, \dots, \delta_i\}$ is a ϕ -nogood of P . The set of decisions contained in the culprit subsequence of Σ is a nogood of P .

Proof. Let $\langle \delta_1, \dots, \delta_j \rangle$ be the culprit subsequence of Σ . Let us demonstrate by recurrence that for any integer k such that $j \leq k \leq i$, the following hypothesis, denoted $H(k)$, holds:

$H(k)$: $\{\delta_1, \dots, \delta_k\}$ is a nogood

First, let us show that $H(i)$ holds. We know that $\{\delta_1, \dots, \delta_i\}$ is a nogood since, by hypothesis, $\{\delta_1, \dots, \delta_i\}$ is a ϕ -nogood of P . Then, let us show that, for $j < k \leq i$, if $H(k)$ holds then $H(k-1)$ also holds. As $k > j$ and $H(k)$ holds, we know that, by recurrence hypothesis, $\{\delta_1, \dots, \delta_{k-1}, \delta_k\}$ is a nogood. Furthermore, δ_k is not a culprit variable (since $k > j$). Hence, by Definition 5, we know that $\forall v \in \text{dom}(X_i), \phi(P|_{\{\delta_1, \dots, \delta_{k-1}, \neg\delta_k, X_i=v\}}) = \perp$. As a result, the set $\{\delta_1, \dots, \delta_{k-1}, \neg\delta_k\}$ is a nogood. By resolution, $\{\delta_1, \dots, \delta_{k-1}\}$ is a nogood. \square

The following property states that identifying an empty culprit subsequence allows proving the unsatisfiability of a CN.

Corollary 1 Let P be a CN and $\Sigma = \langle \delta_1, \dots, \delta_i \rangle$ be a sequence of decisions such that $\{\delta_1, \dots, \delta_i\}$ is a ϕ -nogood of P . If the culprit subsequence of Σ is empty, then P is unsatisfiable.

When we obtain a ϕ -nogood from a sequence of decisions Σ taken along a branch built by a ϕ -search algorithm, it is safe to backjump to the last decision contained in the culprit subsequence of Σ which corresponds to a nogood. We can also remark that the set of decisions contained in a culprit subsequence may not be a minimal nogood, and can be related to the nogood computed using the first Unique Implication Point (1UIP) scheme used in SAT solvers [22].

3.2 Last Conflict reasoning

The identification and exploitation of nogoods as described above can be easily embedded into a ϕ -search algorithm thanks to a simple modification of the variable ordering heuristic. We will call this approach *Last Conflict reasoning* (LC).

In practice, we will exploit LC only when a dead-end has been reached from an opened node of the search tree, that is to say, from a positive decision since when a binary branching scheme is used, positive decisions are generally taken first. It means that LC will be used iff δ_i (the last decision of the sequence mentioned in Definition 5) is a positive decision. To implement LC, it is then sufficient to (i) register the variable whose assignment to a given value directly leads to an inconsistency, and (ii) always prefer this variable in subsequent decisions (if it is still unassigned) over the choice given by the underlying heuristic – whatever heuristic is used. Notice that LC does not require any additional space cost.

Figure 1 illustrates *Last Conflict* reasoning. The leftmost branch on the figure corresponds to the positive decisions $X_1 = v_1, \dots, X_i = v_i$, such that $X_i = v_i$ leads to a conflict. At this point, X_i is registered by LC for future use. As a consequence, v_i is removed from $\text{dom}(X_i)$, i.e. $X_i \neq v_i$. Then, instead of pursuing the search with a new selected variable, X_i is chosen to be assigned with a new value v' . In our illustration, this leads once again to a conflict, v' is removed from $\text{dom}(X_i)$, and the process loops until all values are removed from $\text{dom}(X_i)$, leading to a domain wipe-out. The algorithm then backtracks to the assignment $X_{i-1} = v_{i-1}$, going to the right branch $X_{i-1} \neq v_{i-1}$. As X_i is still recorded by LC, it is then selected in priority, and all values of $\text{dom}(X_i)$ are excluded due to

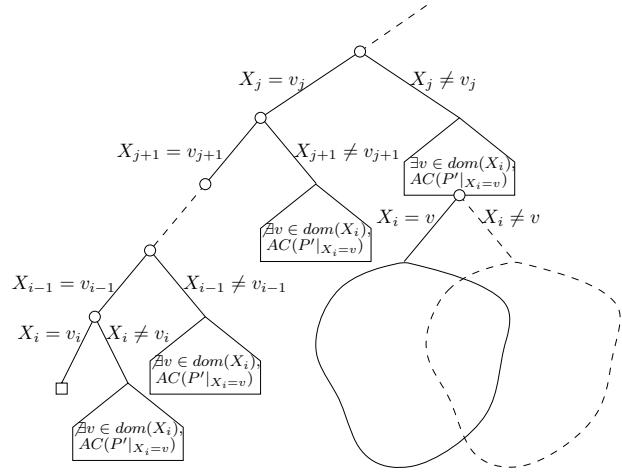

Figure 1. Last Conflict reasoning illustrated in a partial binary branching search tree. P' denotes the constraint network obtained at each node after performing the previous decisions and applying an inference operator ϕ .

the same process as above. The algorithm finally backtracks to the decision $X_j = v_j$, going to the right branch $X_j \neq v_j$. Then, as X_i is still the registered variable, it is preferred again and the values of $\text{dom}(X_i)$ are tested. But, as one of them (v) does not lead to a conflict, the search can continue with the assignment $X_i = v$. The variable X_i is then unregistered, and the choice for subsequent decisions is left to the underlying heuristic, until the next conflict occurs.

By using the ϕ_{AC} operator to identify culprit subsequences as described above, we obtain the following complexity results.

Proposition 2 Let $P = (\mathcal{X}, \mathcal{C})$ be a CN and $\Sigma = \langle \delta_1, \dots, \delta_i \rangle$ be a sequence of decisions such that $\{\delta_1, \dots, \delta_i\}$ is a ϕ_{AC} -nogood of P . The worst case time complexity of computing the culprit subsequence of Σ is $O(eid^3)$, where $e = |\mathcal{C}|$ and $d = |\text{dom}(X_i)|$ with X_i denoting the variable involved in δ_i .

Proof. The worst case is when the computed culprit subsequence of Σ is empty. In this case, it means that, for each decision, we check the singleton arc consistency of X_i . As checking the singleton arc consistency of a variable corresponds to d calls to an arc consistency algorithm, the worst case time complexity is id times the complexity of the used arc consistency algorithm. As the optimal worst case time complexity of establishing arc consistency is $O(ed^2)$ (e.g. AC2001/3.1 [3]), we obtain the overall time complexity $O(ed^3)$. \square

Corollary 2 Let $P = (\mathcal{X}, \mathcal{C})$ be a CN and $\Sigma = \langle \delta_1, \dots, \delta_i \rangle$ be a sequence of decisions that corresponds to a branch built by MAC leading to a failure. The worst case time complexity of computing the culprit subsequence of Σ is $O(\text{end}^3)$, where $n = |\mathcal{X}|$, $e = |\mathcal{C}|$ and $d = |\text{dom}(X_i)|$ with X_i denoting the variable involved in δ_i .

Proof. First, we know, that as positive decisions are performed first by MAC, the number of opened nodes in a branch of the search tree is at most n . Second, for each closed node, we do not have to check the singleton arc consistency of X_i since we have to directly backtrack. So we obtain $O(end^3)$. \square

3.3 Preventing thrashing using LC

Thrashing is the fact of repeatedly exploring the same subtrees. This phenomenon deserves to be carefully studied as an algorithm subject to thrashing can be very inefficient.

Sometimes, thrashing can be explained by some bad choices made earlier during search. In fact, whenever a value is removed from the domain of a variable, it can be explained (with more or less precision). It simply means that it is possible to indicate the decisions (i.e. variable assignments in our case) that entailed removing this value. By recording such so-called eliminating explanations and exploiting this information, one can hope to backtrack up to a level where a culprit variable will be re-assigned, this way, avoiding thrashing.

In some cases, no pertinent culprit variable(s) can be identified by a backjumping technique although thrashing occurs. For example, let us consider some unsatisfiable instances of the queens+knights problem as proposed in [4]. When the two subproblems are merged without any interaction (there is no constraint involving both a queen variable and a knight variable as in the *qk-25-25-5-add* instance), a backjumping technique such as CBJ or DBT is able to prove the unsatisfiability of the problem from the unsatisfiability of the knights subproblem (by backtracking up to the root of the search tree). When the two subproblems are merged with an interaction (queens and knights cannot be put on the same square as in the *qk-25-25-5-mul* instance), CBJ and DBT become subject to thrashing (when they are used with a standard variable ordering heuristic such as *dom*, *bz* and *dom/ddeg*) because the last assigned queen variable is considered as participating to the failure. The problem is that, even if there exists different eliminating explanations for a removed value, only the first one is recorded. One can still imagine to improve existing backjumping algorithms by updating eliminating explanations or computing new ones [15]. However, it is far beyond the scope of this paper.

Last Conflict reasoning is a new way of preventing thrashing, while still being a look-ahead technique. Indeed, guiding search to the last decision of a culprit subsequence behaves similarly to using a form of backjumping to that decision. For example, we can show that when a backjump to a culprit decision occurs with the Gaschnig's technique [10], then LC, in the same context, also reaches this decision in polynomial time.

Table 1 illustrates the powerful thrashing prevention capability of LC on the two instances mentioned above. SBT, CBJ and DBT cannot prevent thrashing for the *qk-25-25-5-mul* instance as, within 2 hours, the instance remains unsolved (even when other standard heuristics are used). On the other hand, in about 1 minute, LC (with SBT) can prove the unsatisfiability of this instance. The reason is that all knight variables are singleton arc inconsistent. When such a variable is reached, LC guides search up to the root of the search tree.

<i>Instance</i>		<i>SBT</i>	<i>CBJ</i>	<i>DBT</i>	<i>LC</i>
<i>qk-25-25-5-add</i>	<i>cpu</i>	> 2h	11.7	12.5	58.9

<i>qk-25-25-5-mul</i>	<i>cpu</i>	> 2h	> 2h	> 2h	66.6
	<i>nodes</i>	—	—	—	9922

Table 1. Cost of running MAC-bz (time out set to 2 hours)

4 Experiments

In order to show the practical interest of the approach described in this paper, we have conducted an extensive experimentation (on a PC Pentium IV 2,4GHz 512Mo under Linux). Performances are measured in terms of the number of visited nodes (nodes) and the cpu time in seconds (cpu). Remark that for our experimentation, we have used MAC (with SBT, i.e. chronological backtracking), and studied the impact of LC wrt various variable ordering heuristics.

First, we have experimented different series of problems. The results that we have obtained are given in Table 2. The series corresponding to composed random instances, random 3-SAT instances

Table 2. Average cost (cpu) of running MAC without LC ($\neg LC$) and with LC on different series of problems

and balanced QWH instances were used as benchmarks² for the first CSP solver competition. Each composed random instance contains a main (under-constrained, here) fragment and some auxiliary fragments, each one being grafted to the main fragment by introducing some binary constraints. Each random 3-SAT instance embeds a small unsatisfiable part and has been converted to CSP using the dual encoding method. Each balanced QWH instance corresponds to a satisfiable balanced quasi-group instance with holes. Finally, the last series correspond to some realistic radar surveillance instances³ as proposed by the Swedish Institute of Computer Science (SICS). The problem is to adjust the signal strength (from 0 to 3) of a given number of fixed radars wrt 6 geographic sectors. Moreover, each cell of the geographic area must be covered exactly by 3 radar stations, except for some insignificant cells that must not be covered. Each set is denoted *rs-i-j* where *i* and *j* represent the number of radars and the number of insignificant cells, respectively.

In Table 2, we can observe the impact of LC when using MAC and different heuristics. Note that the time limit was fixed to 1 hour (except for the random 3-SAT instances, all solved in reasonable time) and that the number of expired instances, i.e. instances not solved within 1 hour of allowed cpu time, is given between brackets. Also, remark that, in case of expired instances, the indicated cpu must be considered as a lower bound.

On the one hand, when standard heuristics *dom/ddeg* and *bz* are used, it clearly appears that LC allows improving the efficiency of MAC in both CPU time and the number of solved instances, especially on composed and radar surveillance instances. In fact, these instances have a structure and a too blind search is subject to thrashing. Using LC avoids this phenomena without disturbing the main behaviour of the heuristics. On the other hand, when the conflict-directed heuristic *dom/wdeg* is used, LC is not so important since thrashing was already prevented by the heuristic.

Finally, we present in Table 3 some representative results obtained for some selected instances of the first international CSP competition. The time limit was also fixed to 1 hour. Once again, it appears that using LC with a standard heuristic greatly improves the efficiency of MAC. This is not always the case for MAC-*dom/wdeg*. Note that most of these instances cannot be efficiently solved using a backjumping technique such as CBJ or DBT combined with a standard heuristic as shown in [18].

5 Conclusion

In this paper, we have introduced an original approach that can be grafted to any search algorithm based on a depth-first exploration. The principle is to select in priority the variable involved in the last conflict (i.e. the last assignment that failed) as long as the network cannot be made consistent. This way of reasoning allows preventing thrashing by backtracking to the most recent culprit of the last conflict. It can be done without any additional cost in space and with a worst-case time complexity in $O(end^3)$. Our extensive experimentation clearly shows the interest of this approach.

In our approach, the variable ordering heuristic is violated, until a backtrack to the culprit variable occurs and a singleton consistent value is found. However, there is an alternative which is to not consider the found singleton consistent value as the next value to be assigned. In this case, the approach becomes a pure inference technique which corresponds to (partially) maintaining a singleton consistency (SAC, for example) on the variable involved in the last conflict. This would be related to the recent “quick shaving” technique [19].

Dynamic Orderings for AND/OR Branch-and-Bound Search in Graphical Models

Radu Marinescu and Rina Dechter¹

Abstract. *AND/OR search spaces* have recently been introduced as a unifying paradigm for advanced algorithmic schemes for graphical models. The main virtue of this representation is its sensitivity to the structure of the model, which can translate into exponential time savings for search algorithms. Since the variable selection can have a dramatic impact on search performance when solving optimization tasks, we introduce in this paper a new *dynamic* AND/OR Branch-and-Bound algorithmic framework which accommodates variable ordering heuristics. The efficiency of the dynamic AND/OR approach is demonstrated empirically in a variety of domains.

1 INTRODUCTION

Graphical models (e.g. constraint and belief networks) are a powerful representation framework for various automated reasoning tasks. These models use graphs to capture conditional independencies between variables, allowing a concise representation of the knowledge, as well as efficient graph-based query processing algorithms. *Constraint Optimization Problems* such as finding a solution that violates the least number of constraints or finding the most likely state of a belief network can be defined within this framework and they are typically tackled with either *search* or *inference* algorithms [9].

The AND/OR search space for graphical models [8] is a newly introduced framework for search that is sensitive to the independencies in the model, often resulting in exponentially reduced complexities. It is based on a pseudo-tree that captures independencies in the graphical model, resulting in a search tree exponential in the depth of the pseudo-tree, rather than in the number of variables.

The AND/OR Branch-and-Bound algorithm (AOBB) is a new search method that explores the AND/OR search tree for solving optimization tasks in graphical models [16]. If restricted to a static variable ordering, the algorithm was shown to outperform a static version of the traditional OR Branch-and-Bound. In practice however, variable selection can have a dramatic influence on search performance for solving constraint satisfaction and optimization tasks [9]. In the context of OR search spaces there exists a whole line of research that mitigates this problem and focuses on the practical use of variable ordering heuristics during search. The most powerful OR Branch-and-Bound solvers developed in the past years, such as those maintaining a form directional local consistency [6] or those guided by bounded tree-clustering inference [7] rely heavily on variable ordering heuristics in order to improve efficiency.

In this paper we introduce a collection of *dynamic* AND/OR Branch-and-Bound algorithms that extend AOOB by combining the AND/OR decomposition principle with variable ordering heuristics. There are three approaches to incorporating dynamic orderings into

AOBB. The first one improves AOOB by applying an independent semantic variable ordering heuristic whenever the partial order dictated by the static decomposition principle allows. The second, orthogonal approach gives priority to the semantic variable ordering heuristic and applies problem decomposition as a secondary principle. Since the structure of the problem may change dramatically during search we introduce a third approach that uses a dynamic decomposition method coupled with semantic variable ordering heuristics.

We apply the dynamic AND/OR Branch-and-Bound algorithms on two optimization tasks: solving Weighted CSPs [6] and pure 0-1 Integer Linear Programming problems [17]. We experiment with various random models and real-world scheduling and resource allocation problems. Our results show conclusively that the new dynamic AND/OR approach outperforms significantly the classic OR as well as the existing static AND/OR tree search algorithms.

2 BACKGROUND

A finite *Constraint Optimization Problem* (COP) is a six-tuple $\mathcal{P} = \langle \mathcal{X}, \mathcal{D}, \mathcal{F}, \otimes, \Downarrow, Z \rangle$, where $\mathcal{X} = \{X_1, \dots, X_n\}$ is a set of variables, $\mathcal{D} = \{D_1, \dots, D_n\}$ is a set of finite domains and $\mathcal{F} = \{f_1, \dots, f_m\}$ is a set of constraints. Constraints can be either *soft* (cost functions) or *hard* (sets of allowed tuples). Without loss of generality we assume that hard constraints are represented as (bi-valued) cost functions. Allowed and forbidden tuples have cost 0 and ∞ , respectively. The scope of function f_i , denoted $\text{scope}(f_i) \subseteq \mathcal{X}$, is the set of arguments of f_i . The operators \otimes and \Downarrow are defined as follows: $\otimes_i f_i$ is a *combination operator*, $\otimes_i f_i \in \{\prod_i f_i, \sum_i f_i\}$ and $\Downarrow_Y f$ is an *elimination operator*, $\Downarrow_Y f \in \{\max_{S-Y} f, \min_{S-Y} f\}$, where S is the scope of function f and $Y \subseteq \mathcal{X}$. The scope of $\Downarrow_Y f$ is Y .

An optimization task is defined by $g(Z) = \Downarrow_Z \otimes_{i=1}^m f_i$, where $Z \subseteq \mathcal{X}$. A *global optimization* is the task of finding the best global cost, namely $Z = \emptyset$. For simplicity we will develop our work assuming a COP instance with *summation* and *minimization* as combination and elimination operators, and a global cost function defined by $f(\mathcal{X}) = \min_{\mathcal{X}} \sum_{i=1}^m f_i$.

The *constraint graph* of a COP instance has the variables \mathcal{X} as its nodes and an arc connects any two variables that appear in the scope of the same function.

3 AND/OR SEARCH TREES

The classical way to do search is to instantiate variables one at a time, following a static/dynamic variable ordering. In the simplest case, this process defines a search tree (called here OR search tree), whose nodes represent states in the space of partial assignments. The traditional search space does not capture independencies that appear in

¹ University of California, Irvine, USA, email: {radum,dechter}@ics.uci.edu

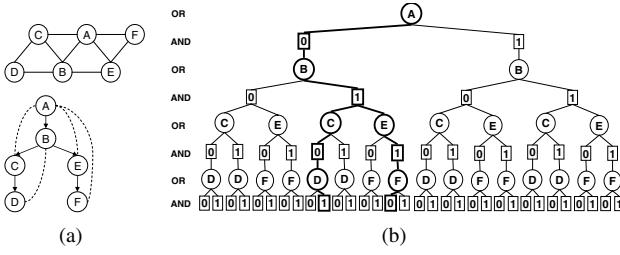

Figure 1. The AND/OR search space.

the structure of the constraint graph. Introducing AND states into the search space can capture the problem structure, decomposing the problem into independent subproblems by conditioning on values. The AND/OR search space is defined using a backbone *pseudo-tree* [10, 1, 8].

DEFINITION 1 (pseudo-tree) Given an undirected graph $G = (V, E)$, a directed rooted tree $T = (V, E')$ defined on all its nodes is called *pseudo-tree* if any arc of G which is not included in E' is a *back-arc*, namely it connects a node to an ancestor in T .

Given a COP instance $\langle \mathcal{X}, \mathcal{D}, \mathcal{F} \rangle$, its constraint graph G and a pseudo-tree T of G , the associated AND/OR search tree S_T has alternating levels of OR nodes and AND nodes. The OR nodes are labeled by X_i and correspond to the variables. The AND nodes are labeled by $\langle X_i, x_i \rangle$ and correspond to value assignments in the domains of the variables. The structure of the AND/OR tree is based on the underlying pseudo-tree T of G . The root of the AND/OR search tree is an OR node, labeled with the root of T .

The children of an OR node X_i are AND nodes labeled with value assignments $\langle X_i, x_i \rangle$, consistent along the path from the root, $path(X_i, x_i) = (\langle X_1, x_1 \rangle, \dots, \langle X_{i-1}, x_{i-1} \rangle)$. The children of an AND node $\langle X_i, x_i \rangle$ are OR nodes labeled with the children of variable X_i in T . In other words, the OR states represent alternative ways of solving the problem, whereas the AND states represent problem decomposition into independent subproblems, all of which need be solved. When the pseudo-tree is a chain, the AND/OR search tree coincides with the regular OR search tree.

A *solution subtree* Sol_{S_T} of S_T is an AND/OR subtree such that: (i) it contains the root of S_T ; (ii) if a nonterminal AND node $n \in S_T$ is in Sol_{S_T} then all its children are in Sol_{S_T} ; (iii) if a nonterminal OR node $n \in S_T$ is in Sol_T then exactly one of its children is in Sol_{S_T} .

Example 1 Figure 1(a) shows the constraint graph of a COP instance and a pseudo-tree together with the back-arcs (dotted lines). Figure 1(b) shows the AND/OR search tree based on the pseudo-tree, for bi-valued variables. A solution subtree is highlighted.

The AND/OR search tree can be traversed by a depth-first search algorithm that is guaranteed to have a time complexity exponential in the depth of the pseudo-tree and can use linear space [16]. The arcs from X_i to $\langle X_i, x_i \rangle$ are annotated by appropriate *labels* of the cost functions. The nodes in S_T can be associated with *values*, defined over the subtrees they root.

DEFINITION 2 (label) The label $l(X_i, x_i)$ of the arc from the OR node X_i to the AND node $\langle X_i, x_i \rangle$ is defined as the sum of all the cost functions values for which variable X_i is contained in their scope and whose scope is fully assigned along $path(X_i, x_i)$.

Figure 2. AND/OR Branch-and-Bound search.

DEFINITION 3 (value) The value $v(n)$ of a node $n \in S_T$ is defined recursively as follows: (i) if $n = \langle X_i, x_i \rangle$ is a terminal AND node then $v(n) = l(X_i, x_i)$; (ii) if $n = \langle X_i, x_i \rangle$ is an internal AND node then $v(n) = l(X_i, x_i) + \sum_{n' \in \text{succ}(n)} v(n')$; (iii) if $n = X_i$ is an internal OR node then $v(n) = \min_{n' \in \text{succ}(n)} v(n')$, where $\text{succ}(n)$ are the children of n in S_T .

Clearly, the value of each node can be computed recursively, from leaves to root.

PROPOSITION 1 Given an AND/OR search tree S_T of a COP instance $\mathcal{P} = (\mathcal{X}, \mathcal{D}, \mathcal{F})$, the value $v(n)$ of a node $n \in S_T$ is the minimal cost solution to the subproblem rooted at n , subject to the current variable instantiation along the path from root to n . If n is the root of S_T , then $v(n)$ is the minimal cost solution to \mathcal{P} .

4 AND/OR BRANCH-AND-BOUND SEARCH

AND/OR Branch-and-Bound (AOBB) was recently proposed by [16] as a depth-first Branch-and-Bound that explores an AND/OR search tree for solving optimization tasks in graphical models. In this section we overview the static version of the algorithm.

4.1 Lower Bounds on Partial Trees

At any stage during search, a node n along the current path roots a current *partial solution subtree*, denoted by $G_{sol}(n)$, which must be connected, must contain its root n and will have a *frontier* containing all those nodes that were generated and not yet expanded. Furthermore, there exists a *static heuristic function* $h(n)$ underestimating $v(n)$ that can be computed efficiently when node n is first generated.

Given the current partially explored AND/OR search tree S_T , the *active path* $\mathcal{AP}(t)$ is the path of assignments from the root of S_T

to the current tip node t . The *inside context* $\text{in}(\mathcal{AP})$ of $\mathcal{AP}(t)$ contains all nodes that were fully evaluated and are children of nodes on $\mathcal{AP}(t)$. The *outside context* $\text{out}(\mathcal{AP})$ of $\mathcal{AP}(t)$, contains all the frontier nodes that are children of the nodes on $\mathcal{AP}(t)$. The *active partial subtree* $\mathcal{APT}(n)$ rooted at a node $n \in \mathcal{AP}(t)$ is the subtree of $G_{\text{sol}}(n)$ containing the nodes on $\mathcal{AP}(t)$ between n and t together with their OR children. A *dynamic heuristic evaluation function* of a node n relative to $\mathcal{APT}(n)$ which underestimates $v(n)$ is defined as follows (see [16] for more details).

DEFINITION 4 (dynamic heuristic evaluation function) *Given an active partial tree $\mathcal{APT}(n)$, the dynamic heuristic evaluation function of n , $f_h(n)$, is defined recursively as follows: (i) if $\mathcal{APT}(n)$ consists only of a single node n , and if $n \in \text{in}(\mathcal{AP})$ then $f_h(n) = v(n)$ else $f_h(n) = h(n)$; (ii) if $n = \langle X_i, x_i \rangle$ is an AND node, having OR children m_1, \dots, m_k then $f_h(n) = \max(h(n), l(X_i, x_i) + \sum_{i=1}^k f_h(m_i))$; (iii) if $n = X_i$ is an OR node, having an AND child m , then $f_h(n) = \max(h(n), f_h(m))$.*

4.2 Static AND/OR Branch-and-Bound

AOBB can calculate a *lower bound* on $v(n)$ for any node n on the active path, by using $f_h(n)$. It also maintains an *upper bound* on $v(n)$ which is the current minimal cost solution subtree rooted at n . If $f_h(n) \geq ub(n)$ then the search can be safely terminated below the tip node of the active path.

Figure 2 shows AOBB. The following notation is used: $(\mathcal{X}, \mathcal{D}, \mathcal{F})$ is the problem with which the procedure is called, st is the current partial solution subtree being explored, in (resp. out) represents the inside (resp. outside) context of the active path. These contexts are constantly updated during search. The algorithm assumes that variables are selected statically according to a pseudo-tree.

If the set \mathcal{X} is empty, then the result is trivially computed (line 1). Else, AOBB selects a variable X_i (i.e. expands the OR node X_i) and iterates over its values (line 5) to compute the OR value $v(X_i)$. For each value x_i the problem rooted by the AND node $\langle X_i, x_i \rangle$ is decomposed into a set of q independent subproblems $P_k = (\mathcal{X}_k, \mathcal{D}_k, \mathcal{F}_k)$, one for each child X_k of X_i in the pseudo-tree. Procedure LB computes the static heuristic function $h(n)$ for every node n in the search tree.

When expanding the AND node $\langle X_i, x_i \rangle$, AOBB successively computes the *dynamic heuristic evaluation function* $f_h(m)$ for every ancestor node m along the active path and terminates the current search path if, for some m , $f_h(m) \geq ub(m)$. Else, the independent subproblems are solved recursively (lines 14-22) and the results accumulated by the AND value $v(X_i, x_i)$ (line 18). A lookahead procedure is also executed in which unfeasible values are removed from future domains (line 15). After trying all feasible values of variable X_i , the minimal cost solution to the problem rooted by X_i remains in $v(X_i)$, which is returned (line 28).

5 DYNAMIC AND/OR BRANCH-AND-BOUND

In this section we go beyond static orderings and introduce a collection of *dynamic AND/OR Branch-and-Bound* algorithms that incorporate variable ordering heuristics used in the classic OR space. Similar structure-aware variable ordering heuristics have been previously investigated in the context of SAT and model counting [2, 11, 15].

We distinguish two classes of variable ordering heuristics. *Graph-based heuristics* (e.g. pseudo-tree arrangements) that try to maximize problem decomposition and *semantic-based heuristics* (e.g.

min-domain, max-degree, min-dom/deg) that aim at shrinking the search space. These two forces are orthogonal, namely we can use one as the primary goal and break ties based on the other. Moreover, we can use each class statically or dynamically. We present next three ways of combining efficiently these two classes of heuristics.

5.1 Partial Variable Ordering (PVO)

The first approach, called *AND/OR Branch-and-Bound with Partial Variable Ordering* (AOBB+PVO) combines the static graph-based decomposition given by a pseudo-tree with a dynamic semantic ordering heuristic. It is an adaptation of the ordering heuristics developed by [11] and [15] for solving large-scale SAT problem instances.

Let us illustrate the idea with an example. Consider the pseudo-tree from Figure 1(a) inducing the following variable group ordering: $\{A,B\}$, $\{C,D\}$, $\{E,F\}$; which dictates that variables $\{A,B\}$ should be considered before $\{C,D\}$ and $\{E,F\}$. Variables in each group can be dynamically ordered based on a second, independent semantic-based heuristic. Notice that after variables $\{A,B\}$ are instantiated, the problem decomposes into independent components that can be solved separately.

AOBB+PVO is similar to the algorithm from Figure 2 traversing an AND/OR search tree guided by a pre-computed pseudo-tree. Procedure `SelectVar` in this case implements the dynamic semantic ordering heuristic which selects next the best scoring variable from the current variable group of the pseudo-tree.

5.2 Dynamic Variable Ordering (DVO)

The second, orthogonal approach to PVO called *AND/OR Branch-and-Bound with Dynamic Variable Ordering* (DVO+AOBB), gives priority to the dynamic semantic ordering heuristic and applies static problem decomposition as a secondary principle during search. This idea was also explored by [2] in the context of SAT model counting.

DVO+AOBB is also based on the algorithm from Figure 2. It instantiates variables dynamically using a semantic ordering heuristic while constantly updating the problem graph structure. Specifically, after variable X_i is selected by procedure `SelectVar`, DVO+AOBB tentatively removes X_i from the graph and, if disconnected components are detected their corresponding subproblems are then solved separately and the results combined in an AND/OR manner (lines 14-22). It is easy to see that in this case a variable may have the best semantic heuristic to tighten the search space, yet, it may not yield a good decomposition for the remaining of the problem, in which case the algorithm would explore primarily an OR space.

5.3 Dynamic Separator Ordering (DSO)

The third approach, called *AND/OR Branch-and-Bound with Dynamic Separator Ordering* (AOBB+DSO), combines a dynamic graph-based decomposition heuristic with a dynamic semantic ordering heuristic giving priority to the first. The idea is supported by the constraint propagation (e.g. lookahead) procedure which may detect singleton variables (i.e. with only one feasible value left in their domains). When the value of a variable is known, we can remove it from the corresponding subproblem. Therefore, we may expect a better decomposition based on a simplified constraint graph.

AOBB+DSO is also based on the algorithm from Figure 2. It creates and maintains a separator S of the current constraint graph. A graph separator can be computed using the hypergraph partitioning method presented in [15]. The next variable is chosen dynamically

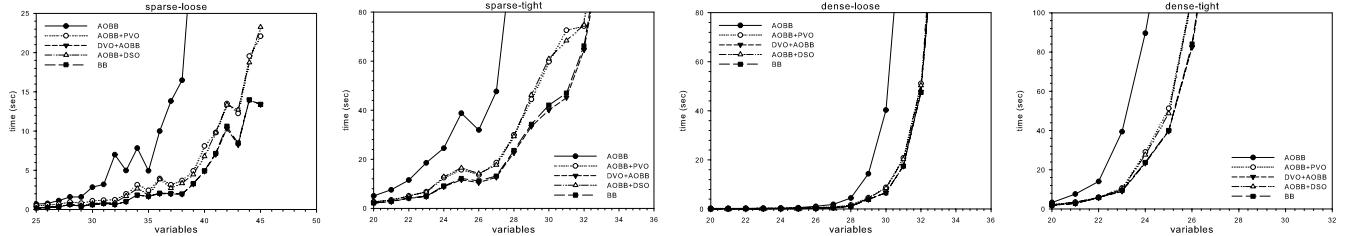

Figure 3. Time in seconds to prove optimality for random binary WCSPs.

from S by the semantic ordering heuristic until all variables are instantiated and the current problem decomposes into several subproblems. These independent subproblems are then solved separately and their solutions combined in an AND/OR fashion. The separator of each component is created from a simplified subgraph resulted from previous constraint propagation steps and it may differ for different value assignments. Clearly, if no singleton variables are discovered by the lookahead steps this approach is computationally identical to AOBB+PVO, although it may have a higher overhead due to the dynamic generation of the separators.

6 EXPERIMENTS

In this section we evaluate empirically the performance of the dynamic AND/OR Branch-and-Bound algorithms on two optimization tasks: solving Weighted CSPs and pure 0-1 Integer Linear Programming problems². For comparison, we include results obtained with the classic OR Branch-and-Bound (BB) algorithm.

BB explores an OR search tree in a depth-first manner maintaining an upper bound, the best solution cost found so far, and a heuristic evaluation function (i.e. lower bound) of the optimal extension of the current partial assignment. The subtree below the current path is pruned as soon as the lower bound exceeds the upper bound. The algorithm uses a dynamic semantic-based variable ordering heuristic.

Weighted CSP (WCSP) [6] extends the classic CSP formalism with so-called *soft constraints* which assign a positive integer penalty cost to each forbidden tuple (allowed tuples have cost 0). The goal is to find a complete assignment with minimum aggregated cost.

A *pure 0-1 Integer Linear Programming* (0-1 ILP) [17] consists of a set of integer decision variables (restricted to values 0 or 1) and a set of linear constraints (equalities or inequalities). The goal is to minimize a global linear cost function subject to the constraints.

The semantic-based variable ordering and heuristic evaluation function used in each domain by the OR and AND/OR Branch-and-Bound algorithms are as follows. For WCSPs we use the *min-dom/deg* heuristic (which selects the variable with the smallest ratio of the domain size divided by the future degree) and the heuristic evaluation function is computed by maintaining Existential Directional Arc Consistency (EDAC) [6]. For 0-1 ILPs we use the *fraction* heuristic (which selects the fractional variable closest to 0.5) and the heuristic evaluation function is computed by solving the linear relaxation of the current subproblem with the SIMPLEX³ method [5, 17]. Ties were broken lexicographically. The pseudo-tree that guides AOBB and AOBB+PVO as well as the graph separator used by AOBB+DSO were generated based on the recursive decomposition of a hypergraph representation of the problem [11, 15].

² All experiments were done on a 2.4GHz Pentium IV with 2GB of RAM.

³ Our code used the SIMPLEX implementation from the open source library

Table 1. Time in seconds to prove optimality for SPOT5 benchmarks.

spot	(w*,h)	BB time	AOBB time	AOBB+PVO time	DVO+AOBB time	AOBB+DSO time
29	(15, 22)	0.41	1.91	1.93	0.33	0.68
42	(38, 46)	-	-	-	4709	-
54	(12, 16)	0.06	1.13	1.07	0.03	0.08
404	(20, 25)	0.03	2.50	2.50	0.02	0.03
503	(11, 21)	11.70	2.78	2.78	0.03	0.13
505	(27, 42)	4010	75.43	75.37	17.28	82.74

We report the average CPU time required for proving optimality of the solution (the nodes visited are not shown for space reasons), the induced width (w^*) and depth of the pseudo-tree (h) obtained for the test instances. The best performance points are highlighted.

6.1 Random Weighted CSPs

We have generated 4 classes of binary random WCSPs with domain size and penalty weight set to 10 (Sparse-Loose, Sparse-Tight, Dense-Loose, Dense-Tight) as proposed in [6]. Figure 3 gives the time results in seconds (each data point represents an average over 20 samples). When comparing AOBB+PVO with static AOBB we notice a considerable improvement in terms of both running time and size of search space explored. AOBB+DSO has a similar performance as AOBB+PVO indicating that both algorithms use decompositions of similar quality. The best performance of all 4 problem classes is offered by DVO+AOBB and BB with no clear winner between the two. This implies that the semantic ordering heuristic is powerful and it does not leave much room for additional problem decompositions.

6.2 Earth Observing Satellites

The problem of scheduling an Earth observing satellite is to select from a set of candidate photographs, the best subset such that a set of imperative constraints are satisfied and the total importance of the selected photographs is maximized. We experimented with problem instances from the SPOT5 benchmark [3] which can be formulated as non-binary WCSPs [3]. For our purpose we considered a simplified MAX-CSP version of the problem where the goal is to minimize the number of imperative constraints violations.

Table 1 shows the results for 6 scheduling problems. We observe that in this domain DVO+AOBB is the best performing algorithm. In spot-42, the hardest instance, DVO+AOBB proves optimality in about one and a half hours, thus demonstrating the power of augmenting a semantic-based ordering heuristic with a static decomposition principle. The other algorithms exceeded the 10 hour time limit. AOBB+DSO is the second best algorithm, always exploring

lp_solve 5.5 available at http://groups.yahoo.com/group/lp_solve/

Table 2. Time in seconds to prove optimality for CELAR6 benchmarks.

celar6	(w*,h)	BB time	AOBB time	AOBB+PVO time	DVO+AOBB time	AOBB+DSO time
sub0	(7, 8)	0.88	0.73	0.81	0.92	0.71
sub1	(9, 9)	2260	3101	2200	2182	2246
sub1-24	(9, 9)	136	171	128	127	132
sub2	(10, 12)	4696	10963	7047	4024	6696
sub3	(10, 13)	14687	32439	28252	11131	28407
sub4-20	(11, 15)	681	137	157	70	179

fewer nodes than the other AND/OR algorithms. Its computational overhead of computing the separators dynamically did not pay off in some test cases (e.g. spot-505).

6.3 Radio Link Frequency Assignment Problem

RLFAP is a communication problem where the goal is to assign frequencies to a set of radio links in such a way that all links may operate together without noticeable interferences [4]. It can be naturally casted as a binary WCSP where each forbidden tuple has an associated penalty cost. Table 2 compares the OR and AND/OR algorithms for solving 6 publicly available RLFAP subinstances called CELAR6-SUB_i ($i = 1, \dots, 4$). We observe that in this domain also DVO+AOBB offers the best performance. On average, the speedups caused by DVO+AOBB over the other algorithms are as follows: 1.9x over AOBB, 1.6x over AOBB+PVO and 2.5x over BB. AOBB+DSO performs similarly to AOBB+PVO indicating that the quality of the dynamic problem decomposition is comparable to the static one.

6.4 Uncapacitated Warehouse Location Problem

In UWLP a company considers opening m warehouses at some candidate locations in order to supply its n existing stores. The objective is to determine which warehouse to open, and which of these warehouses should supply the various stores, such that the sum of the maintenance and supply costs is minimized. Each store must be supplied by exactly one warehouse. UWLP is typically formulated as a pure 0-1 integer linear program [17].

Table 3. Time in seconds to prove optimality for UWLP benchmarks.

uwlp	BB time	AOBB time	AOBB+PVO time	DVO+AOBB time
1	6.27	15.72	6.28	7.23
2	11.34	17.22	5.78	11.75
3	73.66	15.78	5.83	77.94
4	836.52	27.94	11.97	904.15
5	2501.75	32.69	16.98	2990.19
6	43.36	18.70	8.03	45.99
7	1328.40	27.89	8.53	1515.48
8	76.88	25.20	13.70	88.38
9	224.33	46.06	17.17	367.14
10	7737.65	28.03	9.13	9276.98

Table 3 displays the results obtained for 10 randomly generated UWLP problem instances⁴ with 50 warehouses and 200 stores. The warehouse opening and store supply costs were chosen uniformly randomly between 0 and 1000. These are large problems with 10,050 variables and 10,500 constraints. We can see that AOBB+PVO dominates in all test cases, outperforming BB (resp. DVO+AOBB) with several orders of magnitude in terms of running time and size of the search space explored. This is due to the problem's structure partially

⁴ We used the random problem generator from <http://www.mpi-sb.mpg.de/~units/ag1/projects/benchmarks/UfLib/>

captured by a shallow pseudo-tree with depth 123 and induced width 50. DVO+AOBB has a similar performance as BB (it is slower than BB due to its computational overhead), indicating that these problems do not break into disconnected components when semantic variable ordering has higher priority than problem decomposition.

In summary, for WCSP instances with relatively low connectivity (e.g. random WCSPs, SPOT5 networks) as well as for instances with higher graph density (e.g. CELAR6 networks) DVO+AOBB outperforms significantly both its OR and AND/OR competitors. For sparse 0-1 integer programs (e.g. UWLP) which yield extremely shallow pseudo-trees AOBB+PVO appears to be the preferred choice.

7 CONCLUSION

In this paper we extended the AND/OR Branch-and-Bound algorithmic framework with dynamic orderings for combining efficiently variable ordering heuristics with problem decomposition principles. The effectiveness of the dynamic AND/OR approach is demonstrated empirically in a variety of domains including random models as well as hard real-world problem instances.

Related Work: AOBB is related to the Branch-and-Bound method proposed by [13] for acyclic AND/OR graphs and game trees, as well as to the pseudo-tree search algorithm proposed in [14] for boosting Russian Doll search. BTD algorithm developed in [12] for semi-ring CSPs can also be interpreted as an AND/OR graph search algorithm.

Compact Representation of Sets of Binary Constraints

Jussi Rintanen¹

Abstract. We address the problem of representing big sets of binary constraints compactly. Binary constraints in the form of 2-literal clauses are ubiquitous in propositional formulae that represent real-world problems ranging from model-checking problems in computer-aided verification to AI planning problems. Current satisfiability and constraint solvers are applicable to very big problems, and in some cases the physical size of the problem representations prevents solving the problems, not their computational difficulty. Our work is motivated by this observation.

We propose graph-theoretic techniques based on cliques and bicliques for compactly representing big sets of binary constraints that have the form of 2-literal clauses. An n, m biclique in a graph associated with the constraints can be very compactly represented with only $n + m$ binary constraints and one auxiliary variable. Cliques in the graph are associated with *at-most-one* constraints, and can be represented with a logarithmic number of binary constraints. The clique representation turns out to be a special case of the biclique representation. We demonstrate the effectiveness of the biclique representation in making the representation of big planning problems practical.

1 Introduction

Binary constraints in the form of binary clauses $l_1 \vee l_2$ are very common in many applications of CSPs and propositional satisfiability. For example, most of the clauses in the representation of AI planning problems as CNF formulae in the propositional logic are binary clauses [11]. In structured formulae stemming from real-world applications, sets of binary clauses have regularities that make efficient reasoning and more compact representation possible. The goal of this work is to develop techniques for representing big sets of binary clauses more compactly.

The applications that motivate our work are planning and model-checking. The *planning as satisfiability* approach was introduced by Kautz and Selman [10, 11] and later generalized to a wide class of model-checking problems [2]. Current generation of satisfiability algorithms can solve planning and model-checking problems with thousands of variables and tens of thousands of actions. Interestingly, an obstacle to the scalability of the approach to still bigger problems is in some cases the enormous size of the propositional formulae.

For AI planning, for instance, there exist asymptotically optimal linear size translations into the propositional logic [14]. However, a part of the problem-specific information which is necessary for efficient reasoning, in the form of 2-literal *invariants* [3, 13], has a size that is in the worst-case quadratic in the size of the problem instance. Typically these 2-literal clauses constitute between 50 and 95 per cent of the formulae, or even more. An example of a typical invariant in a planning problem is for example $\neg\text{in}(A, \text{London}) \vee \neg\text{in}(A, \text{Paris})$

which indicates that an object cannot be in two locations simultaneously. For n state variables there are $\mathcal{O}(n^2)$ invariants that are 2-literal clauses. For a planning problem with $n = 5000$ state variables and a formula that encodes the search for plans of 100 time points, if only one of the state variables is true at any given time, the corresponding set of binary clauses has cardinality $100 \times \frac{n(n-1)}{2} = 1249750000 \sim 1.2 \times 10^9$. If each clause takes 10 bytes then the total size of the representation is about 12 gigabytes. The problem of representing the constraint graphs compactly arises.

In this paper we propose techniques for representing the constraint graphs more compactly with cliques and bicliques. We show how constraint graphs that contain big cliques or bicliques can be represented more compactly than the explicit representation, and we also show that constraint graphs arising from practically interesting applications indeed do contain big cliques and bicliques. The presence of cliques is more obvious and they have been addressed in earlier research. The main contribution of our work is the introduction of techniques based on bicliques. The underlying ideas in the use of bicliques are simple and powerful, yet their importance has not been recognized before. We show that the clique based techniques are subsumed by the biclique based techniques.

The outline of this paper is as follows. Section 2 introduces the graph-theoretic concepts of cliques and bicliques and discusses their computational properties. In Section 3 we discuss the compact representation of cliques of constraint graphs. In Section 4 we address the compact representation of constraint graphs more generally in terms of bicliques. In Section 5 we show the effectiveness of the biclique representation in reducing the sizes of formulae that represent an industrial size planning problem.

2 Preliminaries: Cliques and Bicliques

The techniques presented in this paper are based on cliques and bicliques of graphs.

Definition 1. Let $\langle N, E \rangle$ be an undirected graph. Then a clique is $C \subseteq N$ such that $\{n, n'\} \in E$ for every $n, n' \in C$ such that $n \neq n'$.

Hence cliques are complete subgraphs. Identification of cliques is expensive. Testing whether a graph contains a clique of size n is NP-complete [9, 6]. Hence we cannot expect to have a polynomial-time algorithm that is guaranteed to find the biggest cliques of a graph. Approximation algorithms for identifying cliques and related subgraphs exist [8]. Hochbaum's algorithms are based on reducing the problem to integer programming and showing that the corresponding linear programs have integers solutions. Linear programming problems can be solved in polynomial time.

Instead of using Hochbaum's algorithm, we have used the simpler polynomial-time algorithm without approximation guarantees that is given in Figure 1. In many of our example applications (see Section

¹ National ICT Australia, Canberra Research Laboratory, Canberra, Australia

5) this algorithm identifies all the maximal cliques because no two maximal cliques share a node. Of course, maximal cliques of many graphs do not have this property.

```

1: procedure partition-to-cliques( $N, E$ )
2:    $n := 1$ ;
3:    $S[1] := N$ ;
4:   change := true;
5:   while change do
6:     change := false;
7:     if there are  $l_1, l_2 \in S[i]$  for some  $i \in \{1, \dots, n\}$ 
8:       such that  $\{l_1, l_2\} \notin E$  and  $l_1 \neq l_2$  then
9:         change := true;
10:         $n := n + 1$ ;
11:         $S[n] := \{l_2\} \cup \{l | \{l, l_2\} \in E\}$ ;
12:         $S[i] := S[i] \setminus S[n]$ ;
13:      end if
14:   end while
```

Figure 1. A polynomial-time algorithm for partitioning the nodes of a graph to cliques. It identifies candidate cliques $S[i]$ that contain two nodes without an edge between them, and splits them to two new candidate cliques.

Theorem 2. *The algorithm partition-to-cliques with input $G = \langle N, E \rangle$ terminates after a number of execution steps that is polynomial in the size of G , and after termination $S[i]$ is a clique of G for every $i \in \{1, \dots, n\}$.*

Proof. Sketch: The loop can only exit if for every $i \in \{1, \dots, n\}$ there is an edge between every two nodes in $S[i]$. Hence on termination every $S[i]$ is a clique.

Since at every iteration n is incremented and the sets $S[1], \dots, S[n]$ form a partition of all literals to nonempty sets, the algorithm terminates at the latest when all $S[i]$ have size 1. Hence the number of literals is an upper bound on the number of iterations. On every iteration the amount of computation is polynomial. \square

A concept related to cliques is that of bicliques.

Definition 3. *Let $\langle N, E \rangle$ be an undirected graph. A biclique is a pair C, C' of sets $C \subseteq N$ and $C' \subseteq N$ such that $C \cap C' = \emptyset$ and $\{\{n_1, n_2\} | n_1 \in C, n_2 \in C'\} \subseteq E$.*

In other words, bicliques are complete bipartite subgraphs of a graph. The problem of testing for existence of bicliques under several size measures is NP-complete [16, 6, 12].

We have used a simple polynomial-time algorithm for identifying bicliques in constraint graphs. The algorithm is given in Figure 2. It

```

1: procedure identify-biclique( $N, E$ )
2:    $C_1 := \emptyset$ ;
3:    $C_2 := N$ ;      (*  $C_1, C_2$  is now a trivial 0-edge biclique *)
4:   repeat
5:      $n :=$  a node in  $N \setminus C_1$ ;          (* Maximizing... *)
6:           (*  $|C_2|$  for the new value of  $C_2$  if  $C_1 = \emptyset$  *)
7:           (*  $(|C_1| \times |C_2|) - (|C_1| + |C_2|)$  if  $C_1 \neq \emptyset$  *)
8:      $C_1 := C_1 \cup \{n\}$ 
9:      $C_2 := C_2 \cap \{m \in N \setminus C_1 | \{n, m\} \in E\}$ ;
10:   until  $|C_1| \times |C_2| - (|C_1| + |C_2|)$  does not increase;
```

Figure 2. A polynomial-time algorithm for finding bicliques

starts with the dummy biclique \emptyset, N , and repeatedly adds nodes to the first part. Nodes from the second part are removed if there is no edge between them and the new node in the first part. The nodes are chosen to maximize the value of the biclique that is being constructed (the size reduction obtained by the compact representation.) The algorithm terminates when the value of the biclique does not increase any more. The passage from \emptyset, N to $\{n\}, N'$ at the first step never increases the value of the biclique and this case is handled specially.

Theorem 4. *The algorithm identify-biclique with input $G = \langle N, E \rangle$ terminates after a number of execution steps that is polynomial in the size of G , and after termination C_1, C_2 is a biclique of G .*

Proof. First verify that after every iteration C_1, C_2 is a biclique.

The number of iterations is bounded by $|N|$ because after $|N| - 1$ iterations $C_1 = N \setminus \{m\}$ for some m and $C_2 \subseteq \{m\}$ and therefore $|C_1| \times |C_2| - (|C_1| + |C_2|)$ is $(|N| - 1) \times 1 - (|N| - 1 + 1) = -1$ or $(|N| - 1) \times 0 - (|N| - 1 - 0) = -|N| + 1$, and after $|N|$ iterations it is $|N| \times 0 - (|N| + 0) = -|N|$, and the iteration terminates. Polynomial runtime follows because computation on every iteration takes polynomial time. \square

3 Cliques in Constraint Graphs

We consider constraint graphs $\langle N, E \rangle$ that represent sets S of 2-literal clauses $l \vee l'$. The set N of nodes of the graph consists of all the literals a and $\neg a$ for $a \in A$ where A is the set of propositional variables, and there is an (undirected) edge $\{l, l'\} \in E$ between the nodes l and l' if and only if $l \vee l' \in S$ or $l' \vee l \in S$.

The clause set may have a very irregular structure and the best way of representing it may be as is, but in many cases there are regularities that make a more compact representation possible. The simplest regularity is perhaps the presence of an *at-most-one* constraint for a subset V of the variables, forbidding more than one of the variables to be true at a time. Hence for all $\{v, v'\} \subseteq V$ such that $v \neq v'$, the constraint graph has an edge $\{\neg v, \neg v'\} \in E$. The set of literals $\{\neg v | v \in V\}$ forms a clique in the constraint graph.

In the following sections we discuss ways of representing cliques and other regularities of constraint graphs more compactly. Irrespective of the details of the representation, the more compact representation of the cliques in a constraint graph proceeds in the same way.

1. Identify a big clique in the constraint graph.
2. If only small cliques were found, go to the last step.
3. Construct a propositional formula that represents the binary constraints corresponding to the clique more compactly (see Sections 3.2 and 3.3).
4. Remove the edges of the clique from the constraint graph.
5. Continue from step 1.
6. Represent the binary constraints corresponding to the remaining edges in the constraint graph explicitly as 2-literal clauses.

In the next sections we discuss three alternative representations of cliques of the constraint graph, starting from the trivial explicit representation.

3.1 Explicit $O(n^2)$ Representation

For a set C of literals forming a clique in the constraint graph the most obvious representation is as 2-literal clauses

$$\{l \vee l' | \{l, l'\} \subseteq C, l \neq l'\}.$$

This quadratic representation of the clique is illustrated in Figure 3 by 5 mutually exclusive literals of the form $v = i$. The number of non-equivalent clauses is $\frac{n(n-1)}{2}$ for n literals.

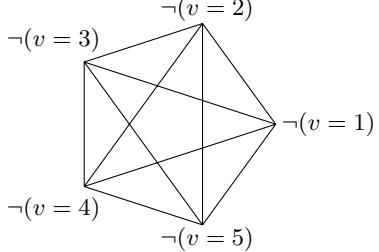

Figure 3. Representation of a clique of the constraint graph with $O(n^2)$ size and $O(1)$ additional propositional variables. An edge between literals $\neg(v = i)$ and $\neg(v = j)$ denotes their disjunction.

The $O(n^2)$ explicit representation of the constraints becomes less and less practical as n increases.

3.2 $O(n)$ Representation with $O(n)$ Auxiliary Variables

We have devised a linear-size representation that uses a linear number of auxiliary variables. This representation is illustrated in Figure 4. The representation can be viewed as a variant of the linear-size representations of interference constraints presented by Rintanen et al. [14] and the representation of many-valued propositions by Giunchiglia et al. [7].

The idea is to impose an arbitrary ordering on the n literals, and starting from each literal introduce a sequence of implications to the right through a sequence of auxiliary variables, leading to the negation of each literal on the right. When one of the literals is true, all of the auxiliary variables right from it must be true, and consequently all of the literals to the right must be false. This guarantees that if one of the literals is set true, all others are set false simply by applications of the unit resolution rule employed by most satisfiability algorithms.

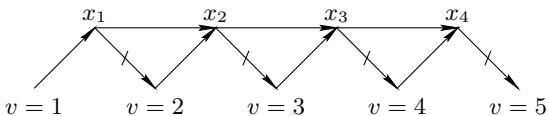

Figure 4. Representation of a clique in terms of $O(n)$ clauses and additional variables. An edge \rightarrow from l to l' denotes the formula $l \rightarrow l'$ and an edge $\not\rightarrow$ from l to l' denotes the formula $l \rightarrow \bar{l}'$.

The number of clauses in this linear-size representation is $3n - 4$ for $n \geq 2$. For 5 values the quadratic-size and linear-size representations respectively require 10 and 11 2-literal clauses, for 6 values respectively 15 and 14 clauses. Hence starting from 6 values the linear-size representation is smaller than the quadratic-size representation.

3.3 $O(n \log n)$ Representation with $O(\log n)$ Auxiliary Variables

Although the previous representation has an asymptotically optimal $O(n)$ size, the linear number of additional auxiliary variables may be considered high. Indeed, we can substantially decrease the number of auxiliary variables with the cost of a small increase in size.

The next representation has $\mathcal{O}(n \log n)$ size and $\mathcal{O}(\log n)$ auxiliary variables. Let $C = \{l_0, \dots, l_{n-1}\}$ be a clique consisting of n literals. Let x_0, \dots, x_{m-1} be new $m = \lceil \log_2 n \rceil$ Boolean variables. The constraint that only one literal can be true at a time is imposed by associating a different binary number with each literal. Since these binary numbers are represented in terms of the same variables, at most one of the literals can be true at a time. The representation is

$$\begin{aligned} l_0 &\rightarrow (\text{bit}_0(0) \wedge \text{bit}_1(0) \wedge \dots \wedge \text{bit}_{m-1}(0)) \\ l_1 &\rightarrow (\text{bit}_0(1) \wedge \text{bit}_1(1) \wedge \dots \wedge \text{bit}_{m-1}(1)) \\ &\vdots \\ l_{n-1} &\rightarrow (\text{bit}_0(n-1) \wedge \text{bit}_1(n-1) \wedge \dots \wedge \text{bit}_{m-1}(n-1)) \end{aligned}$$

where $\text{bit}_i(j) = x_i$ if the i th bit of j is 1 and $\text{bit}_i(j) = \neg x_i$ if the i th bit of j is 0.

For n literals the number of the resulting 2-literal clauses is $n \lceil \log_2 n \rceil$. For 5 values the numbers of clauses are respectively 15 and 11 for this representation and the linear-size representation, and numbers of auxiliary variables are respectively 3 and 4. For 32 values the numbers of clauses are respectively 160 and 92 and number of auxiliary variables are respectively 5 and 31.

This representation has been used by Frisch and Peugniez [5] and in more recent works [1], and the idea of two redundant representations connected by channelling constraints is familiar from the CSP context [4, 15].

4 Bicliques of the Constraint Graph

The presence of cliques in constraint graphs seems to be tied to particular classes of planning, model-checking and constraint satisfaction problems, and cannot be claimed to be extremely common. Indeed, in standard planning benchmarks, cliques of size n restrict an n -valued state variable, which is represented in terms of n Boolean state variables, to have at most one value at a time.

There is a need for techniques for compactly representing more general classes of constraint graphs. It is easy to see by a simple combinatorial argument that most constraint graphs do not have a compact representation, but there are many practically important graphs that do have many regularities that may be taken advantage of.

It seems that bicliques in constraint graphs are much more common than cliques. First, by partitioning any clique C to two disjoint sets C_1 and C_2 yields a biclique C_1, C_2 . So there are bicliques whenever there are cliques. Second, consider a subgraph C that is almost a clique but not quite. Let E' be the missing edges so that $\{\{n, n'\} | n \in C, n' \in C, n \neq n'\} \subseteq E \cup E'$. Now $C' = C \setminus \bigcup_{e \in E'} e$ is a clique, $C \setminus C'$, C' is a biclique because all the missing edges are between nodes in $C \setminus C'$, and $C \setminus C'$ may contain non-trivial bicliques.

A powerful discovery is that bicliques can be represented very compactly. When the literal sets C and C' form a biclique, the $|C| \cdot |C'|$ binary constraints can be represented by only $|C| + |C'|$ 2-literal clauses and only one auxiliary variable. For big bicliques this is a very big size reduction. This is illustrated in Figure 5. Notice that the original clause set can be obtained by resolving every pair of clauses that contain x and $\neg x$.

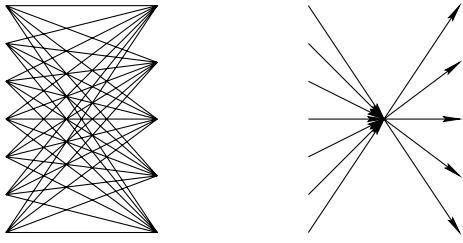

Figure 5. Representation of nm binary constraints forming an n, m biclique (left) in terms of only $n + m$ 2-literal clauses and one auxiliary variable (right). On the left, an edge between l and l' denotes the formula $l \vee l'$ (equivalently $\bar{l} \rightarrow l'$). On the right, an edge \rightarrow from l to the auxiliary variable x denotes $\bar{l} \rightarrow x$ and an edge from x to l' denotes $x \rightarrow l'$.

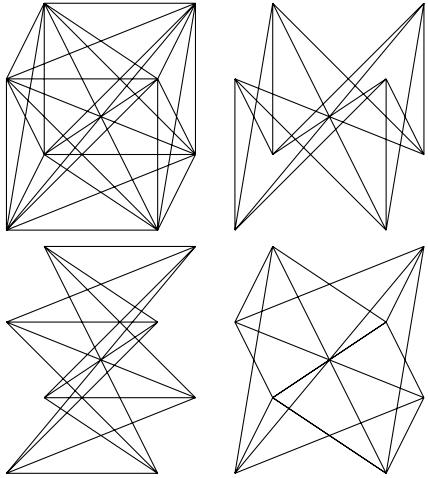

Figure 6. A clique of 8 nodes and 28 edges (upper left) decomposed to three 4,4 bicliques with 16 edges each. Division is along the up-down vertical axis (upper right), along the left-right horizontal axis (lower left), and along the front-back horizontal axis (lower right).

4.1 Relation to Compact Clique Representation

Decomposition of constraint graphs to cliques and their compact representation with only $O(n \log n)$ binary clauses can be understood in terms of bicliques. Hence the clique representation is subsumed by the biclique representation. A clique of n nodes corresponds to $\lceil \log_2 n \rceil$ orthogonal bicliques. Figures 6 and 7 illustrate the reduction from 28 edges of the original clique ($O(n^2)$) to 24 edges ($O(n \log n)$) in the biclique representation. This can also be illustrated by viewing the 8 nodes as 3-bit binary numbers. Now the three bicliques correspond to partitioning the 8 numbers by the values of the three digits. The partitions and bicliques are according to the first bit $\{000, 001, 010, 011\}$, $\{100, 101, 110, 111\}$, the second bit $\{000, 001, 100, 101\}$, $\{010, 011, 110, 111\}$ and the third $\{000, 010, 100, 110\}$, $\{001, 011, 101, 111\}$. The compact representation of these bicliques exactly corresponds to the $n \log n$ representation of cliques from Section 3.3.

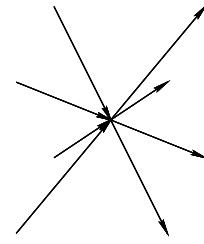

Figure 7. The invariants of the lower left biclique in Figure 6 represented more compactly in terms of an intermediate node.

5 Application: AI Planning

In most of the standard planning benchmarks all of the edges in the constraint graph stem from many-valued state variables that are encoded in terms of binary variables: the graph consists of cliques which say that each many-valued state variable can have only one value at a time. The representations from Section 3 encode these graphs compactly.

For the blocks world problems, if there are n blocks, the constraint that there can be at most one block below and above a block requires $2 \times \frac{n(n-1)}{2} = n(n-1)$ 2-literal clauses. For representing these cliques compactly by using the $O(n)$ representation only $6n - 8$ 2-literal clauses are needed. For 20 blocks this means a reduction from $20 \times 20 \times 19 = 7600$ to $20 \times (6 \times 20 - 8) = 2240$ clauses. For 40 blocks the reduction is from 62400 to 9280.

However, for many other problems the structure of constraint graphs is more complex and there are few cliques. One problem with only few big cliques is the airport scheduling problem from the 2004 planning competition. Most of this problem series can be efficiently solved by the planning as satisfiability approach but the biggest instances require the generation of huge propositional formulae with sizes of several gigabytes that exceed the physical memory restrictions of current 32-bit microprocessors. The invariants constitute more than 90 per cent of all the clauses in the CNF representation of the problems, and only a fraction of them forms cliques. The locations of airplanes correspond to many-valued state variables, but invariants on a number of related state variables that control the legal movement of airplanes through the airport do not.

We have very successfully used bicliques for making the representation of the invariants more compact. See Table 1. The size reduction of the formulae by a factor of about 9 makes it possible to generate all the formulae required for solving the problem series, and solve almost all of them efficiently save some of the last ones.

Interestingly, despite the big reduction in the formula sizes, those instances that were solvable before the reduction in formula size, the SAT solver (HaifaSAT, Siege) runtimes are improved not at all or only minimally. The biggest reductions in total runtimes are due to faster disk I/O and processing times during formula generation.

In addition to the airport problems, for other problems substantial reductions in the number of clauses for invariants are obtained, but the total reductions in the formula sizes are smaller, for example for the 30 block blocks world problems 50 per cent, because the invariants do not as strongly dominate the size of the formulae. For the simplest problems our biclique algorithm finds all maximal bicliques. This is probably not true for more complicated problems, for example the airport problem. Hence it would be interesting to test algorithms with approximation guarantees [8].

instance	clauses for invariants		size in MB

Table 1. Size reduction by the biclique representation. For each problem instance we give the number of clauses when each invariant is represented by one 2-literal clause and when bicliques of the constraint graph are represented compactly. The formula sizes are for DIMACS-encoded CNF formulae per time point, including the invariants and the rest of encoding of the planning problem. For example for 100 time points the total formula size is obtained by multiplying by 100. The first problem instance has 1696 state variables, the last has 4957. Solving the last instances of the series (42 to 50) require formulae with sizes up to 8 gigabytes which do not fit in the memory of a computer with a 32-bit address space. The shortest plan for instance 22 has length 53 and the corresponding formula without compression is 222 megabytes in the DIMACS CNF format, with clique compression 187 megabytes, and with biclique compression 31 megabytes. The numbers of clauses for invariants are respectively 275927, 231673 and 21388.

We also made a small experiment with constraint graphs that represent interference constraints for preventing simultaneous actions if they interfere [11]. These constraint graphs have in the worst case n^2 edges for n actions but there is a specialized representation with an asymptotically optimal linear size [14]. The biclique representation was often moderately or much smaller than the explicit and the specialized $\mathcal{O}(n)$ representation, but in some cases there was very little reduction and the specialized $\mathcal{O}(n)$ representation was by far the most compact. This possibility makes the biclique representation unattractive for this application.

6 Conclusions and Related Work

We have considered the problem of representing big constraint graphs more compactly based on representations that involve decomposing parts of the graphs to cliques and bicliques. The biclique representation, which is the new contribution of this work, turned out to be the more general representation as the clique representation is subsumed by it.

Constraint graphs with n nodes may have n^2 edges and our compact biclique representation does not improve this $\mathcal{O}(n^2)$ worst-case size. However, our experiments in Section 5 show that for practically interesting constraint graphs big size reductions are possible, by a factor of 10, and this may be the difference between an impractically big SAT problem (with respect to the memory requirements) and a relatively easily solvable one.

Pessimistic Heuristics Beat Optimistic Ones in Real-Time Search

Aleksander Sadikov and Ivan Bratko¹

Abstract. Admissibility is a desired property of heuristic evaluation functions, because when these heuristics are used with complete search methods, such as A* and RBFS, they guarantee that an optimal solution will be found. Since every optimistic heuristic function is admissible, optimistic functions are widely used. We show, however, that with incomplete, real-time search, optimistic functions lose their appeal, and in fact they may hinder the search under quite reasonable conditions. Under these conditions the exact opposite is to be preferred, i.e. pessimistic heuristic functions that never *underestimate* the difficulty of the problem. We demonstrate that such heuristics behave better than optimistic ones of equal quality on a standard testbed using RTA* search method.

1 INTRODUCTION

Admissibility is a desired property of heuristic evaluation functions, because when these heuristics are used with complete search methods, such as A* [6] and RBFS [8], they guarantee that an optimal solution will be found. A known theorem about the admissibility states that a heuristic function, which always gives an optimistic assessment of the position, is admissible [6]. This theorem made optimistic heuristic functions popular and widely used. The main problems with complete search methods, though, are their exponential running time and the necessity to wait until the search completes before the first step towards the goal can be taken. To alleviate these problems, incomplete search methods have been proposed, such as RTA* [7]. Since these methods can tackle much larger problems, they can often be the only practical option.

Incomplete search methods do not guarantee finding an optimal solution even when used in conjunction with admissible heuristics. Thus, the main reason for using admissible and consequently optimistic heuristics is void. Nevertheless, people use optimistic heuristic functions with incomplete search methods, because: (a) they are often readily available, since they were developed for complete search algorithms, (b) common sense saying that since they proved useful with complete search methods, perhaps they are useful with incomplete search methods as well, and (c) it was never shown that they could be counterproductive.

In this paper we show that under very reasonable conditions, optimistic functions are counterproductive in real-time (incomplete) search. Our results indicate that pessimistic functions should be used instead.

Section 2 of the paper derives the condition under which optimistic heuristics harm real-time search. It also shows that pessimistic

heuristics behave much better under these same conditions. An intuitive explanation for this phenomenon is given. Section 3 compares pairs of heuristic functions of equal quality, one optimistic, the other pessimistic, and demonstrates that the latter give much better results when used with RTA* search in the 8-puzzle domain. Section 4 discusses some consequences of this finding. Section 5 concludes the paper and gives some pointers for further work.

2 OPTIMISTIC AND PESSIMISTIC HEURISTICS

Let RTA* evaluate node n with an evaluation function f of the common form $f(n) = g(n) + h(n)$. Here $g(n)$ is the cost of the path from the current node to node n , and $h(n)$ is a heuristic estimate of the cost of an optimal path from node n to the nearest goal node. Let us denote the true cost of such an optimal path from node n with $h^*(n)$. The relationship between the true and heuristic value of node n is governed by the following equation:

$$h(n) = h^*(n) + e(n) \quad (1)$$

where $e(n)$ is an error the heuristic makes at node n .

Suppose the current state has two successors, nodes a and b , a being better than b . The immediate task of the search is to choose between node a and node b . RTA* will choose a if $f(a) < f(b)$. We will simplify the analysis slightly by assuming without loss that all the edges have unit cost. Then the condition $f(a) < f(b)$ for choosing a is equivalent to the condition $h(a) < h(b)$. If this condition holds then RTA* will make the correct decision (i.e. choose a), otherwise it will commit a decision error by choosing b . So a decision error occurs when

$$h(a) > h(b). \quad (2)$$

This can be rewritten in terms of true costs h^* and heuristic errors e :

$$h^*(a) + e(a) > h^*(b) + e(b). \quad (3)$$

Since a is better than b , $h^*(a) < h^*(b)$, and the difference $\Delta h^* = h^*(b) - h^*(a)$ is positive. The condition for decision error can be stated as:

$$e(a) - e(b) > \Delta h^* > 0. \quad (4)$$

Now let us consider what happens in two special cases: (1) when the algorithm uses an *optimistic* heuristic function, and (2) when it uses a *pessimistic* heuristic function. By definition, for optimistic heuristics, heuristic errors e are always negative because heuristic approximations underestimate true costs. So for optimistic heuristics, for all nodes n , $e(n) = -|e(n)|$. The decision error condition then becomes:

$$|e(b)| - |e(a)| > \Delta h^* > 0. \quad (5)$$

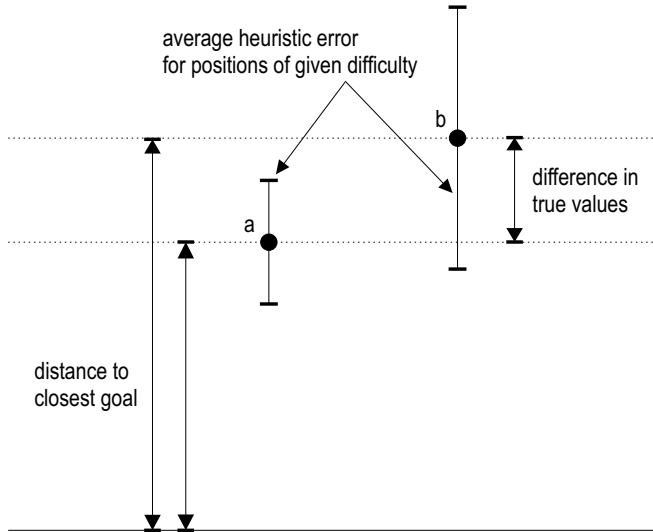

Figure 1. The difference in true values

Equation 5 has an interesting consequence. It basically says that if the heuristic function's absolute error increases with increasing difficulty of the problems (nodes requiring more costly paths to reach the goal), then for optimistic heuristics the chance to make a decision error *increases*. In our example, node b is more difficult than a , so under this assumption, absolute heuristic error at b will tend to be greater than at a . This indicates a problem with optimistic heuristics when heuristic errors (in absolute terms) increase with the difficulty of the problems. Conversely, if heuristic errors decrease with the difficulty of the problems, then the optimistic heuristic will have better chance of making correct decisions. However, as also discussed later in the paper, this second case (heuristic error decreasing with the cost) seems to be rather unrealistic in practice.

For pessimistic heuristics, by definition heuristic errors e are always positive, and the condition for RTA* making a decision error is:

$$|e(a)| - |e(b)| > \Delta h^* > 0. \quad (6)$$

If we compare Equations 5 and 6, we can see that just the opposite of what is true for optimistic heuristics holds for pessimistic heuristics. Pessimistic heuristics have better chances to produce correct decision if the heuristic error increases with increasing difficulty of the nodes, and worse if the heuristic error decreases with increasing difficulty of the nodes. According to this, in the case of absolute error increasing with difficulty, i.e. the case to be expected more likely in practice, optimistic heuristics will tend to make decision errors more frequently than pessimistic heuristics.

2.1 Intuitive explanation

Figure 1 shows a decision task we discussed. The tails stemming from nodes a and b represent the average heuristic error for the problems of given difficulty. To commit a decision error, the heuristic values have to overcome the difference in true values between the two nodes. Suppose the heuristic's errors increase with increasing difficulty of the problems. Since node b represents a more difficult

problem, the heuristic will on the average make a larger error in it. This is represented in the figure with a longer tail coming out of node b than the one coming out of node a . Furthermore, if the heuristic is optimistic, only downward part of the tail is possible, and vice versa, if the heuristic is pessimistic only the upward part of the tail is possible. If the heuristic is optimistic, the longer tail, coming out of node b has to overcome the difference in true values to give a chance for a decision error to be committed. However, if the heuristic is pessimistic, it is the shorter tail coming out of node a that has to overcome the difference in true values. Since the longer tail can more easily overcome this difference than the shorter tail, it follows that the optimistic heuristic can more easily commit a decision error when the heuristic's errors increase with increasing difficulty of the problems.

3 EXPERIMENTS

We have tested our theoretical results on a classical testbed for single-agent search methods, the 8-puzzle sliding tiles problem, described e.g. in [2]. We have chosen this small puzzle, because for complete evaluation of success of search we needed to know the true value of every state in the domain — the reason for this will become apparent in the next subsection.

3.1 The two heuristic functions

To empirically test our theoretical findings, we compared two heuristic functions, one optimistic, the other pessimistic. The functions needed to be of equal quality (in terms of their relative errors), so that neither one of them has an unfair advantage. To get such a pair of functions, we had to artificially construct them.

We first calculated the true values of all legal 8-puzzle positions with the use of retrograde analysis, a technique known from computer chess, where it is used to generate endgame databases [13]. An indexed array of distances to nearest goal defines the perfect evaluation function h^* . Then we proceeded to generate the two heuristic functions by appropriately corrupting our perfect heuristics.

We modelled the distribution of our optimistic heuristic after the distribution of Manhattan distance heuristic — a well-known optimistic heuristic for the 8-puzzle domain. On average, Manhattan distance heuristic's error increases with increasing difficulty of the problems (the average error over all positions of a given difficulty level). We measure the difficulty of the problem as the number of steps needed to reach the goal assuming optimal play, i.e. with the problem's true value. The dispersion of heuristic values around the average evaluation for a given difficulty level is more or less constant.

We created our artificial heuristics by corrupting the perfect evaluations in a controlled manner. Our method of doing this is as follows. We take a position's true value $h^*(n)$ and add to it a certain amount of Gaussian noise, described with the formula:

$$P(x) = \frac{1}{\sigma\sqrt{2\pi}} e^{-(x-\mu)^2/(2\sigma^2)}. \quad (7)$$

The formula gives the probability $P(x)dx$ that given the correct evaluation $\mu = h^*(n)$ and standard deviation σ , the heuristic evaluation, $h(n) = x \in \mathbf{R}$, will take on a value in the range $[x, x + dx]$. The error of heuristic evaluation $h(n)$ is $e(n) = x - \mu$. We do this for all legal positions. A more detailed description of this process is given in [11]. Parameter σ controls the level of corruption. Since we modelled our heuristics after the Manhattan heuristic, we chose $\sigma = 2.5$ steps to equal the standard deviation of Manhattan heuristic's evaluations.

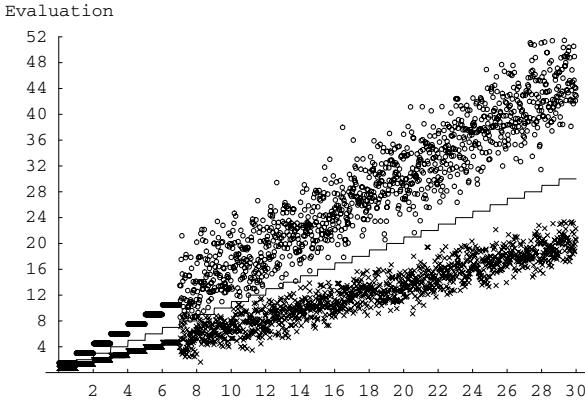

Figure 2. The evaluations given by our heuristic functions

To get the optimistic heuristic, we multiplied the obtained corrupted heuristic by a constant c :

$$h(n) = c \cdot (h^*(n) + e(n)). \quad (8)$$

We chose $c = 2/3$ to emulate the level of errors Manhattan heuristic commits. The pessimistic heuristic of comparable relative error was obtained by multiplying the corrupted heuristic by inverted constant $1/c$, that is with $3/2$. The random process of corrupting the true evaluations was of course repeated for the pessimistic heuristic (we did not use the same errors as with the optimistic heuristic). If some evaluations in either heuristic were not pessimistic or optimistic as intended, their values were corrupted again.

Both heuristics are plotted in Figure 2. The x-axis gives the difficulty (true value) of the position, the y-axis gives the heuristic evaluation of the position. The crosses represent the optimistic heuristic, the circles the pessimistic heuristic, and the solid line represents the true evaluations. A random sample of 50 positions of each difficulty is displayed. The figure clearly shows that the average heuristic error grows close to linear with increasing difficulty of positions for both heuristics.

The first seven levels of difficulty deserve an explanation. For these levels we did not corrupt the true evaluations, we just multiplied them with the appropriate constant. The reason for this is that few positions belong to these levels and it is therefore practically impossible to corrupt them so that they would maintain more or less constant dispersion. Thus, we once again decided to model after the Manhattan distance heuristic, which also without exception gives correct estimates for the first seven levels of difficulty.

3.2 The search engine

We varied the depth of RTA* lookahead from 1 to 30, thirty being the difficulty of the hardest 8-puzzle problems. We were able to reach these very high depths of lookahead by employing transposition tables — yet another technique known from computer chess. We took advantage of the comparatively small number of possible positions in the 8-puzzle domain. We calculated depth 1 lookahead evaluations for all positions and stored these values in an array. Then we calculated depth 2 evaluations for all positions by doing one ply of search and using previously stored depth 1 evaluations, again storing

the calculated evaluations. We repeated the process for other depths. A more detailed description of the procedure is given in [11].

3.3 Results

We were interested in two characteristics: the percentage of correct decisions each of our heuristics makes when used in conjunction with RTA* search and the actual solution length such a search produces.

3.3.1 Percentage of correct decisions

When measuring the percentage of correct decisions we varied the difficulty of the problems to be solved and the depth of lookahead. For a given difficulty level of problems and a given depth of lookahead, we measured the average percentage of correct decisions on *all* possible puzzles of this level where one path is clearly better from the others (otherwise there is nothing to decide between).

The results of the experiments are presented in Figure 3. The x-axis represents the depth of lookahead, and the y-axis represents the percentage of correct decisions made. Figure 3 shows a representative subset of the results. The chart on the left represents moderately difficult puzzles, the middle one hard puzzles, and the right chart represents a random mixture of 1,000 puzzles of various difficulties — this way of testing is quite common and was used for example in [3, 7]. The first two charts do not represent a single puzzle, but rather all puzzles of the given difficulty.

It is obvious from the charts that the pessimistic heuristic, represented by a dashed line, gives rise to a higher average percentage of correct decisions than the optimistic heuristic for all difficulty levels of the puzzles. This is especially so when the lookahead depth is close to the difficulty level of puzzles.

One may argue that perhaps the constant $c = 3/2$ used to get the pessimistic heuristic is misguided, and that $c = 4/3$ should be used instead. The latter gives the same level of errors in absolute terms, while the first one gives the same relative errors. We indeed constructed such a pessimistic heuristic as well, and the results were, as expected, even more in favour of the pessimistic heuristic.

3.3.2 Solution length

When measuring the solution length we varied the depth of lookahead and the quality of heuristics used (by varying the parameter σ for the pair of heuristic functions). The results are presented in Figure 4. The x-axis again represents the depth of lookahead, and the y-axis represents the solution length. The results are averaged over all legal puzzles. The dotted line at 21.50 represents the length of optimum solution averaged over all legal puzzles. The left chart represents the case for $\sigma = 2.5$ (the pair of heuristics modelled after the Manhattan heuristic), while the other two charts represent the cases with larger heuristic errors, $\sigma = 3$ and $\sigma = 4$, respectively.

We can see that pessimistic heuristics (dashed line) clearly outperform their optimistic counterparts (solid line) by consistently finding shorter solutions. It is interesting that after the depth of lookahead reaches 5 moves, the gain in solution length (thick line) is quite constant. At very high search depths the gain of course decreases, eventually reaching zero, because more and more puzzles are solved optimally since the solution is seen directly from the starting state.

The gain in solution length for the pessimistic heuristic over its optimistic counterpart, modelled by Manhattan heuristic, is about 5% to 10% (on the interesting interval with lookahead depth over 5 and before too many solutions are directly found). The decreasing quality

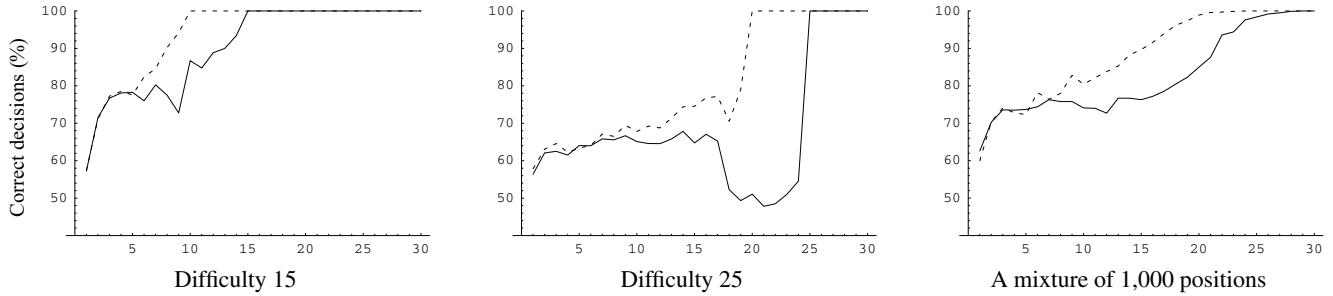

Figure 3. The comparison of correct decisions made between optimistic (solid line) and pessimistic (dashed line) heuristic

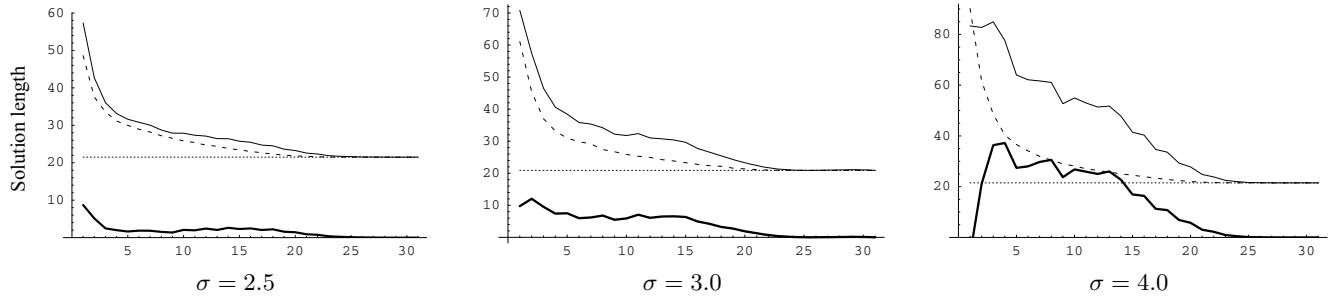

Figure 4. The comparison of solution length between optimistic (solid line) and pessimistic (dashed line) heuristic; the thick line represents the difference between them (the gain by pessimistic heuristic)

of heuristics, however, causes a sharp increase in the gain. For $\sigma = 3$ the gain is slightly below 20% and for $\sigma = 4$ it is already about 50%.

3.4 Search depth pathology

A search depth pathology is a phenomenon when deeper lookahead results in more decision errors committed or worse solutions found. This pathology was first discovered in two-player games in the late 1970s [1, 9]. An overview is given in [10, 11]. Recently, such pathology has also been detected in single-agent search [3, 5]. As we can see from the charts in Figures 3 and 4 our artificial heuristics also display such pathological behaviour. However, it is interesting that the pessimistic heuristic displays lesser inclination towards such behaviour than its optimistic counterpart. As we can see the pathological behaviour is not limited only to decision quality but also manifests itself in solution length. This was also observed by Korf [7]. With lower quality of heuristics the optimistic ones become more and more pathological while the pessimistic ones behave normally. This deserves further study.

4 DISCUSSION

We have shown that if the error committed by the heuristic evaluation increases with the difficulty of the problems, pessimistic heuristics are comparatively more successful than optimistic ones of equal quality, and vice versa, if the heuristic error decreases with the difficulty of the problems, then optimistic heuristics are better. This gives

rise to an important question: which is more plausible, increasing or decreasing heuristic errors? We believe that the majority of real-life heuristics belong to the first group, namely that their heuristic errors increase with increasing difficulty of the problems. For example, imagine a task scheduling problem and a heuristic for it. If the optimal solution is that the tasks complete in, say, 10 hours, it is easy to imagine a heuristic estimating this time as somewhere between 8 and 12 hours, that is committing an error of ± 2 hours. However, if the optimal solution is that the tasks complete in 1,000 hours, it is quite unimaginable that the heuristic would estimate this time as somewhere between 998 and 1,002 hours. That would be an incredibly accurate heuristic. It is much more likely that the heuristic would estimate the time needed as something between 800 and 1,200 hours, committing the error of ± 200 hours. We believe it is quite conceivable that the error is usually *relative* to the size/difficulty of the problem; that the heuristic is, say, 20% off the mark. However, the equations in Section 2 only need this error to increase in absolute terms, it does not matter that the heuristic is more or less equally wrong in relative terms. From this we conclude that pessimistic heuristics seem to be preferable. We can give one more example: to which group do the two well-known heuristics for the 8-puzzle belong? Both, Manhattan distance and “Manhattan distance + Sequence score” heuristics, described e.g. in [2], belong to the first group — their error rises with increasing difficulty of the problems.

A possible argument in favour of optimistic heuristics could be that they may be easier to construct than pessimistic ones. But is this really so? Probably it is just that people are more used to opti-

mistic heuristics since they were usually preferred. For example, it is trivial to use air distance as a heuristic when approximating the road distance between two cities. But it is similarly trivial to use as a heuristic the distance based solely on highways, not on all the roads. This heuristic is pessimistic. Another point should be noted here. The equations in Section 2 do not say that it is strictly necessary for a heuristic to be pessimistic for *every* position, just for most of them. This, on the other hand, is not the case with the admissibility theorem — it necessitates that *all* positions are optimistically evaluated for the heuristic to be admissible.

The difference in the decision accuracy between the two heuristic functions in our experiments is a few percent, unless the search reaches the vicinity of goal nodes, where this difference increases. How much are these few percent worth? Not so little, because the search makes a series of decisions and for every single one of them the pessimistic heuristic gives it an extra few percent. For example, in the 8-puzzle domain, each mistake means the search will have to make at least two additional steps — one going back to the position where it came from, the other taking the right path (which it could have taken in the first place if it would not make a mistake).

Suppose we have an optimistic heuristic for some problem, e.g., the Manhattan distance for the 8-puzzle. We could make it pessimistic by adding a constant to it. Unfortunately this approach does not work, because by doing so the new heuristic's error would actually increase with decreasing problem difficulty, so all we would do is transform one disadvantageous case into another. How about multiplying an optimistic heuristic by a constant to get a pessimistic one?² This approach might actually work, though not for every heuristic. In some cases, like with Manhattan distance, we could again get a pessimistic heuristic whose error again increases with decreasing difficulty of the problems. But for some heuristics we could succeed. But even in this case we would have to experiment with finding the right constant, since if the constant is too big, we degrade the heuristic too much, and if the constant is too small, the resulting heuristic might not be pessimistic.

In section 2, we showed that RTA* using optimistic heuristics is likely to make more decision errors than RTA* with pessimistic heuristics. A related question is how the fixed-depth lookahead performed by RTA* affects the accuracy of heuristic evaluations. When RTA* decides which node to move to next, it considers the minimin backed-up heuristic values rather than the original, “static” heuristic values. The relevant question is: Are these backed-up heuristic values more accurate than the static heuristic estimates themselves? We will here indicate, without full mathematical proof, the intuition behind the following answer: Minimin backed-up heuristic values have on average smaller absolute error when the terminal nodes of lookahead are evaluated by pessimistic heuristics than when they are evaluated optimistically. Of course in all detail this depends on the distribution of true values and on error distribution. It is however easy to see the advantage of pessimistic heuristics in the cases when there are several lookahead terminal nodes all of which having true values close to the lowest true value. Minimin lookahead will return the minimum heuristic value encountered at the fringe of the lookahead. In the case of pessimistic heuristics, this minimum heuristic value will tend to be the *least distorted* among the true values close to optimal. This is because minimin will tend to return the least overestimated node close to optimal. On the contrary, in the case of optimistic heuristics, this

minimum heuristic value will tend to be the *most distorted* among the values close to optimal, because minimin will tend to return the most underestimated node value close to optimal.

5 CONCLUSIONS AND FURTHER WORK

We have shown that pessimistic heuristic functions are more effective than their optimistic counterparts of equal quality when used with incomplete search methods under the condition that the heuristic's errors grow with increasing difficulty of the problems. We have argued that such a condition is often met in practice, and that therefore pessimistic heuristics should be preferred.

We have also mentioned that our preconditions do not strictly necessitate that the heuristic is pessimistic for every single node. We believe it would be worthwhile to study how the percentage of such violations of pessimistic evaluation affect the gain.

The experiments also indicated that while both heuristic functions display some pathological behaviour, the pessimistic heuristics seem less inclined to do so. Why is this so is an interesting topic for further work.

² Both, adding a constant or multiplying with a constant is used in the weighted LRTA* algorithm [4, 12]. However, while the purpose there is to allow *some* states to be evaluated pessimistically, here we would like *all* states to be evaluated pessimistically.

Inverse Consistencies for Non-binary Constraints

Kostas Stergiou¹ and Toby Walsh²

Abstract. We present a detailed study of two inverse consistencies for non-binary constraints: relational path inverse consistency (rel PIC) and pairwise inverse consistency (PWIC). These are stronger than generalized arc consistency (GAC), even though they also only prune domain values. We propose algorithms to achieve rel PIC and PWIC, that have a time complexity better than the previous generic algorithm for inverse consistencies. One of our algorithms for PWIC has a complexity comparable to that for GAC despite doing more pruning. Our experiments demonstrate that inverse consistencies can be more efficient than GAC on a range of non-binary problems.

1 INTRODUCTION

Local consistency techniques are of great importance in constraint programming. They prune values from the domain of variables and terminate branches of the search tree, saving much fruitless exploration of the search tree. Local consistency techniques that only filter domains like (generalized) arc consistency (GAC) tend to be more practical than those that alter the structure of the constraint graph or the constraints' relations (e.g. path consistency). For binary constraints, many domain filtering consistencies have been proposed and evaluated, including inverse and singleton consistencies [8, 6, 13]. The situation is very different for non-binary constraints. A number of consistencies that are stronger than GAC have been developed, including relational consistency [12] and pairwise consistency [9]. However, these are typically not domain filtering.

We study here two promising domain filtering techniques for non-binary constraints: relational path inverse consistency (rel PIC) and, the stronger, pairwise inverse consistency (PWIC). Relational consistencies [12] have rarely been used in practice as most are not domain filtering, and have high time complexities. Pairwise consistency [9] (also called inter-consistency [10]) has also rarely been used as it is not domain filtering and the algorithm proposed in [9] has a high time complexity and requires all constraints to be extensional. Rel PIC and PWIC are local consistency techniques that do not suffer from these problems. They are domain filtering and are not prohibitively expensive to enforce. Our theoretical analysis reveals some surprises. For example, when restricted to binary constraints, rel PIC does not reduce to the variable based definition of path inverse consistency.

We propose algorithms to enforce rel PIC and PWIC that can be applied to constraints intentionally or extensionally specified. Their time complexity is better than the complexity of the generic algorithm for inverse consistencies given in [13]. The time complexity of the second algorithm for PWIC is $O(e^2 k^2 d^k)$ where e is the number of constraints, k is the maximum arity and d is the maximum domain size. This is significantly lower than the complexity of the generic algorithm, and is comparable to the complexity

of standard GAC algorithms, like GAC-Schema ($O(ekd^k)$) [3] and GAC2001/3.1 ($O(ek^2 d^k)$) [5]. However, this improvement comes at a cost as the space required is exponential in the number of *shared* variables. Experimental results demonstrate that it is feasible to maintain rel PIC and PWIC during search, and they can be more cost-effective than GAC on certain problems.

2 BACKGROUND

A *Constraint Satisfaction Problem* (CSP) is defined as a tuple (X, D, C) where: X is a set of n variables, D is a set of domains, and C is a set of e constraints. Each constraint c_i is a pair $(var(c_i), rel(c_i))$, where $var(c_i) = \{x_{j_1}, \dots, x_{j_k}\}$ is an ordered subset of X , and $rel(c_i)$ is a subset of the *Cartesian* product $D(x_{j_1}) \times \dots \times D(x_{j_k})$. A tuple $\tau \in rel(c_i)$ is *valid* iff none of the values in the tuple has been removed from the domain of the corresponding variable. Any two constraints c_i and c_j *intersect* iff the set $var(c_i) \cap var(c_j)$ of variables involved in both constraints is not empty. We assume that the number of variables that any two constraints have in common (denoted by f) is uniform. This assumption is made to simplify the description and complexity analysis of the algorithms, and can be easily lifted.

The assignment of value a to variable x_i is denoted by (x_i, a) . The set of variables over which a tuple τ is defined is $var(\tau)$. For any subset var' of $var(\tau)$, $\tau[var']$ is the sub-tuple of τ that includes only assignments to the variables in var' . Any two tuples τ and τ' of $rel(c_i)$ can be lexicographically ordered. In this ordering, $\tau <_l \tau'$ iff there exists a subset $\{x_1, \dots, x_j\}$ of $var(c_i)$ such that $\tau[x_1, \dots, x_j] = \tau'[x_1, \dots, x_j]$ and $\tau[x_{j+1}] <_l \tau'[x_{j+1}]$. An assignment τ is *consistent* iff for all constraints c_i , where $var(c_i) \subseteq var(\tau)$, $\tau[var(c_i)] \in rel(c_i)$. A *solution* is a consistent assignment to all variables. A value $a \in D(x_j)$ is consistent with a constraint c_i , where $x_j \in var(c_i)$, iff $\exists \tau \in rel(c_i)$ such that $\tau[x_j] = a$ and τ is valid. In this case, we say that τ is a GAC-support of a in c_i . A constraint c_i is *Generalized Arc Consistent* (GAC) iff $\forall x_j \in var(c_i)$, $\forall a \in D(x_j)$, there exists a GAC-support for a in c_i . A problem is GAC iff domains are non-empty and all constraints are GAC.

A binary problem is (i, j) *consistent* iff it has non-empty domains and any consistent instantiation of i variables can be extended to a consistent instantiation involving j additional variables [7]. A problem is *strong* (i, j) -consistent iff it is (k, j) consistent for all $k \leq i$. A problem is *arc consistent* (AC) iff it is $(1, 1)$ -consistent. A problem is *(strong) path consistent* (PC) iff it is *(strong) $(2, 1)$ -consistent*. A problem is *(strong) m -consistent* iff it is *(strong) $(m, 1)$ -consistent*. A problem is *path inverse consistent* (PIC) iff it is $(1, 2)$ -consistent.

A problem is *relationally arc consistent* (rel AC) iff any consistent instantiation for all but one of the variables in a constraint can be extended to the final variable so as to satisfy the constraint [12]. A problem is *strongly relationally arc consistent* (strong rel AC) iff any consistent instantiation of a subset of the variables in a constraint

¹ Department of Information & Communication Systems Engineering University of the Aegean, Greece.

² National ICT Australia & University of New South Wales, Australia.

can be extended to all the variables in the constraint. A problem is *relationally* (i, m)-consistent iff any consistent instantiation for i of the variables in a set of m constraints can be extended to all the variables in the set. We can construct singleton versions of all the relational consistencies in a straightforward manner [6]. For example, a problem is *relationally singleton arc consistent* (rel SAC) iff it has non-empty domains and for any instantiation of a variable, the resulting subproblem can be made relationally AC. A problem is *pairwise consistent* (PWC) iff it has non-empty relations and any consistent tuple in a constraint c can be consistently extended to any other constraint that intersects with c [9]. As shown in [9], applying PWC to a non-binary CSP is equivalent to applying AC to the dual encoding.

Following [6], we call a consistency property A stronger than B iff in any problem in which A holds then B holds, and strictly stronger (written $A \rightarrow B$) iff it is stronger and there is at least one problem in which B holds but A does not. We call a local consistency property A incomparable with B (written $A \otimes B$) iff A is not stronger than B nor vice versa. Finally, we call a local consistency property A equivalent to B (written $A \leftrightarrow B$) iff A is stronger than B and vice versa.

3 INVERSE CONSISTENCIES

In practice, most strong local consistency techniques have prohibitive space and time complexities. One way around this problem is to use inverse consistencies [8]. These require limited space as they only prune domains. When an inverse local consistency is enforced, it removes from the domain of a variable the values that cannot be consistently extended to some additional variables. For example, when enforcing PIC we remove values that cannot be consistently extended to any set of two other variables. By analogy with the definition of PIC, relational (1, 2) consistency is called *relational path inverse consistency* (rel PIC). We also define *pairwise inverse consistency* (PWIC), an inverse version of PWC. A value $a \in D(x_j)$ is PWIC iff \forall constraints c_i , where $x_j \in var(c_i)$, $\exists \tau \in rel(c_i)$ such that $\tau[x_j] = a$ and τ is valid and $\forall c_l$, s.t. $var(c_i) \cap var(c_l) \neq \emptyset$, $\exists \tau' \in rel(c_l)$, s.t. $\tau'[var(c_i) \cap var(c_l)] = \tau'[var(c_i) \cap var(c_j)]$ and τ' is valid. In this case we say that τ' is a PW-support of τ . A constraint c_i is PWIC iff $\forall x_j \in var(c_i)$, $\forall a \in D(x_j)$, a is PWIC. A problem is PWIC iff domains are non-empty and all constraints are PWIC.

We first compare rel PIC and PWIC with GAC, the most popular local consistency for non-binary constraints.

Theorem 1 $PWIC \rightarrow rel\ PIC \rightarrow GAC$

Proof: By definition, PWIC is stronger than rel PIC which is stronger than GAC. To show strictness, consider: $alldiff(x_1, x_2, x_3)$ and $x_1 = x_2$. If domains are $\{0, 1, 2\}$ then the problem is GAC but is not rel PIC. Now consider a constraint c_1 over variables x_1, x_2, x_3 and two other constraints c_2 and c_3 involving x_2 and x_3 (and other variables). Assume that value 0 of x_1 can be extended to tuples $(0, 0, 0)$ and $(0, 1, 1)$ in c_1 but only the first tuple can be extended to a consistent tuple in c_2 , while only the second tuple can be extended to a consistent tuple in c_3 . The problem is rel PIC but not PWIC. \square

Not surprisingly, when all constraints intersect on at most one variable, PWIC and rel PIC collapse down to GAC.

Theorem 2 *On constraints that intersect on at most one variable:*

$$PWIC \leftrightarrow rel\ PIC \leftrightarrow GAC$$

Proof: Suppose that the constraints intersect on at most one variable and are GAC. Consider an assignment for a variable and the set of constraints involving this variable. Take one of these constraints. As this is GAC, we can find a satisfying tuple including this assignment.

Consider all the intersecting constraints and the value of the intersection variable in our tuple. As all these constraints are GAC, we can extend the tuple to satisfy them. Hence, we can extend any assignment to a tuple that can be extended to satisfy all intersecting constraints. The problem is thus PWIC (and hence rel PIC). \square

When restricted to binary constraints, PWIC collapses down to rel PIC. We might expect rel PIC to reduce to the corresponding variable based definition. Surprisingly, this is not the case.

Theorem 3 *On binary constraints:*

$$\begin{array}{ccc} PWIC & \leftrightarrow & rel\ PIC \rightarrow rel\ AC \\ \uparrow & & \uparrow \\ PIC & \rightarrow & AC \end{array}$$

Proof: We first show $PWIC \leftrightarrow rel\ PIC$. Since binary constraints intersect on at most one variable unless they involve the same two variables, consider such a case with two variables x_1, x_2 , where all constraints are rel PIC. Take any two constraints. Since the constraints are rel PIC, any instantiation (x_1, a) can be extended to an instantiation (x_2, b) that satisfies both constraints. Since this holds for all pairs of constraints that involve x_1 and x_2 , these instantiations are consistent with all such constraints. Therefore, the problem is PWIC.

To show $PIC \rightarrow rel\ PIC$, consider the constraints: $x_1 \neq x_2, x_1 \neq x_3$ and $x_2 \neq x_3$. If all variables are 0/1 then the problem is rel PIC but not PIC. The other relations follow in a straightforward way. \square

Non-binary constraints can sometimes be decomposed into binary constraints on the same variables. For example, an all-different constraint can be decomposed into binary not-equals constraints. On such constraints, we can directly compare relational consistencies with binary consistencies on the decomposition.

Theorem 4 *On decomposable non-binary constraints:*

$$\begin{array}{c} \text{strong PC} \\ \otimes \quad \otimes \\ PWIC \rightarrow rel\ PIC \rightarrow AC \\ \otimes \quad \otimes \quad \otimes \quad \otimes \\ SAC\ PIC \quad SAC\ PIC \end{array}$$

Proof: To show $rel\ PIC \rightarrow AC$ on the decomposition, consider a problem that is rel PIC. Given any two constraints, any instantiation for a variable can be extended to all the variables in the two constraints. Hence, it can be extended to at least one other variable. Thus, the decomposition is AC. To show strictness, consider the constraints: $alldiff(x_1, x_2, x_3)$ and $x_3 = x_4$. If all variables are 0/1, then the problem is not rel PIC but its decomposition is AC.

To show the other relationships, consider the constraints: $alldiff(x_1, x_2, x_3, x_4)$ and $x_4 = x_5$. If domains are $\{0, 1, 2\}$, then the problem is not rel PIC (and hence not PWIC). However, its decomposition is strong PC (and thus SAC and PIC). For the reverse, consider the constraints: $x_1 \neq x_2, x_1 \neq x_3$, and $x_2 \neq x_3$. If all variables are 0/1, then the problem is rel PIC and PWIC, but its decomposition is not PIC (and hence not SAC nor strong PC). \square

One way to deal with non-binary constraints is to encode them into binary ones, and apply binary techniques (as for example in [1]). We now position rel PIC and PWIC with respect to other relational consistencies and consistencies enforced in the hidden variable and dual encodings of a non-binary problem. Each result has the precondition that the non-binary constraints are GAC so that the hidden variable or dual encoding is node consistent (and not trivially unsatisfiable).

Theorem 5 *On (non-binary) constraints which are GAC:*

$$\begin{array}{ccccc} SAC_{\text{hidden}} & \rightarrow & PIC_{\text{hidden}} & \leftrightarrow & AC_{\text{hidden}} \\ \downarrow & & \uparrow & & \\ rel\ SAC & \rightarrow & rel\ PIC & \otimes & (strong)\ rel\ AC \\ \uparrow & & \uparrow & & \otimes \\ SAC_{\text{dual}} & \rightarrow & PIC_{\text{dual}} & \rightarrow & AC_{\text{dual}} \end{array}$$

$$(PWC) \leftrightarrow PWIC$$

Proof: Due to space limitations we only give proofs of $\text{AC}_{\text{dual}} \leftrightarrow \text{PWIC}$, $\text{PIC}_{\text{dual}} \rightarrow \text{rel PIC}$ and $\text{rel PIC} \otimes (\text{strong}) \text{ rel AC}$.

To compare PWIC to AC_{dual} (and PWC), we only consider the values that are pruned by these consistencies. For AC_{dual} (and PWC), which delete tuples from constraints, this can be done if GAC is applied as a second step. In this case, a value is deleted iff all the tuples in some dual variable x , that include that value, are deleted. A tuple is deleted iff it has no support in some other dual variable (i.e. it is not pairwise consistent). In the non-binary problem, PWIC deletes the same values because it finds that all their extensions (i.e. tuples) in the constraint corresponding to x are not pairwise consistent. Therefore PWIC achieves the same pruning as AC_{dual} .

To show $\text{PIC}_{\text{dual}} \rightarrow \text{rel PIC}$, consider a problem whose dual encoding is PIC. Take any pair of constraints. There are two cases. In the first case, the two constraints are disjoint. As each constraint is GAC, we can extend any assignment for a variable in one of the constraints to satisfy all the variables in both constraints. In the second case, the two constraints overlap. As each constraint is GAC, we can extend any assignment for a variable in one of the constraints to satisfy all the variables in the constraint. As the dual encoding is PIC, we can extend this assignment for the dual variable associated with this constraint, to the dual variable associated with the second constraint, and any other third dual variable. That is, we can extend the assignment to satisfy all the variable in both the constraints. In both cases, the problem is rel PIC. To show strictness, consider the constraints: $x_1 \neq x_2$, $x_1 \neq x_3$ and $x_2 \neq x_3$. If all variables are 0/1 then the dual encoding is not PIC, whilst the original problem is rel PIC.

To show $\text{rel PIC} \otimes (\text{strong}) \text{ rel AC}$, consider the constraints: $\text{alldiff}(x_1, x_2, x_3)$ and $x_1 = x_2$. If domains are $\{0, 1, 2\}$ then the problem is (strong) rel AC but is not rel PIC. For the reverse, consider $\text{alldiff}(x_1, x_2, x_3)$. If domains are $\{0, 1, 2\}$, then the problem is not (strong) rel AC, but it is rel PIC. \square

One surprise here is that rel PIC is incomparable to (strong) rel AC whilst the binary local consistency PIC is strictly stronger than AC.

4 ALGORITHMS FOR PWIC

The generic AC-7 based algorithm for inverse local consistencies proposed in [13] can easily be adapted to enforce rel PIC. However, adapting the generic algorithm to enforce PWIC is more involved. The time and space complexities of this algorithm for rel PIC are $O(e^2kd^{2k})$ and $O(e^2k^2d)$ respectively, while for PWIC a naive adaptation would result in a very inefficient algorithm, in terms of time complexity. The time complexity of the PWC algorithm given in [9] is $O(e^2kd^{2k})$. This algorithm enforces PWC by applying AC in the dual encoding of the problem. Since PWC does not prune values from domains but instead deletes tuples from constraint relations, domains can be pruned if GAC is applied as a second step [9]. Apart from its high time complexity, this pruning method also suffers from a high space complexity, since constraints need to be extensionally represented. The time complexity of PWC can be reduced to $O(e^3d^k)$ if the algorithm of [11] for AC in the dual encoding is used. However, the space complexity can still be prohibitive.

In what follows we describe two algorithms for PWIC, which is stronger and more efficient than rel PIC, with better time complexity than a generic algorithm. These algorithms can be easily modified to achieve rel PIC. Our algorithms achieve the same pruning as a two-step procedure of PWC followed by GAC with better time and space complexity.

4.1 PWIC-1: A Simple Algorithm for PWIC

From the definition of PWIC we can immediately derive a simple algorithm by extending a GAC algorithm so that whenever it finds a GAC-supporting tuple for a value in a constraint c_i , it also checks if this tuple has a PW-support in all constraints intersecting with c_i . Figure 1 gives PWIC-1, an algorithm for PWIC based on the GAC algorithm GAC2001/3.1 [5].

```

function PWIC-1
1:    $Q \leftarrow \emptyset$ ;
2:   for each constraint  $c_i$ 
3:     for each variable  $x_j$  where  $x_j \in \text{var}(c_i)$ 
4:       if  $\text{Revise}(x_j, c_i) > 0$ 
5:         if  $D(x_j)$  is empty return INCONSISTENCY;
6:         put in  $Q$  each constraint  $c_m$  such that  $x_j \in \text{var}(c_m)$ ;
7:   return Propagation;
function Propagation
8:   while  $Q$  is not empty
9:     pop constraint  $c_i$  from  $Q$ ;
10:    for each unassigned variable  $x_j$  where  $x_j \in \text{var}(c_i)$ 
11:      if  $\text{Revise}(x_j, c_i) > 0$ 
12:        if  $D(x_j)$  is empty return INCONSISTENCY;
13:        put in  $Q$  each  $c_m \neq c_i$  such that  $x_j \in \text{var}(c_m)$ ;
14:   return CONSISTENCY;
function Revise( $x_j, c_i$ )
15:   for each value  $a \in D(x_j)$ 
16:     PW  $\leftarrow$  FALSE;
17:     for each valid  $\tau(\in \text{rel}(c_i)) \geq_l \text{lastGAC}_{x_j, a, c_i}$ 
           such that  $\tau[x_j] = a$ 
18:     PW  $\leftarrow$  TRUE;
19:     for each  $c_m$  such that  $\text{var}(c_i) \cap \text{var}(c_m) > 1$ 
20:       if  $\nexists$  valid  $\tau'(\in \text{rel}(c_m))$  such that
            $\tau[\text{var}(c_i) \cap \text{var}(c_m)] = \tau'[\text{var}(c_i) \cap \text{var}(c_m)]$ 
21:       PW  $\leftarrow$  FALSE; break;
22:     if PW=TRUE  $\text{lastGAC}_{x_j, a, c_i} \leftarrow \tau$ ; break;
23:     if PW=FALSE remove  $a$  from  $D(x_j)$ ;
24:   return number of deleted values;

```

Figure 1. A simple algorithm for PWIC.

Algorithm PWIC-1 uses a stack (or queue) of constraints to propagate value deletions, and works as follows. In the initial phase it iterates over each constraint c_i (line 2) and updates the domain of every variable x_j involved in c_i by calling Revise (line 4). During each revision, for each value a of $D(x_j)$ we first look for a tuple in $\text{rel}(c_i)$ that GAC-supports it. As in GAC2001/3.1, we store a pointer $\text{lastGAC}_{x_j, a, c_i}$. This is now the most recently discovered tuple in $\text{rel}(c_i)$ that GAC-supports value a of variable x_j and is pairwise consistent. If this tuple is valid then we know that a is GAC-supported. Otherwise, we look for a new GAC-support starting from the tuple immediately “after” $\text{lastGAC}_{x_j, a, c_i}$ (line 17). If $\text{lastGAC}_{x_j, a, c_i}$ is valid or a new GAC-support is found then the algorithm checks if the GAC-support (tuple τ) is pairwise consistent. Note that this check must be performed in the case where $\text{lastGAC}_{x_j, a, c_i}$ is valid, since this tuple may have lost its PW-supports on some of c_i ’s intersecting constraints.

To check if τ has PW-supports, PWIC-1 iterates over each constraint c_m that intersects with c_i on more than one variable. Constraints intersecting on one variable are not considered because PWIC offers here no more pruning than GAC. It checks if there is a tuple $\tau' \in \text{rel}(c_m)$ such that τ' is a PW-support of τ (lines

19-20). If such tuples are found for all intersecting constraints then $lastGAC_{x_j, a, c_i}$ is updated (line 22). If no PW-support is found on some intersecting constraint, then the iteration stops (line 21) and the algorithm looks for a new GAC-support. If no pairwise consistent GAC-support is found, a is removed from $D(x_j)$ (line 23). In this case, all constraints involving $D(x_j)$ not already in the stack are put on the stack (line 6). Constraints are then removed from the stack sequentially and their variables are revised. The algorithm terminates if a domain is wiped out, in which case the problem is not PWIC, or if the stack becomes empty, in which case the problem is PWIC.

Proposition 1 The worst-case time complexity of algorithm PWIC-1 is $O(e^2 k^3 d^{2k-f})$.

Proof: The complexity is determined by the *revise* function. $\text{Revise}(x_j, c_i)$ can be called at most kd times for each constraint c_i ; once for every deletion of a value from $D(x_j)$, where x_j is one of the k variables in $\text{var}(c_i)$. In each call, the algorithm performs one check to see if $\text{lastGAC}_{x_j, a, c_i}$ is valid. If $\text{lastGAC}_{x_j, a, c_i}$ is not valid, it tries to find a new GAC-support for a in $\text{rel}(c_i)$. The cost to make a GAC for the total number of calls to $\text{Revise}(x_j, c_i)$ is $O(kd^{k-1})$ (see [5] for details).

For each GAC-support τ found, PWIC-1 iterates over the, at most e , constraints that intersect with c_i to determine if τ has PW-supports. For each such constraint c_m , it checks at most d^{k-f} tuples, i.e. those that take the same values in variables $\text{var}(c_i) \cap \text{var}(c_m)$ as in τ . The cost of each such check is $O(k - f)$ if we assume this is linear in the arity of the tuple. Therefore, for each value of x_j , *Revise* makes $O(kd^{k-1} \times e(k - f)d^{k-f})$ checks. For kd values, the upper bound in checks performed to make one constraint PWIC is $O(ek^3d^{2k-f})$. For e constraints the complexity is $O(e^2k^3d^{2k-f})$. \square

The space complexity of PWIC-1 is $O(ekd)$.

4.2 PWIC-2: An Improved Algorithm for PWIC

Although the asymptotic time complexity of PWIC-1 is lower than that of the generic algorithm of [13], it can still be prohibitive in practice. PWIC-2 offers a significant improvement in terms of time complexity, but with an increase in the space complexity. The major bottleneck for PWIC-1 is that each time a GAC-support τ for a value $a \in D(x_j)$ is found in $rel(c_i)$, it has to check if τ is pairwise consistent. This is done by iterating through all constraints that intersect with c_i . In each such iteration the algorithm may check **all** the d^{k-f} sub-tuples that include the assignment $\tau[var(c_i) \cap var(c_m)]$. This process is repeated each time c_i is revised. To overcome this problem, for each constraint c_i algorithm PWIC-2 keeps a set of d^f pointers for every constraint c_m intersecting with c_i . Each such pointer $lastPW_{c_i, c_m, s}$ corresponds to the s -th sub-tuple among the d^f sub-tuples containing the possible combinations of values for variables $var(c_i) \cap var(c_m)$. Each pointer points to the most recently discovered tuple in $rel(c_m)$ that extends sub-tuple s and is a PW-support for the current GAC-support of a value (x_j, a) on c_i .

Figure 2 gives lines 20-21 of function Revise of PWIC-2 (the rest of the algorithm is the same as PWIC-1). During each revision, for each value a of $D(x_j)$ we first look for a tuple in $rel(c_i)$ that GAC-supports it, in the same way as in PWIC-1. If such a tuple τ is found then the algorithm checks if τ is pairwise consistent. For each constraint c_m that intersects with c_i PWIC-2 first checks if tuple $lastPW_{c_i, c_m, s}$ is valid, where s is the sub-tuple $\tau[\text{var}(c_i) \cap \text{var}(c_m)]$. If it is valid then it PW-supports τ since they have the same values for the variables $\text{var}(c_i) \cap \text{var}(c_m)$. Otherwise, the algorithm looks for a new PW-support starting from the tuple that

```

function Revise( $x_j, c_i$ )
     $s \leftarrow \tau [var(c_i) \cap var(c_m)];$ 
    if  $lastPW_{c_i, c_m, s}$  is not valid
        if  $\exists$  valid  $\tau' (\in rel(c_m)) >_l lastPW_{c_i, c_m, s}$ 
            and  $\tau' [var(c_i) \cap var(c_m)] = s$ 
             $lastPW_{c_i, c_m, s} \leftarrow \tau';$ 
    else PW  $\leftarrow$  FALSE; break;

```

Figure 2. Function Revise of PWIC-2.

includes the assignment s and is immediately “after” $\text{lastPW}_{c_i, c_m, s}$ in the lexicographic order. If such a tuple τ' is found, $\text{lastPW}_{c_i, c_m, s}$ is updated. If no tuple is found in $\text{rel}(c_i)$ that is both a GAC-support for a and is pairwise consistent, then a is removed from $D(x_j)$.

The following example demonstrates the savings in constraint checks that PWIC-2 achieves compared to PWIC-1.

Example 1 Consider the problem of Figure 3. There are four variables $\{x_1, \dots, x_4\}$ and two constraints that intersect on x_1 and x_2 . Tuples in italics are inconsistent and the rest are consistent. Assume we wish to determine if the values for x_3 are PWIC. PWIC-1 checks all 5 tuples of c_2 for each value of x_3 , as depicted in Figure 3a (for each tuple τ in c_1 , all tuples of c_2 between the pair of edges starting from τ are checked against τ). PWIC-2 checks all 5 tuples only for value 0 of x_3 . After locating $\{0, 0, 4\}$ of c_2 as a PW-support for $\{0, 0, 0\}$ of c_1 , $lastPW_{c_1, c_2, s}$, where $s = \{0, 0\}$, points to $\{0, 0, 4\}$. For the rest of x_3 's values, PWIC-2 only checks this tuple.

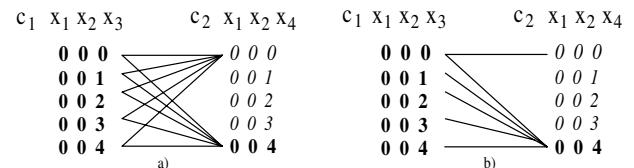

Figure 3. Applying PWIC-1 and PWIC-2.

Proposition 2 The worst-case time complexity of algorithm PWIC-2 is $O(e^2 k^2 d^k)$.

Proof: The complexity is again determined by the calls to `Revise`. When looking for a GAC-support within `Revise`, PWIC-2 is identical to PWIC-1 and therefore the two algorithms have the same cost for this part. That is, $O(kd^{k-1})$ to make a value $a \in D(x_j)$ GAC for all calls to `Revise`(x_j, c_i). Once a GAC-support τ is found, PWIC-2 iterates over the constraints that intersect with c_i . Assuming that $\tau[\text{var}(c_i) \cap \text{var}(c_m)] = s$, for any intersecting constraint c_m PWIC-2 searches through the tuples that include assignment s . However, these tuples are not searched from scratch every time. Since the pointer $\text{lastPW}_{c_i,c_m,s}$ is used, the tuples that include assignment s are searched from scratch **only** during the first time a GAC-support τ with $\tau[\text{var}(c_i) \cap \text{var}(c_m)] = s$ is located. In any subsequent iteration of the for loop in line 17 of Figure 1, and in any subsequent call to `Revise`(x_j, c_i), whenever a GAC-support that includes s is located, the algorithm first checks if $\text{lastPW}_{c_i,c_m,s}$ is still valid. If it is not, then only tuples “after” $\text{lastPW}_{c_i,c_m,s}$ are searched. As a result, in the $O(d^{k-1})$ times a GAC-support for a is located, each

tuple of each intersecting constraint is checked at most once (with each check costing $O(k - f)$) and there are at most d^{k-1} checks for the validity of $\text{last } PW_{c_i, c_m, s}$. Thus, the cost of $\text{Revise}(x_j, c_i)$ is $O(kd^{k-1} + e(d^{k-1} + (k-f)(d^{k-1}))) = O(ekd^{k-1})$. For the $O(kd)$ times Revise is called to make a constraint PWIC, the upper bound in checks is $O(ek^2d^k)$. For e constraints the worst-case complexity is $O(e^2k^2d^k)$. \square

The space complexity of PWIC-2 is $O(e^2d^f)$. PWIC-2 is thus not practical for large arity constraints sharing many variables. Note that, even when constraints share just two variables (and the space complexity is $O(e^2d^2)$), PWIC is stronger than GAC. It may be beneficial to apply PWIC only to variables participating in certain constraints, based on properties like the arity and the number of shared variables, and to apply GAC to the rest of the variables. Indeed, our two algorithms for PWIC apply such a hybrid propagation scheme, as they apply GAC to constraints that intersect on just one variable.

5 EXPERIMENTS

We compared algorithms that maintain GAC2001/3.1, PWIC-1, PWIC-2, RPIC-1, and RPIC-2 throughout search (RPIC-1 and RPIC-2 are algorithms for rel PIC similar to the corresponding algorithms for PWIC). We simply refer to these search algorithms by the consistency enforced. All algorithms used the dom/deg variable ordering heuristic [4]. Figure 4 shows the average CPU time to solve 50 instances of randomly generated problems with 30 variables, uniform domain size of 10, 28 4-ary constraints, and varying constraint looseness (along the x-axis). The problems were generated using the extended model B [2]. On these instances, PWIC-1 and PWIC-2 are faster than GAC and RPIC-1 and RPIC-2 are slower. From experiments with other parameters, we conjecture that PWIC is more efficient than GAC on sparse problems, especially when the domain size is large. On the other hand, PWIC is too expensive on problems with medium or high density. Although it significantly reduces the nodes visited, it is outperformed by GAC in CPU time. Rel PIC is generally less efficient than both GAC and PWIC.

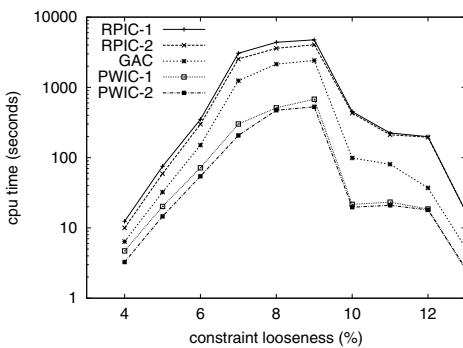

Figure 4. Comparison on random problems.

We also ran experiments on the CLib configuration benchmark library (see www.it.u.edu/VeCoS/clib). To obtain hard instances, each problem was slightly altered by adding a few variables (5-6) and constraints (8-10) randomly, as described in [11].

Table 1 gives results for GAC, and (for space reasons) only PWIC-1 and RPIC-1. There is a significant difference in run times in favor of the algorithms that maintain inverse consistencies due to the additional pruning they perform. PWIC-2 and RPIC-2 are faster than

problem	n	e	k	d	GAC nodes-time	PWIC-1 nodes-time	RPIC-1 nodes-time
machine	30	22	4	9	535874-14,38	12600-1,31	36046-4,27
fx	24	21	5	44	193372-4,06	1315-0,09	17624-1,32
fs	29	18	6	51	618654-23,29	19-0,00	1698-0,23
esvs	33	20	5	61	6179966-153,71	7859-0,24	39021-3,21

Table 1. Configuration problems. k and d are the maximum arity and domain size. Averages are over 50 hard instances for each benchmark.

PWIC-1 and RPIC-1, by a small margin on average. The PWIC algorithms are again more efficient than the rel PIC ones.

6 CONCLUSION

Although domain filtering consistencies tend to be more practical than consistencies that change the constraint relations and the constraint graph, very few such consistencies have been proposed for non-binary constraints. In this paper, we performed a detailed study of two such consistencies, rel PIC and PWIC. Our theoretical study revealed some surprising results. For example, rel PIC and PWIC are weaker than PIC when restricted to binary constraints, while for non-binary constraints rel PIC and PWIC are incomparable to rel AC. We also described algorithms that can be used to achieve PWIC and rel PIC. One has a particularly good time complexity, competitive with GAC algorithms, though with a higher space cost. Experiments demonstrated the potential of inverse consistencies as an alternative or complementary to GAC. As future work, we will investigate ways to combine inverse consistencies with specialized GAC propagators.

ACKNOWLEDGEMENTS

We would like to thank Patrick Prosser for useful comments and suggestions on an early draft of the paper.

Guiding Search using Constraint-level Advice

Radoslaw Szymanek and Barry O'Sullivan¹

Abstract. Constraint satisfaction problems are traditionally solved using some form of backtrack search that propagates constraints after each decision is made. The efficiency of search relies heavily on the use of good variable and value ordering heuristics. In this paper we show that constraints can also be used to guide the search process by actively proposing the next choice point to be branched on. We show that search effort can be reduced significantly.

1 INTRODUCTION

Constraint programming (CP) has become one of the dominant approaches to modelling and solving real-world combinatorial problems [19]. However, while CP has many success stories, it is believed that improving the usability of the technology is a key factor in its future success [15]. This is largely due to the fact that using constraints technology often requires considerable expertise in the use of constraint programming tools. It has been argued [15] that the constraints community should focus on developing techniques that do not require the user to tweak the search algorithm, for example by selecting variable and value ordering heuristics. Instead the solver should automatically configure itself based on the problem formulation. It is this need that motivates the work we present in this paper.

The objective of this work is to show that constraints can be used to efficiently guide search. Our results show that search effort can be reduced significantly. We see the major contribution of this paper being a step towards an approach to CP where the constraint solver dynamically modifies its behaviour in response to the particular formulation of the problem, specifically the semantics of the constraints among variables rather than simply the existence of them. We demonstrate this by showing that the functionality of global constraints can be augmented so they can successfully guide search.

The remainder of this paper is organised as follows. Section 2 presents the framework for constraint-level guiding. An example of how constraints can guide search is presented in Section 3. A detailed empirical evaluation is presented in Section 4. In Section 5 we relate our work to the relevant literature. We outline some directions for future work and make some concluding remarks in Section 6.

2 THE FRAMEWORK

A constraint satisfaction problem (CSP) is a 3-tuple $P \doteq \langle \mathcal{X}, \mathcal{D}, \mathcal{C} \rangle$ where \mathcal{X} is a finite set of variables $\mathcal{X} \doteq \{x_1, \dots, x_n\}$, \mathcal{D} is a set of finite domains $\mathcal{D} \doteq \{D(x_1), \dots, D(x_n)\}$ where the domain $D(x_i)$ is the finite set of values that variable x_i can take, and a set of constraints $\mathcal{C} \doteq \{c_1, \dots, c_m\}$. Each constraint c_i is defined by the ordered set $\text{var}(c_i)$ of the variables it involves, and a set $\text{sol}(c_i)$ of

allowed combinations of values. An assignment of values to the variables in $\text{var}(c_i)$ satisfies c_i if it belongs to $\text{sol}(c_i)$. A solution to a CSP is an assignment to each variable with a value from its domain such that every constraint in \mathcal{C} is satisfied.

Many modern constraint solvers by default use a 2-way, or binary branching, search strategy [13, 18]. When a variable x is selected for instantiation, a value is chosen to generate a binary choice point. For example, if value v is selected, the corresponding choice point (x, v) creates two branches, $x = v$ and $x \neq v$. The first (the left branch) is explored; if that branch fails, the search backtracks, and the right branch is followed instead by propagating $x \neq v$. In general, if a dynamic variable ordering is being used, the choice of variable may change after propagating $x \neq v$ (right branch).

For each choice point we can use individual constraints to estimate the amount of pruning that can be achieved in each branch in a number of ways. We assume that each constraint $c_i \in \mathcal{C}$ has an associated function $\mathbf{g}_i(\cdot)$ that, when given a choice point cp as an argument², computes a pair of values $(\min_{cp}^{c_i}, \max_{cp}^{c_i})$, where $\min_{cp}^{c_i}$ (resp. $\max_{cp}^{c_i}$) is an estimate of the minimum (resp. maximum) amount of pruning associated with the choice point cp by propagating constraint c_i , e.g. measured in terms of the number of values removed from the domains of the variables in $\text{var}(c_i)$. There are many ways of defining the function $\mathbf{g}_i(\cdot)$ depending on the type of constraint being considered. For example, in the case of an ALLDIFFERENT or PERMUTATION constraint [17], the estimate of pruning that can be achieved from a choice point can be based on the number of arcs removed from the value graph maintained by the constraint. Similarly, in the case of an extensionally represented constraint the estimate can be based on the number of lost supports associated with both branches of the choice point; in the case of the SUM constraint [1], which achieves bounds consistency, it can be based on how much the bounds are tightened.

We can compare the quality of choice points based on their respective pruning estimates using a comparison operator \succ , which induces a total order over choice points. There are many ways to define the semantics of \succ . For example, given two choice points cp_a, cp_b and a constraint c_i we might say that $\mathbf{g}_i(cp_a) \succ \mathbf{g}_i(cp_b) \leftrightarrow \min_{cp_a}^{c_i} > \min_{cp_b}^{c_i}$, i.e. that we consider cp_a to be better than cp_b with respect to constraint c_i iff the minimum amount of pruning associated with cp_a is larger than that of cp_b . It is also useful to compare pruning due to different constraints, i.e. comparing $\mathbf{g}_i(cp_a) \succ \mathbf{g}_j(cp_b)$.

In order to use constraints to guide search, our approach is to firstly *use each constraint to evaluate the default choice point* proposed by the default variable and value orderings used in the search algorithm. Formally, consider a choice point $cp_0 = (x, v)$ proposed by the default search orderings. The best pruning estimate, $\text{eval}(cp_0)$, for this choice point is computed by $\mathbf{g}_i(cp_0)$ such that

¹ Cork Constraint Computation Centre, University College Cork, Ireland.
 {r.szymanek|b.osullivan}@4c.ucc.ie

² Implicitly \mathbf{g}_i also takes a second argument representing the current state of the domains of the variables, but we omit this to keep our notation simpler.

$\neg \exists c_j \in (\mathcal{C} - \{c_i\}).(\mathbf{g}_j(cp_0) \succ \mathbf{g}_i(cp_0))$. Secondly, once the best pruning estimate is obtained, we use each constraint in turn to propose the best choice point from its local perspective. If a constraint's local best choice point proposal is better, according to \succ , than the best proposed to date, we use it as the baseline when querying the next constraint. Formally, for each constraint c_i we can define the best choice point for that constraint, \mathbf{best}_i , as follows: let $\Delta = \{(x, v) | x \in \text{var}(c_i), v \in D(x)\}$, thus $\mathbf{best}_i = cp \in \Delta$ such that $\neg \exists cp' \in (\Delta - \{cp\}).\mathbf{g}_i(cp') \succ \mathbf{g}_i(cp)$.

The choice point we branch on is the best one found having considered each constraint in \mathcal{C} . Formally, we recursively consider each constraint $c_1 \dots c_m \in \mathcal{C}$ to compute the overall best choice point, cp_m , as follows:

$$cp_m = \begin{cases} cp_{m-1} & \mathbf{g}_k(cp_{m-1}) \succ \mathbf{g}_m(\mathbf{best}_m), \\ \mathbf{best}_m & \text{otherwise.} \end{cases}$$

where \mathbf{g}_k is the evaluation given to the choice point cp_{m-1} by the constraint c_k that proposed it; cp_0 is the choice point proposed by the default search orderings, and $\mathbf{g}_0(cp_0) = \text{eval}(cp_0)$.

In practice, this framework may be modified in two ways. Firstly, we may wish to use only a subset of the constraints \mathcal{C} to guide search. In this situation the remaining constraints are not considered in the evaluation and proposal of choice points. Secondly, if the user does not wish to define a default search strategy, the guiding constraints can guide search without firstly evaluating the default choice point, thus reducing the overhead associated with search guiding. The modifications to the description, and the algorithms presented later, are obvious.

3 AN EXAMPLE

We present an example of how constraints can be used to guide search. The example uses the PERMUTATION constraint to demonstrate how the internal data structures maintained by this global constraint can be used to evaluate and propose choice points. A PERMUTATION constraint is applicable when the number of variables and values is equal and we wish to ensure that each variable takes a different value. Therefore, the PERMUTATION constraint can be regarded as a special case of the ALLDIFFERENT constraint [17]. A filtering algorithm for PERMUTATION can be readily derived from the filtering algorithm for ALLDIFFERENT.

We will consider an example permutation problem: quasigroup completion (QCP). Essentially, a quasigroup can be viewed as an $n \times n$ multiplication table defining a Latin square, which must be filled with unique integers on each row and column. One possible model for a QCP of order n is to have n^2 variables, $x_1, \dots, x_{(n^2)}$, and specify a PERMUTATION constraint on each set of n variables representing each row and column. An example of QCP with four cells preassigned is presented in Figure 1. We will concentrate only on one of the permutation constraints in this model, which is imposed over variables from the top row, comprising variables x_1, \dots, x_4 . The PERMUTATION constraint maintains an internal data structure called the value graph to achieve generalised arc consistency (GAC) [17]. The value graph is a bipartite graph in which the edges link variables to values in their current domain. The state of the value graph after propagating all initial assignments is presented in Figure 1. This value graph can be reused to identify values that can be assigned to a small number of variables, as well as variables with small domain.

In order to implement a variant of the PERMUTATION constraint that can propose choice points, the constraint must be modified to

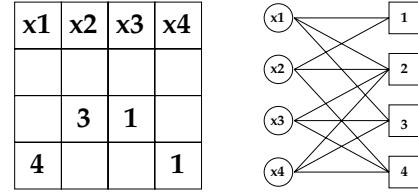

Figure 1. An example QCP and the PERMUTATION value graph.

evaluate multiple candidates. Evaluating every possible choice point may be too costly, so a heuristic can be used to reduce the set of candidates.

To compare choice points, and ultimately propose them based on constraint-level advice, we can consider a variety of heuristics. For example, in Figure 2 we present two candidate choice points. The first candidate uses variable x_1 and value 3. The pruning achieved in both branches of this choice point is depicted in Figure 2(a). The left branch gives a lot of pruning, unfortunately the right branch achieves the least amount of pruning possible. If we choose the left branch first and it does not lead to a solution, then the discovery of this mistake has negligible positive effect on the search. If we choose the right branch first and it does not lead to a solution, then the discovery of this may take long time, as little pruning is achieved. The second choice point uses variable x_2 and value 1. The pruning achieved by this choice point is depicted in Figure 2(b). This choice point offers an interesting trade-off. If the left branch does not lead to a solution, we still obtain a reasonable amount of pruning after backtracking from it. We might prefer this type of choice point because it tends to hedge against the possibility that we make a mistake when selecting the left branch.

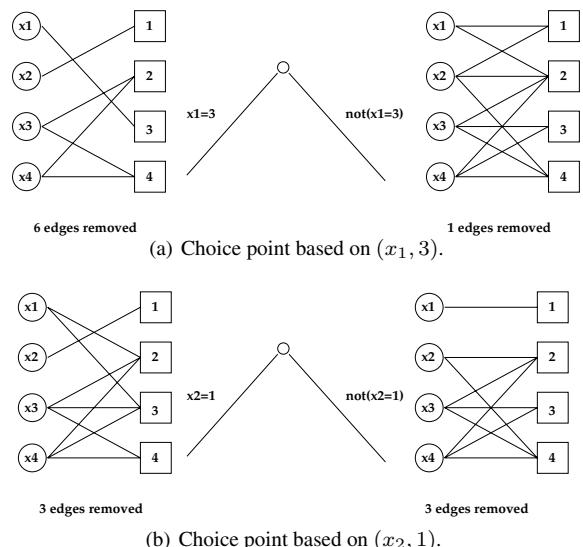

Figure 2. An comparison of alternative choice points.

It is also possible to obtain value guidance only. Given a variable selected by the default variable ordering heuristic, e.g. x_1 , then after the analysis of the value graph, value 1 for this variable might be proposed, for example, based on the fact that it can be assigned to the

fewest number of variables. Similarly, we can also obtain *variable guidance only*, using other external methods to decide on a value.

4 EMPIRICAL EVALUATION

We report on experiments conducted to verify the utility of our approach to constraint-guided search. Our experiments show that such guidance can be very successful in many problem domains such as QCP, Magic Squares and Langford's Problem. We describe our problem domains and the models in Section 4.1. In Section 4.2 we present the details of the constraint-level guidance mechanism used in the experiments. Our results are presented in Section 4.3.

4.1 Problem Domains and Models

The problem domains studied, taken from CSPLIB³, are as follows:

Quasigroup Completion. A quasigroup is a set Q with a binary operation $\star : Q \times Q \rightarrow Q$, such that for all a and b in Q there exist unique elements in Q such that $a \star x = b$ and $y \star a = b$. The cardinality of the set, $n = |Q|$, is called the order of the quasigroup. A quasigroup can be viewed as an $n \times n$ multiplication table defining a Latin square, which must be filled with unique integers on each row and column. The Quasigroup Completion Problem (QCP) is the problem of completing a partially filled Latin square.

Magic Squares. An order n magic square is a $n \times n$ matrix containing the numbers 1 to n^2 , with each row, column and the main diagonals summing up to the same number.

Generalization of Langford's Number Problem. An instance $L(k, n)$ of Langford's Number problem seeks to arrange k sets of numbers 1 to n , so that each appearance of the number m is m numbers from the last. For example, the $L(3, 9)$ problem is to arrange 3 sets of the numbers 1 to 9 so that the first two 1's and the second two 1's appear one number apart, the first two 2's and the second two 2's appear two numbers apart, etc. A solution to $L(2, 4)$ is 41312432.

All models and algorithms used in our evaluation were implemented using the JACOP constraint programming system [12]. Experiments were run on a Pentium 4 processor (1800 MHz), with 512Mb RAM running Linux Fedora Core 4. The models used for each problem were those from [11]. For each problem domain we compared the guided approach against both a primal model and a dual model. In both models the variable ordering heuristic used preferred variables with the smallest domain (ties broken lexicographically) with values selected lexicographically. However, for the dual model the set of search variables included both the primal and dual variables. Therefore, in the dual model the search heuristic was equivalent to the $SD(p + d)$ heuristic presented in [11]. The dual model differed from the primal model since it had dual variables and channelling constraints between primal and dual variables. The channelling constraints were implemented as one global constraint to increase the efficiency. There was no need to post PERMUTATION on the dual variables since PERMUTATION on the primal variables achieved GAC. Therefore, the dual model, and its heuristic, used in our experiments was the most efficient one studied in [11].

In addition to the guidance of the PERMUTATION constraint discussed in Section 3, we also implemented a simple form of guidance for the SUM constraint. Our implementation of the SUM constraint achieves bounds consistency. The choice point that tightens the bounds on the domains of the variables most is preferred.

³ <http://www.csplib.org>.

4.2 Implementation of Guidance

We implemented the guidance framework presented in Section 2 using Algorithm 1. The algorithm consists of an evaluation phase, in which the choice point proposed by the default heuristic is analysed to compute $\text{eval}(cp_0)$, and a proposal phase where the best choice point to be branched on is computed. The function $g_i(\cdot)$ is implemented using $\min(cp, c)$ and $\max(cp, c)$, which compute the minimal and maximal pruning obtained by constraint c given choice point cp , respectively, based on the heuristic estimate outlined earlier. The only constraints used to guide in our models were the PERMUTATION and SUM constraints.

Algorithm 1: GUIDEDCHOICE(cp_0, \mathcal{C})

```

Input: A choice point  $cp_0 = (var, val)$  where  $var$  is the variable proposed by the default variable ordering and  $val$  is the value proposed by the default value ordering.
 $\mathcal{C}$ , the constraints in the problem.
Output: A choice point,  $cp$ , considered best by the constraints in  $\mathcal{C}$ .
 $cp \leftarrow cp_0$ ;
 $\min_{cp} \leftarrow 1$ ;
 $\max_{cp} \leftarrow \infty$ ;
foreach constraint  $c_i$  in  $\mathcal{C}$  do
    if BETTER( $\min(cp_0, c_i), \max(cp_0, c_i), \min_{cp}, \max_{cp}$ ) then
         $\min_{cp} \leftarrow \min(cp_0, c_i)$ ;
         $\max_{cp} \leftarrow \max(cp_0, c_i)$ ;
foreach constraint  $c_i$  in  $\mathcal{C}$  do
     $\text{best}_i \leftarrow \text{PROPOSEBESTCHOICE}(c_i)$ ;
    if BETTER( $\min(\text{best}_i, c_i), \max(\text{best}_i, c_i), \min_{cp}, \max_{cp}$ ) then
         $cp \leftarrow \text{best}_i$ ;
         $\min_{cp} \leftarrow \min(\text{best}_i, c_i)$ ;
         $\max_{cp} \leftarrow \max(\text{best}_i, c_i)$ ;
return  $cp$ ;

```

The function PROPOSEBESTCHOICE returns the best choice point from the perspective of a guiding constraint, c_i , based on \succ . The comparison operator, \succ , was implemented using Algorithm 2. The first criterion used by \succ is to maximise the minimal amount of pruning obtained by a choice point, denoted \min_{cp_x} . If two choice points have the same amount of minimal pruning then a tie-breaker based on the maximal amount of pruning, \max_{cp_x} , is employed. The tie-breaker behaves differently depending on the minimal amount of pruning. In experiments this implementation of the \succ operator was found to be the most robust over all problem classes studied.

Algorithm 2: BETTER($\min_{cp_x}, \max_{cp_x}, \min_{cp_y}, \max_{cp_y}$)

```

Input : Estimates of minimal and maximal pruning of choice points,  $cp_x$  and  $cp_y$ .
Output: A boolean reflecting whether the pruning estimate for  $cp_x$  is considered better than the estimate for  $cp_y$ .
if ( $\min_{cp_x} > \min_{cp_y}$ ) then
    return TRUE;
else if ( $\min_{cp_x} = \min_{cp_y} = 1 \wedge \max_{cp_x} \leq \max_{cp_y}$ ) then
    return TRUE;
else if ( $\min_{cp_x} = \min_{cp_y} \neq 1 \wedge \max_{cp_x} \geq \max_{cp_y}$ ) then
    return TRUE;
else return FALSE;

```

4.3 Results and Discussion

In Table 1 we present results for the QCP. We used problems of order 20 with 187 holes to give us instances at the peak of difficulty for filtered QCP. We generated 3000 instances, using code based on Carla

Gomes' *Isencode* quasigroup generator, from which we filtered and retained only the satisfiable ones, giving us 1749 instances.

We present results for the dual model, the primal non-guided model, the primal model with value-only guiding, the primal model with variable-only guiding and the primal model with choice point (variable and value) guiding. With the exception of the dual model, whose heuristic has been discussed above, in each case we used the smallest-domain-first (sdf), random and largest-domain-first (i.e. anti-sdf) variable ordering heuristics. Values were chosen lexicographically. The model we used for these problems employed PERMUTATION constraints to ensure uniqueness of elements across columns and rows.

In each case we present the percentage of instances solved within a limit of 100000 backtracks. Any problems that exceeded this number of backtracks were removed from the data-set when computing our results. We also present the median number of nodes, median number of backtracks and median time required in seconds. These measurements were taken due to maladies suffered by each measure on its own and according to the definitions given in [3].

Table 1. Results for filtered QCP order 20 (guided highlighted).

model (heuristic)	% solved	nodes	backt.	time (s)
dual (sdf,sdf)	99.9	326	149	17.52
primal (sdf)	99.9	323	149	3.46
val guided (sdf)	99.9	244	105	2.77
var guided (sdf)	99.8	169	69	2.70
guided (sdf)	99.8	162	67	2.66
primal (random)	91.8	6,138	3,055	34.95
val guided (random)	98.7	1,926	946	12.06
var guided (random)	99.7	162	66	2.46
guided (random)	99.7	164	68	2.45
primal (anti-sdf)	76.4	14,184	7,068	57.96
val guided (anti-sdf)	97.1	4,069	2,017	19.18
var guided (anti-sdf)	99.7	165	68	2.40
guided (anti-sdf)	99.7	166	69	2.41

It is clear that a standard dual model does not help for this problem, and is outperformed by the primal (sdf) model. This is due to the structural properties of the QCP problem and the fact that PERMUTATION constraints enforcing GAC were used. It is clear that the additional variables, dual constraints and channelling constraints are simply adding overhead. Considering the primal, value guided, variable guided and (choice) guided cases, we note that as the sophistication of the type of guiding employed increases, we observe improvements in search effort, regardless of the default search heuristics used.

Comparing the primal (sdf) results with the guided (sdf) results it can be seen that guiding improves upon the already good variable ordering used by default. Clearly as search progresses, the guiding mechanism is capable of proposing alternative choice points that are of sufficiently high quality to improve overall performance.

When a poor default search heuristic is selected (random and anti-sdf) the guiding mechanism is strong enough to redirect search in a way that is essentially as good as the best search strategy observed in the experiment, i.e. guided (sdf). This is quite a significant result since it shows that the poor choice of heuristic is essentially irrelevant in this case. The guiding mechanism that has been incorporated into the global constraints used to model the problem is capable of compensating for the poor choice of heuristic. In a sense, the search strategy is being dynamically improved by knowledge that is available at little extra cost within the global constraints.

The primal model without guiding was able to solve two more instances comparing to some guided searches. This is reflected in the marginal difference in the percentage of solved instances. We looked at these two instances carefully and after analysing them we concluded that guided search in those two cases had chosen the wrong branch at the root of the tree and was not able to recover before hitting the cutoff limit. This simply emphasises the fact that even the best variable ordering can fall victim to bad value ordering. However, two instances are of no statistical significance.

Table 2. Results for Magic Squares (guided highlighted).

instance	model	nodes	backt.	time (s)
3	primal	4	0	0.22
3	dual	4	0	0.28
3	guided	4	0	0.28
4	primal	18	3	0.44
4	dual	11	0	0.45
4	guided	18	0	0.52
5	primal	1,365	658	2.23
5	dual	1,016	490	2.91
5	guided	814	375	2.11
6	primal	111,153	55,525	124.28
6	dual	—	—	—
6	guided	37,116	18,512	65.14

In the case of the Magic Squares (Table 2) we report results for three different approaches. The first one employs a primal model with the sdf heuristic. The second one is a primal model where all SUM constraints are guiding search. The guided search uses sdf as the default heuristic. Finally, the third approach uses a dual model and the $SD(p+d)$ heuristic. For small and easy problems the best approach is the primal model, as the worst case search space is small and cost per search node is the deciding factor. For larger orders, namely 5 and 6, constraint-guided search can significantly reduce the number of search nodes and can bring almost a 50% reduction in search time compared to the primal model. The dual model could not find any solution for order 6 as it reached the cutoff limit, which was increased to 500000 backtracks for these problems.

For the generalised Langford's problem, we only present results for instances that involved more than 1000 nodes to solve (Table 3). Again, it is clear that constraint-guided search is superior than solving using a traditional approach based on ordering heuristics only. We see improvements using all metrics (backtracks, nodes and time) when comparing the primal model with the guided one. We can also see that the guided model can be of benefit over a primal model, achieving a factor of 15 reduction in search time for the largest instance studied. The guiding approach, while not requiring us to formulate a dual model of our problem, out-performs the dual model in most cases in terms of time since the savings in nodes and backtracks that are gained by the dual model do not payoff when the overhead of the dual model is taken into consideration.

5 RELATED WORK

Variable and value ordering heuristics are the most common approaches to guiding search. Many variable ordering heuristics have been proposed in the literature [2, 5, 6, 10]. The disadvantage of variable ordering heuristics is that they are usually based on macro features of a CSP, such as the domain size of variables and the number

of constraints that each variable is involved in. While such heuristics are cheap to employ, they are often neither sufficiently aware of the semantics of the constraints nor the problem's structure. However, a number of approaches proposed recently that try to actively modify the search in an online fashion are notable exceptions [5, 16]. Our work is complementary to such approaches.

There has been work on using dual viewpoint models to improve the efficiency with which a CSP can be solved [7, 11]. Given an arbitrarily formulated primal model, a dual viewpoint can be formulated by regarding the variables in the primal as domain values in the dual model and the primal domain values as dual variables. The constraints in the primal can be reformulated in order to be applied in the dual. Channelling constraints between the models ensure that inferences made in one viewpoint can be propagated in the other viewpoint, thus potentially giving efficiency benefits. The dual-viewpoint approach is closely related to earlier work on heuristics that consider both variable and value selection simultaneously [9]. Our work can also be seen as complementary to such approaches.

Recent work on global constraints has envisaged using the information they compute to guide search heuristics. For example, counting the number of solutions using global constraints could be used to inform search heuristics [14]. It has been shown how shortest path information can be used as a value ordering [8]. Others have used a modular search heuristic that exploits global constraints to use heuristic information to inform variable and value choice [4]. These approaches are specific instances of the framework we propose here.

6 CONCLUSIONS

In this paper we have shown that constraints can be used to guide the search process by proposing the next variable and/or value to be branched on. Experimental results on a variety of problem classes show very positive results. There are a number of possible directions

for future work. We would like to develop guiding schemes for other constraints, particularly more global constraints. We will also evaluate the impact of using other measures of pruning on the quality of the guidance, while considering the overhead costs associated with more elaborate schemes.

We regard this work as a step towards a novel type of self-configuring constraint solver. Our vision is one where the search strategy, for problem models developed by non-expert humans, is determined automatically by the guidance provided by individual constraints. Such a vision moves us closer to the goal of declarative, efficient, but most importantly, user-friendly constraint programming.

Beyond Singleton Arc Consistency

M.R.C. van Dongen¹

Abstract. *Shaving algorithms*, like *singleton arc consistency* (SAC), are currently receiving much interest. They remove values which are not part of any solution. This paper proposes an efficient shaving algorithm for enforcing stronger forms of consistency than SAC. The algorithm is based on the notion of weak *k-singleton arc consistency*, which is equal to SAC if $k = 1$ but stronger if $k > 1$. This paper defines the notion, explains why it is useful, and presents an algorithm for enforcing it. The algorithm generalises Lecoutre and Cardon's algorithm for establishing SAC. Used as pre-processor for MAC it improves the solution time for structured problems. When run standalone for $k > 1$, it frequently removes more values than SAC at a reasonable time. Our experimental results indicate that at the SAC phase transition, it removes many more values than SAC-1 for $k = 16$ in less time. For many problems from the literature the algorithm discovers *lucky solutions*. Frequently, it returns satisfiable CSPs which it proves *inverse consistent* if all values participate in a lucky solution.

1 Introduction

The notion of *local consistency* plays an important role in constraint satisfaction, and many such notions have been proposed so far. For the purpose of this paper we restrict our attention to binary Constraint Satisfaction Problems (CSPs).

A CSP having variables X is (s, t) -consistent [6] if any consistent assignment to the s variables in S can be extended to some consistent assignment to the $s + t$ variables in $S \cup T$, for any sets $S \subseteq X$ and $T \subseteq X \setminus S$ such that $|S| = s$ and $|T| = t$. Local consistency notions are usually enforced by removing tuples and/or recording nogoods. As s increases enforcing (s, t) -consistency becomes difficult because it requires identifying and recording $\mathcal{O}(\binom{n}{s}d^s) = \mathcal{O}(n^s d^s)$ nogoods, where n is the number of variables in the CSP and d is the maximum domain size. For example, $(2, 1)$ -consistency, also known as path consistency [9], is in the most benign class beyond $s = 1$ but it is considered prohibitive in terms of space requirements. The space complexity issues arising with increasing s are the reason why practical local consistency algorithms keep s low. Usually, this means setting s to 1, which means enforcing consistency by removing values from the domains.

Shaving algorithms also enforce consistency by removing values from the domains. They fix variable-value assignments and remove values that inference deems inconsistent. They terminate if no values can be removed. A shaving algorithm, which is currently receiving much attention, is singleton arc consistency (SAC) [4; 5; 11; 1; 8].

¹ Cork Constraint Computation Centre (4C). 4C is supported by Science Foundation Ireland under Grant 00/PI.1/C075.

Another computational complexity source of (s, t) -consistency is the requirement that each consistent assignment to the s variables in S be extendable to a consistent assignment to the $s+t$ variables in $S \cup T$, for each set $S \subseteq X$ having Cardinality s and any set $T \subseteq X \setminus S$ having Cardinality t . Relaxing this requirement by substituting *some* for *any* would make it considerably more easy to enforce the resulting consistency notion, which we call *weak (s, t) -consistency*.

At first glance weak (s, t) -consistency may seem too weak to do useful propagation. However, it has strong advantages:

1. We don't have to find a consistent extending assignment to the variables of *all* sets T of size t . This is especially useful if the problem is already (s, t) -consistent or if s is small.
2. By cleverly selecting T we may still find inconsistencies. For example, if there is no consistent assignment to the variables in $S \cup T$ for the first set T then the current assignment to the variables in S cannot be extended.
3. By increasing t we can enforce levels of consistency which, in a certain sense, are stronger and stronger.

This paper proposes to exploit these strengths, proposing an algorithm which switches between enforcing weak and full consistency, taking the best from both worlds. Given a consistent assignment to the variables in S , the algorithms only seek a consistent assignment to $S \cup T$ for a, cleverly chosen, *first* set T , for which such consistent assignment is unlikely to exist. Should there be a consistent assignment then the current assignment to S is weakly consistent and otherwise it is inconsistent. If $s = 1$ then this allows us to prune the value that is currently assigned to the variable in S .

From now on let $s = 1$. We apply the idea of switching between weak and full consistency to *k-singleton arc consistency*, which generalises SAC [4; 5; 11; 1; 8]. Here, a CSP, \mathcal{P} , is *k-singleton arc consistent* (*weakly k-singleton arc consistent*) if for each variable x , and each value v in its domain, the assignment $x := v$ can be extended by assigning values to each (some) selection of $k - 1$ other variables such that \mathcal{P} can be made arc consistent. SAC is equivalent to *k-singleton* and weak *k-singleton arc consistency* if $k = 1$ but weaker if $k > 1$. Switching between weak and full *k-singleton arc consistency* allows us, in a reasonable time, to enforce stronger levels of consistency, which go beyond SAC. Using an algorithm which enforces weak *k-singleton arc consistency* as a pre-processor for MAC [12] allows the solution of CSPs which cannot be solved by other known algorithms in a reasonable amount of time. Our algorithm is inspired by Lecoutre and Cardon's algorithm for enforcing SAC [8]. Like theirs it frequently detects *lucky solutions* [8] (solutions discovered while enforcing consistency), making search unnecessary for certain

satisfiable problems. Going beyond SAC, our algorithm detects certain *unsatisfiable* problems without search, including problems that *can* be made SAC. A problem is *inverse consistent* if all values participate in some solution. Our algorithms make and prove many problems inverse consistent, including (un)modified radio link frequency assignment problems, and forced random binary problems. Sometimes this is done more quickly than it takes SAC-1 to make these problems SAC.

We start by recalling definitions of constraint satisfaction, by recalling existing notions of consistency, and by introducing new consistency notions. This includes *weak k-singleton arc consistency*. Next we describe an algorithm for enforcing it. Finally, we present experimental results and conclusions.

2 Constraint Satisfaction

A *binary constraint satisfaction problem* (CSP), \mathcal{P} , comprises a set of n variables X , a finite domain $D(x)$ for each $x \in X$, and a set of e binary constraints. The maximum domain size is d . Each constraint is a pair (σ, ρ) , where $\sigma = \langle x, y \rangle \in X^2$ is the *scope*, and $\rho \subseteq D(x) \times D(y)$ is the *relation* of the constraint. Without loss of generality we assume that $x \neq y$ for any scope $\langle x, y \rangle$. We write $\mathcal{P} \neq \perp$ if \mathcal{P} has no empty domains.

Let $\langle \langle x, y \rangle, \rho \rangle$ be a constraint. Then $v \in D(x)$ and $w \in D(y)$ are *arc consistent* if $\{v\} \times D(y) \cap \rho \neq \emptyset$ and $D(x) \times \{w\} \cap \rho \neq \emptyset$. The *arc consistent equivalent* of \mathcal{P} , denoted $ac(\mathcal{P})$, is obtained from \mathcal{P} by repeatedly removing all arc inconsistent values (and, if needed, adjusting constraint relations).

The *density* of \mathcal{P} is defined $2e/(n^2 - n)$. The *tightness* of constraint $\langle \langle x, y \rangle, \rho \rangle$ is defined $|\rho|/|D(x) \times D(y)|$.

An *assignment* is a partial function with domain X . A *k-assignment* assigns values to k variables (only). By abuse of notation we write $\{x_1 = f(x_1), \dots, x_k = f(x_k)\}$ for k -assignment f . Let $f = \{x_1 = v_1, \dots, x_k = v_k\}$ be a k -assignment. We call f *consistent* if $k = 1$ and $v_1 \in D(x_1)$ or $k > 1$ and $\langle v_i, v_j \rangle \in \rho$ for each constraint $\langle \langle x_i, x_j \rangle, \rho \rangle$ such that $1 \leq i, j \leq k$. A consistent n -assignment is a *solution*. $\mathcal{P}|_f$ is obtained from \mathcal{P} by substituting $D(x_i) \cap \{v_i\}$ for $D(x_i)$ for all i such that $1 \leq i \leq k$.

3 Consistency

Definition 1 ((s, t)-consistency). A CSP with variables X is (s, t) -consistent if for any variables $S = \{x_1, \dots, x_s\} \subseteq X$ and any variables $\{x_{s+1}, \dots, x_{s+t}\} \subseteq X \setminus S$, any consistent s -assignment to x_1, \dots, x_s is extendable to some consistent $(s+t)$ -assignment to x_1, \dots, x_{s+t} .

Enforcing (s, t) -consistency may require processing (almost) all assignments to all combinations of s variables and all assignments to all combinations of t additional variables. As s and t become large, enforcing (s, t) -consistency usually results in a large average running time and (generally) requires $\mathcal{O}(n^s d^t)$ space for recording nogoods. The following relaxes (s, t) -consistency by substituting *some* for the second occurrence of *any* in the definition of (s, t) -consistency.

Definition 2 (Weak (s, t) -Consistency). A CSP with variables X is weakly (s, t) -consistent if for any variables $S = \{x_1, \dots, x_s\} \subseteq X$ and some variables $\{x_{s+1}, \dots, x_{s+t}\} \subseteq X \setminus S$, any consistent s -assignment to x_1, \dots, x_s is extendable to some consistent $(s+t)$ -assignment to x_1, \dots, x_{s+t} .

A CSP is *inverse k -consistent* [6] if it is $(1, k-1)$ -consistent. Inverse consistency does not require additional constraints and can be enforced by shaving. A CSP is *inverse consistent* if it is inverse n -consistent. It is *weakly inverse k -consistent* if it is weakly $(1, k-1)$ -consistent. Then (weak) inverse K -consistency implies (weak) inverse k -consistency if $K \geq k$.

A CSP is called *k-consistent* if it is $(k-1, 1)$ -consistent and it is called *arc consistent* if it is 2-consistent. The following formally defines singleton arc consistency.

Definition 3 (Singleton Arc Consistency). A CSP, \mathcal{P} , with variables X is called *singleton arc consistent* (SAC) if

$$(\forall x_1 \in X)(\forall v_1 \in D(x_1))(ac(\mathcal{P}|_{\{x_1=v_1\}}) \neq \perp).$$

The following seems a natural generalisation of SAC.

Definition 4 (k -Singleton Arc Consistency). A CSP \mathcal{P} with variables X is called *k-singleton arc consistent* if

$$\begin{aligned} & (\forall x_1 \in X)(\forall v_1 \in D(x_1))(\forall \{x_2, \dots, x_k\} \subseteq X \setminus \{x_1\}) \\ & (\exists \{v_2, \dots, v_k\} \in D(x_2) \times \dots \times D(x_k)) \\ & (ac(\mathcal{P}|_{\{x_1=v_1, \dots, x_k=v_k\}}) \neq \perp). \end{aligned}$$

We define *weak k-singleton arc consistency* (weak k -SAC) by substituting an existential quantifier for the last universal quantifier in Definition 4. Then weak 1-SAC is equivalent to 1-SAC and SAC, and (weak) K -SAC implies (weak) inverse k -consistency and (weak) k -SAC if $K \geq k$.

4 A Weak k -SAC Algorithm

This section presents our algorithms, which use greedy search to establish a weakly k -SAC equivalent of the input CSP \mathcal{P} . They exploit that $ac(\mathcal{P}|_{\{x_1=v_1, \dots, x_l=v_l\}}) \neq \perp$ implies $ac(\mathcal{P}|_{\{x_{i_1}=v_{i_1}, \dots, x_{i_k}=v_{i_k}\}}) \neq \perp$, for any $\{x_{i_1}, \dots, x_{i_k}\} \subseteq \{x_1, \dots, x_l\}$. This generalises the SAC algorithms in [8], which use greedy search, exploiting that $ac(\mathcal{P}|_{\{x_1=v_1, \dots, x_l=v_l\}}) \neq \perp$ implies $ac(\mathcal{P}|_{\{x_{i_1}=v_{i_1}\}}) \neq \perp$, for any $\{x_{i_1}\} \subseteq \{x_1, \dots, x_l\}$.

The algorithms are depicted in Figure 1. The outer **while** loop of *wksac* is executed while there are changes, while there is no inconsistency, and while no lucky solution has been found. (Removing the statement *solved := true* in *extendable* prohibits finding lucky solutions.) The second outer **while** loop selects the next variable, x . The inner-most **while** loop removes singleton inconsistent values. For any remaining value, v , *wksac* tries to extend the assignment $x = v$, to some K -SAC assignment, for some $K \geq k$ by executing *extendable*($k-1, wksac, solved, X \setminus \{x\}$). If this fails then v is removed. The underlying arc consistency algorithm is *ac*.

Like SAC3 and SAC3+ [8] *extendable* also searches for assignments of length greater than k . This allows the discovery of *lucky solutions* [8] as part of consistency processing. If it finds a k -SAC assignment then *extendable* allows no digressions when trying to find an extending K -SAC assignment, for $K > k$. This can be generalised to more digressions.

The space complexity of *wksac* is equal to the space complexity of MAC plus the space required for storing the array *wksac*[\cdot, \cdot]. The space complexity of *wksac*[\cdot, \cdot] is $\mathcal{O}(nd)$, which cannot exceed the space complexity of MAC. Therefore, the space complexity of *wksac* is equal to the space complexity of MAC. The outer loop of *wksac* is executed $\mathcal{O}(nd)$ times. For

each of the $\mathcal{O}(nd)$ values, finding an extending k -SAC assignment takes $\mathcal{O}(d^{k-1}T)$ time, where T is the time complexity of ac . For each k -SAC assignment it takes $\mathcal{O}((n-k)T)$ time for trying to find a lucky solution. Therefore, $wksac$'s time complexity is $\mathcal{O}(n^2d^{k+1}T + (n-k)n^2d^2T)$.

Termination and correctness proofs are straightforward. The following two propositions provide the basis for a correctness proof. Proofs are omitted due to space restrictions.

Proposition 1. *If $extendable(k-1, wksac, solved, X \setminus \{x\})$ succeeds then the assignment $x = v$ extends to a K -SAC assignment, for some $K \geq k$. Otherwise $x = v$ is inconsistent.*

Proposition 2. *If $wksac(k, X)$ succeeds then it computes a solution or some weakly k -SAC equivalent of the input CSP. If it fails then the input CSP is unsatisfiable.*

```

function wksac(in k, in X) do
  local variables consistent, change, solved;
  consistent := ac(); change := true; solved := false;
  while consistent and change and ~solved do
    foreach value v in the domain of each variable x do
      wksac[x, v] := false;
    od;
    change := false; vars := X;
    while consistent and ~change and ~solved and vars ≠ ∅ do
      Select and remove any variable x from vars;
      vals := { v ∈ D(x) : ~wksac[x, v] };
      while vals ≠ ∅ and consistent and ~change do
        Select and remove any v from vals;
        assign v to x;
        if ac() and extendable(k-1, wksac, solved, X \ {x})
          undo ac(); unassign v; wksac[x, v] := true;
        else
          remove v from D(x);
          change := true; undo ac(); unassign v; consistent := ac();
        fi;
      od;
    od;
    return consistent;
  od;

function extendable(in k, in/out wksac, in/out solved, in X) do
  local variables consistent, extendable, values;
  if X = ∅
    solved := true; /* Remove line if not used for solving. */
    return true;
  else
    select any x from X;
    values := D(x);
    extendable := false;
    while ~extendable and values ≠ ∅ do
      select and remove any v from values;
      assign v to x;
      if ac() and extendable(k-1, wksac, solved, X \ {x}) then
        wksac[x, v] := true; extendable := true;
      fi;
      undo ac(); unassign v;
    od;
    return extendable or k ≤ 0;
  fi;
od;

```

Figure 1. Algorithms for enforcing weak k -SAC.

The algorithms in Figure 1 do not represent efficient implementations. The following are suggestions for improvement.

The computation time usually improves if $extendable$ first selects variables from the set $vars$ used by $wksac$, and if it first selects $v \in D(x)$ such that $wksac[x, v] = false$.

Finally, note that a good variable ordering is essential. For example, given a CSP consisting of k connected components, it makes no sense to select one variable from each component since *any* assignment to these variables is consistent, not allowing any pruning. The conflict directed variable order dom/w_{deg} [3] is good for our algorithms. This heuristic uses the current degrees and the numbers of previously failed revisions, selecting a variable that quickly leads to a dead-end [3].

Remember that $k = 1$. If $extendable$ has not been called yet then a dead-end immediately proves the assignment $x = v$ inconsistent. Otherwise, it immediately proves $x = v$ weakly K -SAC, for some $K \geq k$. Ties are broken lexically. Values for x are selected preferring value v such that $wksac[x, v] = false$, breaking ties using the order $svoh_2$ [10]. Other variable and value orders usually result in worse results.

For certain CSPs and $K > k > 0$, $wksac$ may prune *more* for k than for K . However, experimental evaluation of the algorithm indicates that this usually is not the case.

5 Experimental Results

To investigate their behaviour, we experimentally compared SAC-1, and $wksac$ for $k \in \{1, 2, 4, 8, 16\}$. We (1) investigate their shaving capabilities for problems known from the literature, (2) investigate their behaviour for random problems, and (3) investigate their use as a preprocessor for MAC [12].

All algorithms were implemented in C. They were run on a Linux 2.8GHz PC, having 500Mb of RAM. The underlying arc consistency algorithm is AC-3. Some authors prefer optimal arc consistency algorithms, but we feel that AC-3 is a good general purpose algorithm. For example, the best solvers in the binary and overall categories of the First International CSP Solver Competition are based on AC-3 [13].

Shaving Problems from the Literature The algorithms have been applied to known problems, including forced random binary problems `frb`, RLFAP, modified RLFAP, attacking prime queen problems `qa1`, and job-shop instances `enddr1-10-by-5-10` and `enddr2-10-by-5-2` (they are called `js-1` and `js-2` in [8]). All problems are described in [2] and may be downloaded from <http://cpai.ucc.ie/>.

Table 1 lists the main results for the first experiment. It lists the problem instances, and for each instance: the number of variables, the number of values, the number of removed values, and the time this took for SAC-1 and $wksac$ for $k \in \{1, 2, 4, 8, 16\}$. The satisfiable instances are indicated by a + in the column `sat`. An i in the column `del` indicates that the CSP has been made and proved inverse consistent. The column `min` (`max`) lists the minimum (maximum) cardinalities of sets of lucky solutions, which were found in the process of enforcing weak 1-SAC. These sets are found when there are no more constraints among the future variables, in which case the number of solutions is equal to the product of the domain sizes. The column `count` lists the total number of such solutions. Due to the number of sets of lucky solutions and their size, it was impossible, for some problem classes, to compute the actual number of lucky solutions, in which case the entry for column `count` has a question mark. [8] also report the finding of lucky solutions. [8] report 0 lucky solutions for `qa-5`, `qa-6`, 1 for `scen5` and `enddr2-10-by-5-2`, 4 for `enddr1-10-by-5-10`, 10 for `graph14`, and 16 for `scen2`, which is less than the numbers reported here. Perhaps these differences are caused by differences in variable and value ordering.

Many values in the job-shop problems are inverse consistent. At the First International CSP Solver Competition they were difficult to solve by MAC [13]. This may explain why it is difficult to enforce higher level of k -SAC using search: for $k \in \{8, 16\}$ it takes too much time. For the attacking prime

queen problems *wksac* is removing more values as k increases, but for $k = 16$ it needs too much time.

For these structured problems the new algorithms are about as efficient as SAC-1 for $k = 1$, if not better. All unsatisfiable modified *rlfap* instances (the unsatisfiable unmodified instances are proved inconsistent by arc consistency) are proved inconsistent by *wksac* for $k \geq 8$, whereas SAC-1 fails to prove some of these instances inconsistent. Note that instance **scen11-f1** is very difficult and, to the best of our knowledge, has not been classified; days of MAC search could not solve it. However, enforcing weak 8-SAC proves it inconsistent within an hour. Finally, some satisfiable problems (they are not all listed in Table 1) are made and proved inverse consistent within a few seconds. Here a problem is proved inverse consistent if all values participate to some lucky solution. For example, **scen2** is proved to be already inverse consistent, **graph2**, **scen3**, **scen4**, and **scen5** are made and proved inverse consistent by making them weak k -SAC ($k \geq 1$), and all fifteen instances from the classes **frb-30-15**, **frb-35-17**, and **frb-40-19** are made and proved inverse consistent by making them weakly k -SAC for $k = 8$ or $k = 16$.

Shaving Random Problems We now study the behaviour of the algorithms for random model B problems [7]. A model B class is typically denoted $\langle n, d, D, T \rangle$, where n is the number of variables, d is the uniform domain size, D is the density, and T is the uniform tightness. Results are presented for the same class of problems as presented in [1; 8]. For each tightness $t = 0.05 i$, $2 \leq i \leq 18$, the average shaving time is over 50 random instances from $\langle 100, 20, 0.05, t \rangle$.

Figure 3 does not depict all data. For $T \leq 0.50$ all algorithms remove less than 0.06, and for $T \geq 0.8$ they remove about 1989.6 values on average. Figure 3 confirms that SAC and weak 1-SAC are equivalent. Comparing SAC-1 and **w1sac** in Figure 2, **w1sac** is better in time when T is small and large. However, near the SAC complexity peak SAC-1 is about three times quicker than **w1sac**. The majority of the problems in that region are unsatisfiable and most values are SAC. Typically, SAC-1 will find that a value is SAC and stop. The extra work put in by **w1sac** in trying to find a lucky solution will fail at a shallow level. This work cannot do pruning and does not lead to many values that were not known to be SAC.

The weak k -SAC algorithms only behave differently near the SAC phase transition. The higher k the more values are removed. At $T = 0.7$, the nearest point to the SAC phase tran-

sition, **weak16sac** outperforms SAC-1 marginally in time and significantly in the number of removed values. At $T = 0.65$ **w16sac** removes about 114.2 values on average, whereas all other algorithms remove between 2 and 3 values on average. However, **w16sac** spends (much) more time. Clearly the algorithms cannot be compared in time at $T = 0.65$.

Search We now compare the algorithms as a preprocessor for MAC. The first solver is MAC, denoted **mac**, the second is **sac+mac**, which is SAC-1 followed by MAC, and the third and fourth solvers are **w1sac+mac** and **w8sac+mac**, i.e. *wksac* for enforcing weak k -singleton arc consistency followed by MAC, for $k \in \{1, 8\}$. All solvers used the variable ordering *dom/w_{deg}* [3] and the value ordering *svoh₂* [10], breaking ties lexicically. The support counters [10] for the value ordering are initialised after establishing initial arc consistency. Should *wksac* prune more values, then they are also initialised before search.

Table 2 lists the results. The column **sat** denotes the satisfiability of the instances. A + and an L indicates satisfiable instances, the L indicating the discovery of lucky solutions. For all problems, if lucky solutions are found by **w1sac+mac** then they are also found by **w8sac+mac** and vice versa.

Overall, and these results are typical for these problems, **sac+mac** performs worse in time and checks than **wksac+mac**. **Mac** performs better than **sac+mac** for some instances, especially some **graph** instances, otherwise the two algorithms are about equally efficient. Compared to **w1sac+mac** and **w8sac+mac** it is clear that **sac+mac** is worse in time and checks. Compared to **mac** the results are not so clear but overall **w1sac+mac** and **w8sac+mac** are better. The only exceptions are for “easy” problems, for which **mac** is easy. For these problems there is no need to establish more consistency before search and this results in slightly more solution time. We have also observed this for unsatisfiable problem instances where **sac** alone is sufficient to detect the inconsistency. For example, for the queens-knight problems **qk1** [2] SAC-1 is more efficient than the weak SAC algorithms. However, these problems are relatively easy and do not require much time, even with *wksac*. For the problems that are difficult for **mac** and **sac+mac** the two need a considerable amount of time more than *wksac*.

It is recalled that it turned out impossible to compute the weak k -SAC equivalent of the job-shop instances for $k = 8$ and $k = 16$. However, when the algorithms are used to find solutions, they perform much better and find lucky solutions. Lucky solutions are also found for all satisfiable **rlfap**, and all

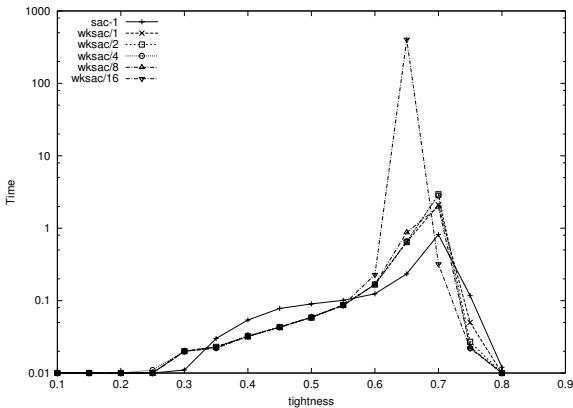

Figure 2. Shaving time for random B class $\langle 100, 20, 0.05, t \rangle$ for different algorithms, where $0.1 \leq T \leq 0.9$

satisfiable modified **r1fap** instances, including instances from these classes for which no results are presented in Table 1. It is interesting to note that if lucky solutions are found, it takes the same amount of checks for $k = 8$ and $k = 16$. This may indicate that both algorithms carry out exactly the same amount of work, which seems possible only if, in addition, they make the same decisions about value and variable ordering. If this is true, then it is probably because these problems are loose, making any arc consistent 1-assignment, easily extendable to an arc consistent k -assignment for $k \geq 8$, which makes it impossible to prune more for **w8sac** than for **w1sac**.

6 Conclusions

This paper introduces *k-singleton consistency* (*k*-SAC) and weak *k*-SAC, which are generalisations of SAC and inverse *k*-consistency. Weak *k*-SAC is equal to SAC if $k = 1$ but stronger if $k > 1$. A weak *k*-SAC algorithm is presented, which uses greedy search. At the SAC phase transition, it removes many more values than SAC-1 for $k = 16$ using less time. Like SAC-3 and SAC-3+ the algorithm sometimes finds lucky solutions. If it does it usually finds many. SAC cannot solve unsatisfiable instances which can be made SAC. However, by enforcing higher degrees of weak SAC some of these instances can be proved inconsistent within a reasonable time. When used as a preprocessor for MAC the algorithm compares favourably to existing algorithms. By increasing the level of weak SAC we are able to solve difficult problems, including **scen11-f1**, which had not been solved before.

Symmetry Breaking using Value Precedence

Toby Walsh¹

Abstract. We present a comprehensive study of the use of value precedence constraints to break value symmetry. We first give a simple encoding of value precedence into ternary constraints that is both efficient and effective at breaking symmetry. We then extend value precedence to deal with a number of generalizations like wreath value and partial interchangeability. We also show that value precedence is closely related to lexicographical ordering. Finally, we consider the interaction between value precedence and symmetry breaking constraints for variable symmetries.

1 INTRODUCTION

Symmetry is an important aspect of many search problems. Symmetry occurs naturally in many problems (e.g. if we have two identical machines to schedule, or two identical jobs to process). Symmetry can also be introduced when we model a problem (e.g. if we name the elements in a set, we introduce the possibility of permuting their order). We must deal with symmetry or we will waste much time visiting symmetric solutions, as well as parts of the search tree which are symmetric to already visited parts. One simple but highly effective mechanism to deal with symmetry is to add constraints which eliminate symmetric solutions [3].

Two common types of symmetry are variable symmetries (which act just on variables), and value symmetries (which act just on values). With variable symmetries, we have a number of well understood symmetry breaking constraints. For example, many problems can be modelled using matrices of decision variables, in which the rows and columns of the matrix are symmetric and can be freely permuted. We can break such symmetry by lexicographically ordering the rows and columns [4]. Efficient propagators have therefore been developed for such ordering constraints [5, 2].

Value symmetries are also common. However, symmetry breaking for value symmetry is less well understood. In this paper, we study a common type of value symmetry where the values for variables are interchangeable. For example, if we assign orders to machines and two orders are identical, we can swap them in any schedule. We show here how to deal with such symmetry. In particular, we give a simple encoding that breaks all the symmetry introduced by interchangeable values. We also show how this is closely related to the lexicographical ordering constraint.

2 BACKGROUND

A constraint satisfaction problem consists of a set of variables, each with a domain of values, and a set of constraints specifying allowed combinations of values for given subsets of variables. A solution is an assignment of values to variables satisfying the constraints. Finite

domain variables take values which are integers, or tuples of integers taken from some given finite set. Set variables takes values which are sets of integers. A set variable S has a lower bound $lb(S)$ for its definite elements and an upper bound $ub(S)$ for its definite and potential elements.

Constraint solvers typically explore partial assignments enforcing a local consistency property. We consider the two most common local consistencies: arc consistency and bound consistency. Given a constraint C , a *bound support* on C is an assignment of a value to each finite domain variable between its minimum and maximum and of a set to each set variable between its lower and upper bounds which satisfies C . A constraint C is *bound consistent (BC)* iff for each finite domain variable, its minimum and maximum values belong to a bound support, and for each set variable S , the values in $ub(S)$ belong to S in at least one bound support and the values in $lb(S)$ belong to S in all bound supports. Given a constraint C on finite domain variables, a *support* is assignment to each variable of a value in its domain which satisfies C . A constraint C on finite domains variables is *generalized arc consistent (GAC)* iff for each variable, every value in its domain belongs to a support.

A *variable symmetry* is a bijection on variables that preserves solutions. For example, in a model of the rehearsal problem (prob039 in CSPLib) in which we assign musical pieces to time slots, we can always invert any schedule. This is a reflection symmetry on the variables. A *value symmetry* is a bijection on values that preserves solutions. For example, in our model of the rehearsal problem, two pieces requiring the same musicians are interchangeable and can be freely permuted in any solution. Note that some authors call these *global* value symmetries as they act globally on values [12]. Finally, a pair of values are *interchangeable* if we can swap them in any solution.

3 VALUE PRECEDENCE

We can break all symmetry between a pair of interchangeable values using a global value precedence constraint [9].

$$\text{PRECEDENCE}([v_j, v_k], [X_1, \dots, X_n])$$

This holds iff $\min\{i \mid X_i = v_j \vee i = n+1\} < \min\{i \mid X_i = v_k \vee i = n+2\}$. Law and Lee give a specialized algorithm for enforcing GAC on such a global constraint [9]. We show here that this is unnecessary. We can encode the constraint efficiently and effectively into a simple sequence of ternary constraints.

We introduce a sequence of 0/1 variables, where $B_i = 1$ if $X_l = v_j$ for some $l < i$. Value precedence prevents us assigning $X_i = v_k$ unless $B_i = 1$. To ensure this, we post the sequence of ternary constraints, $C(X_i, B_i, B_{i+1})$ for $1 \leq i \leq n$ which hold iff $X_i = v_j$ implies $B_{i+1} = 1$, $X_i \neq v_j$ implies $B_i = B_{i+1}$, and $B_i = 0$ implies $X_i \neq v_k$. We also set $B_1 = 0$. We assume that we can enforce GAC on each individual ternary constraint C using a table constraint

¹ National ICT Australia and University of New South Wales, email: tw@cse.unsw.edu.au

or using primitives like implication and equality constraints. As the constraint graph is Berge-acyclic, enforcing GAC on the ternary constraints achieves GAC on $\text{PRECEDENCE}([v_j, v_k], [X_1, \dots, X_n])$. Since C is functional in its first two arguments and there are $O(n)$ ternary constraints, this takes $O(nd)$ time where d is the maximum domain size of the X_i . This is therefore optimal (as was Law and Lee's specialized algorithm). The incremental behavior is also good. Law and Lee's algorithm maintains three pointers, α , β and γ to save re-traversing the vector. A constraint engine will also perform well incrementally on this encoding provided it ignores constraints once they are entailed. Our experimental results support this claim.

4 MULTIPLE VALUE INTERCHANGEABILITY

Many problems involve *multiple* interchangeable values. For example, in a finite domain model of the social golfer problem (prob010 in CSPLib) in which we assign groups to golfers in each week, all values are interchangeable. To break all such symmetry, Law and Lee [9] propose the global constraint:

$$\text{PRECEDENCE}([v_1, \dots, v_m], [X_1, \dots, X_n])$$

This holds iff $\min\{i \mid X_i = v_i \vee i = n+1\} < \min\{i \mid X_i = v_j \vee i = n+2\}$ for all $1 \leq i < j < m$. To propagate this constraint, Law and Lee suggest decomposing it into pairwise precedence constraints of the form $\text{PRECEDENCE}([v_i, v_j], [X_1, \dots, X_n])$ for all $i < j$ [9]. Law has conjectured (page 77 of [8]), that such a decomposition does not hinder GAC propagation. We prove this is not the case.

Theorem 1 *Enforcing GAC on $\text{PRECEDENCE}([v_1, \dots, v_m], [X_1, \dots, X_n])$ is strictly stronger than enforcing GAC on $\text{PRECEDENCE}([v_i, v_j], [X_1, \dots, X_n])$ for all $1 \leq i < j \leq m$.*

Proof: Clearly it is at least as strong. To show strictness, consider $\text{PRECEDENCE}([1, 2, 3, 4], [X_1, X_2, X_3, X_4])$ with $X_1 \in \{1\}$, $X_2 \in \{1, 2\}$, $X_3 \in \{1, 3\}$, and $X_4 \in \{3, 4\}$. Then enforcing GAC on $\text{PRECEDENCE}([1, 2, 3, 4], [X_1, X_2, X_3, X_4])$ prunes 1 from the domain of X_2 . However, $\text{PRECEDENCE}([i, j], [X_1, X_2, X_3, X_4])$ is GAC for all $1 \leq i < j \leq 4$. \diamond

We propose instead a simple encoding of $\text{PRECEDENCE}([v_1, \dots, v_m], [X_1, \dots, X_n])$ into a sequence of ternary constraints. We introduce $n + 1$ finite domain variables, where Y_i records the greatest index of the values used so far in the precedence order. We then post a sequence of ternary constraints, $D(X_i, Y_i, Y_{i+1})$ for $1 \leq i \leq n$ which hold iff $X_i \neq v_j$ for any $j > Y_i + 1$, $Y_{i+1} = Y_i + 1$ if $X_i = v_{1+Y_i}$ and $Y_{i+1} = Y_i$ otherwise. We set $Y_1 = 0$. Again, we achieve GAC on the global constraint simply by enforcing GAC on the individual ternary constraints. This takes $O(nmd)$ time. By comparison, enforcing GAC on the decomposition into precedence constraints between all pairs of interchangeable values takes $O(nm^2d)$ time.

5 PARTIAL INTERCHANGEABILITY

We may have a partition on the values, and values within each partition are interchangeable. For example, in the model of the rehearsal problem in which we assign musical pieces to time slots, we can partition the musical pieces into those requiring the same musicians. Suppose the values are divided into s equivalence classes, then we can break all symmetry with the global constraint:

$$\text{PRECEDENCE}([v_{1,1}, \dots, v_{1,m_1}], \dots, [v_{s,1}, \dots, v_{s,m_s}], [X_1, \dots, X_n])$$

This holds iff $\min\{i \mid X_i = v_{j,k} \vee i = n+1\} < \min\{i \mid X_i = v_{j,k+1} \vee i = n+2\}$ for all $1 \leq j \leq s$ and $1 \leq k < m_j$. This global constraint can be decomposed into s precedence constraints, one for each equivalence class. However, such decomposition hinders propagation.

Theorem 2 *Enforcing GAC on $\text{PRECEDENCE}([v_{1,1}, \dots, v_{1,m_1}], \dots, [v_{s,1}, \dots, v_{s,m_s}], [X_1, \dots, X_n])$ is strictly stronger than enforcing GAC on $\text{PRECEDENCE}([v_{i,1}, \dots, v_{i,m_i}], [X_1, \dots, X_n])$ for $1 \leq i \leq s$.*

Proof: Clearly it is at least as strong. To show strictness, consider $\text{PRECEDENCE}([[1, 2, 3], [4, 5, 6]], [X_1, \dots, X_5])$ with $X_1, X_2, X_3 \in \{1, 2, 3, 4, 5, 6\}$, $X_4 \in \{3\}$ and $X_5 \in \{6\}$. Then $\text{PRECEDENCE}([[1, 2, 3], [4, 5, 6]], [X_1, \dots, X_5])$ is unsatisfiable. However, $\text{PRECEDENCE}([1, 2, 3], [X_1, \dots, X_5])$ and $\text{PRECEDENCE}([4, 5, 6], [X_1, \dots, X_5])$ are both GAC. \diamond

Decomposition is again unnecessary as we can encode the global constraint into a sequence of ternary constraints. The idea is to keep a tuple recording the greatest value used so far within each equivalence class as we slide down the sequence. We introduce $n + 1$ new finite-domain variables, Y_i whose values are s -tuples. We write $Y_i[j]$ to indicate the j th component of the tuple. We then post a sequence of ternary constraints, $E(X_i, Y_i, Y_{i+1})$ for $1 \leq i \leq n$ which hold iff for all $1 \leq j \leq s$ we have $X_i \neq v_{j,k}$ for all $k > Y_i[j] + 1$, $Y_{i+1}[j] = Y_i[j] + 1$ if $X_i = v_{j,Y_i[j]+1}$ and $Y_{i+1}[j] = Y_i[j]$ otherwise. The value taken by $Y_{i+1}[j]$ is the largest index within the j th equivalence class used up to X_i . Since E is functional in its third argument, this takes $O(nds)$ time where $e = \prod_{i \leq s} m_i$. Note that if all values are interchangeable with each other, then $s = 1$ and $m_1 = m$, and enforcing GAC takes $O(nmd)$ time. Similarly, for just one pair of interchangeable values, $s = n - 1$, $m_1 = 2$ and $m_i = 1$ for $i > 1$, and enforcing GAC takes $O(nd)$ time.

6 WREATH VALUE INTERCHANGEABILITY

Wreath value interchangeability [13] is a common type of symmetry in problems where variables are assigned a pair of values from $D_1 \times D_2$, values in D_1 are fully interchangeable, and for a fixed value in D_1 , values in D_2 are interchangeable as well. For example, if we are scheduling a conference, the days of the week might be interchangeable, and given a particular day, the meeting rooms might then be interchangeable. For simplicity, we assume the same precedence ordering is used for the values in D_2 for every fixed value in D_1 . However, we can relax this assumption without difficulty.

We can break all the symmetry of wreath-value interchangeability with the global constraint:

$$\text{PRECEDENCE}([u_1, \dots, u_m, [v_1, \dots, v_p]], [X_1, \dots, X_n])$$

This holds iff $\min\{i \mid X_i[1] = u_j \vee i = n+1\} < \min\{i \mid X_i[1] = u_{j+1} \vee i = n+2\}$ for all $1 \leq j < m$, and $\min\{i \mid X_i = \langle u_j, v_k \rangle \vee i = n+1\} < \min\{i \mid X_i = \langle u_j, v_{k+1} \rangle \vee i = n+2\}$ for all $1 \leq j \leq m$ and $1 \leq k < p$. This can be decomposed into precedence constraints of the form $\text{PRECEDENCE}([\langle u_i, v_j \rangle, \langle u_k, v_l \rangle], [X_1, \dots, X_n])$, but this hinders propagation.

Theorem 3 *Enforcing GAC on $\text{PRECEDENCE}([u_1, \dots, u_m, [v_1, \dots, v_p]], [X_1, \dots, X_n])$ is strictly stronger than enforcing GAC on $\text{PRECEDENCE}([\langle u_i, v_j \rangle, \langle u_k, v_l \rangle], [X_1, \dots, X_n])$ for all $1 \leq i < k \leq m$, and for all $i = j$, $1 \leq i, j \leq m$, $1 \leq k < l \leq p$.*

Proof: Clearly it is at least as strong. To show strictness, consider $\text{PRECEDENCE}([1, 2, [3, 4]], [X_1, X_2, X_3, X_4])$

with $X_1 \in \{(1, 3)\}$, $X_2 \in \{(1, 3), (1, 4)\}$, $X_3 \in \{(1, 3), (2, 3)\}$, $X_4 \in \{(2, 3), (2, 4)\}$. Then enforcing GAC on $\text{PRECEDENCE}([1, 2, [3, 4]], [X_1, X_2, X_3, X_4])$ prunes $(1, 3)$ from X_2 . However, $\text{PRECEDENCE}([\langle u, v \rangle, \langle w, z \rangle], [X_1, X_2, X_3, X_4])$ is GAC for all $1 \leq u < w \leq 2$ and $3 \leq v, z \leq 4$, and for all $u = w$, $1 \leq u, w \leq 2$, $3 \leq v < z \leq 4$. \diamond

We again can propagate such a precedence constraint using a simple encoding into ternary constraints. We have a finite domain variable which records the greatest pair used so far down the sequence. We can then encode $\text{PRECEDENCE}([u_1, \dots, u_m, [v_1, \dots, v_p]], [X_1, \dots, X_n])$ by means of a sequence of ternary constraints, $F(X_i, Y_i, Y_{i+1})$ for $1 \leq i \leq n$ which hold iff $X_i[1] \neq u_j$ for all $j > Y_i[1] + 1$, if $X_i[1] = u_{Y_i[1]}$ then $X_i[2] \neq v_j$ for all $j > Y_i[2] + 1$, $Y_{i+1} = \langle Y_i[1] + 1, 1 \rangle$ if $X_i[1] = u_{Y_i[1]} + 1$ and $Y_i[2] = m$, $Y_{i+1} = \langle Y_i[1], Y_i[2] + 1 \rangle$ if $X_i = \langle u_{Y_i[1]}, v_{Y_i[2]} + 1 \rangle$, and $Y_{i+1} = Y_i$ otherwise. Enforcing GAC using this encoding takes $O(ndmp)$ time. The extension to wreath value partial interchangeability and to wreath value interchangeability over k -tuples where $k > 2$ are both straight forwards.

7 MAPPING INTO VARIABLE SYMMETRY

An alternative way to deal with value symmetry is to convert it into variable symmetry [4, 10]. We introduce a matrix of 0/1 variables where $B_{ij} = 1$ iff $X_i = j$. We assume the columns of this 0/1 matrix represent the interchangeable values, and the rows represent the original finite domain variables. We now prove that value precedence is equivalent to lexicographically ordering the columns of this 0/1 matrix, but that channelling into 0/1 variables hinders propagation.

Theorem 4 $\text{PRECEDENCE}([v_1, \dots, v_m], [X_1, \dots, X_n])$ is equivalent to $X_i = v_j$ iff $B_{i,j} = 1$ for $0 < j \leq m$ and $0 < i \leq n$, and $[B_{1,j}, \dots, B_{n,j}] \geq_{\text{lex}} [B_{1,j+1}, \dots, B_{n,j+1}]$ for $0 < j < m$.

Proof: By induction on n . In the base case, $n = 1$, $X_1 = v_1$, $B_{1,1} = 1$ and $B_{1,j} = 0$ for $1 < j \leq m$. In the step case, suppose the value precedence constraint holds for a ground assignment in which v_k is the largest value used so far. Consider any extension with $X_{n+1} = v_l$. There are two cases. In the first, $l = k + 1$. The l th column is thus $[0, \dots, 0, 1]$. This is lexicographically less than all previous columns. In the other case, $l \leq k$. Adding a new row with a single 1 in the l th column does not change the ordering between the $l - 1$ th, l th and $l + 1$ th columns. The proof reverses in a similar way. \diamond

We could thus impose value precedence by channelling into an 0/1 matrix model and using lexicographical ordering constraints [4]. However, this decomposition hinders propagation as the lexicographical ordering constraints do not exploit the fact that the 0/1 matrix has a single non-zero entry per row. Indeed, even if we add this implied constraint to the decomposition, propagation is hindered. It is thus worth developing a specialized propagator for the global PRECEDENCE constraint.

Theorem 5 GAC on $\text{PRECEDENCE}([v_1, \dots, v_m], [X_1, \dots, X_n])$ is strictly stronger than GAC on $X_i = v_j$ iff $B_{i,j} = 1$ for $0 < j \leq m$ and $0 < i \leq n$, GAC on $[B_{1,j}, \dots, B_{n,j}] \geq_{\text{lex}} [B_{1,j+1}, \dots, B_{n,j+1}]$ for $0 < j < m$, and GAC on $\sum_{j=1}^m B_{i,j} = 1$ for $0 < i \leq n$.

Proof: Clearly it is as strong. To show strictness, consider $X_1 = 1$, $X_2 \in \{1, 2, 3\}$, $X_3 = 3$, $B_{1,1} = B_{3,3} = 1$, $B_{1,2} = B_{1,3} = B_{3,1} = B_{3,2} = 0$, and $B_{2,1}, B_{2,2}, B_{2,3} \in \{0, 1\}$. Then the decomposition is

GAC. However, enforcing GAC on the value precedence constraint will prune 1 and 3 from X_2 . \diamond

It is not hard to show that partial value interchangeability corresponds to partial column symmetry in the corresponding 0/1 matrix model. As with full interchangeability, we obtain more pruning with a specialized propagator than with lexicographical ordering constraints.

8 SURJECTION PROBLEMS

A surjection problem is one in which each value is used at least once. Puget converts value symmetries on surjection problems into variable symmetries by channelling into dual variables which record the first index using a value [11]. For interchangeable values, this gives $O(nm)$ binary symmetry breaking constraints: $X_i = j \rightarrow Z_j \leq i$, $Z_j = i \rightarrow X_i = j$, and $Z_k < Z_{k+1}$ for all $1 \leq i \leq n$, $1 \leq j \leq m$ and $1 \leq k < m$. Any problem can be made into a surjection by introducing m additional new variables to ensure each value is used once. In this case, Puget's symmetry breaking constraints ensure value precedence. However, they may not prune all possible values. Consider $X_1 = 1$, $X_2 \in \{1, 2\}$, $X_3 \in \{1, 3\}$, $X_4 \in \{3, 4\}$, $X_5 = 2$, $X_6 = 3$, $X_7 = 4$, $Z_1 = 1$, $Z_2 \in \{2, 5\}$, $Z_3 \in \{3, 4, 6\}$, and $Z_4 \in \{4, 7\}$. Then all the binary implications are AC. However, enforcing GAC on $\text{PRECEDENCE}([1, 2, 3, 4], [X_1, \dots, X_7])$ will prune 1 from X_2 .

9 SET VARIABLES

We also meet interchangeable values in problems involving set variables. For example, in a set variable model of the social golfers problem in which we assign a set of golfers to the groups in each week, all values are interchangeable. We can break all such symmetry with value precedence constraints. For set variables, $\text{PRECEDENCE}([v_1, \dots, v_m], [S_1, \dots, S_n])$ holds iff $\min\{i \mid (v_j \in S_i \wedge v_k \notin S_i) \vee i = n+1\} < \min\{i \mid (v_k \in S_i \wedge v_j \notin S_i) \vee i = n+2\}$ for all $1 \leq j < k \leq m$ [9]. That is, the first time we distinguish between v_j and v_k (because both values don't occur in a given set variable), we have v_j occurring and not v_k . This breaks all symmetry as we cannot now swap v_j for v_k . Law and Lee again give a specialized propagator for enforcing BC on $\text{PRECEDENCE}([v_j, v_k], [S_1, \dots, S_n])$. We prove here that this decomposition hinders propagation.

Theorem 6 Enforcing BC on $\text{PRECEDENCE}([v_1, \dots, v_m], [S_1, \dots, S_n])$ is strictly stronger than enforcing BC on $\text{PRECEDENCE}([v_i, v_j], [S_1, \dots, S_n])$ for all $1 \leq i < j \leq m$.

Proof: Clearly it is at least as strong. To show strictness, consider $\text{PRECEDENCE}([0, 1, 2], [S_1, S_2, S_3, S_4, S_5])$ with $\{\} \subseteq S_1 \subseteq \{0\}$, $\{\} \subseteq S_2 \subseteq \{1\}$, $\{\} \subseteq S_3 \subseteq \{1\}$, $\{\} \subseteq S_4 \subseteq \{0\}$, and $S_5 = \{2\}$. Then enforcing BC on $\text{PRECEDENCE}([0, 1, 2], [S_1, S_2, S_3, S_4, S_5])$ sets S_1 to $\{0\}$. However, $\text{PRECEDENCE}([i, j], [S_1, S_2, S_3, S_4, S_5])$ is BC for all $0 \leq i < j \leq 2$. \diamond

As with finite domain variables, we do need to introduce a new propagator nor to decompose this global constraint. We view each set variable in terms of its characteristic function (a vector of 0/1 variables). This gives us an n by d matrix of 0/1 variables with column symmetry in the d dimension. Unlike the case with finite domain variables, rows can now have any sum. We can break all such column symmetry with a simple lexicographical ordering constraint [4]. If we use the lex chain propagator [2], we achieve BC on the original value precedence constraint in $O(nd)$ time.

In many constraint solvers, set variables also have restrictions on their cardinality. Unfortunately, adding such cardinality information makes value precedence intractable to propagate.

Theorem 7 Enforcing BC on PRECEDENCE([v_1, \dots, v_m], [S_1, \dots, S_n]) where set variables have cardinality bounds is NP-hard.

Proof: We give a reduction from a 1-in-3 SAT problem in N Boolean variables, x_1 to x_N and M positive clauses. We let $n = 2N + M$, $m = 2N$ and $v_i = i$. To encode the truth assignment which satisfies the 1-in-3 SAT problem, we have $S_{2i} = \{2i, 2i+1\}$ and $\{2i\} \subseteq S_{2i+1} \subseteq \{2i, 2i+1\}$ for $1 \leq i \leq N$. S_{2i+1} will be $\{2i\}$ iff x_i is false and $\{2i, 2i+1\}$ otherwise. The remaining M CSP variables represent the M clauses. Suppose the i th clause is $x_j \vee x_k \vee x_l$. We let $S_{2N+i} \subseteq \{2j+1, 2k+1, 2l+1\}$. Finally, we force S_{2N+i} to take two of the values $2j+1, 2k+1, 2l+1$ from its upper bound. Value precedence only permits this if exactly two out of S_{2j}, S_{2k} and S_{2l} take the set value representing “false”. The global value precedence constraint thus has bound support iff the corresponding 1-in-3 SAT problem is satisfiable. Hence, enforcing BC is NP-hard. \diamond

10 VALUE AND VARIABLE SYMMETRY

In many situations, we have both variable and value symmetry. Can we safely combine together symmetry breaking constraints for variable symmetries and value symmetries? Do we break all symmetry?

INTERCHANGEABLE VARIABLES

Suppose that all n variables and m values are interchangeable. We can safely combine a global value precedence constraint (which breaks all the value symmetry) with a simple ordering constraint (which breaks all the variable symmetry). However, this does not break all symmetry. For example, [1, 2, 2] and [1, 1, 2] are symmetric since inverting the first sequence and permuting 1 with 2 gives the second sequence. However, both sequences satisfy the value precedence and ordering constraints. We can break all symmetry with the global constraint INCREASINGSEQ([X_1, \dots, X_n]) which holds iff $X_1 = v_1, X_{i+1} = X_i$ or ($X_i = v_j$ and $X_{i+1} = v_{j+1}$) for all $0 < i < n$, and $|\{i \mid X_i = v_j\}| \leq |\{i \mid X_i = v_{j+1}\}|$ for all $0 < j < m$. That is, the values and the number of occurrences of each value increase monotonically. We can also have the values increasing but the number of occurrences decreasing. One way to propagate this constraint is to consider the corresponding 0/1 matrix model. The INCREASINGSEQ constraint lexicographically orders the rows and columns, as well as ordering the columns by their sums.

Consider, now, (partially) interchangeable set variables taking (partially) interchangeable values. This corresponds to an 0/1 matrix with (partial) row and (partial) column symmetry. Unfortunately, enforcing breaking all row and column symmetry is NP-hard [1]. We cannot expect therefore to break all symmetry when we have interchangeable set variables and interchangeable values. We can break symmetry partially by lexicographical ordering the rows and columns of the corresponding 0/1 matrix.

MATRIX SYMMETRY

Variables may be arranged in a matrix which has row and/or column symmetry [4]. Lexicographical ordering constraints will break such symmetries. Suppose that values are also (partially) interchangeable.

As lexicographical ordering constraints can be combined in any number of dimensions [4], and as value precedence is equivalent to lexicographically ordering the 0/1 model, we can safely combine value precedence and row and column symmetry breaking constraints.

VARIABLE REFLECTION SYMMETRY

Suppose we have a sequence of $2n$ variables with a reflection symmetry. Then we can break all such symmetry with the lexicographical ordering constraint: $[X_1, \dots, X_n] \leq_{\text{lex}} [X_{2n}, \dots, X_{n+1}]$. For an odd length sequence, we just miss out the middle element. If values are also (partially) interchangeable, we can combine such a reflection symmetry breaking constraint with precedence constraints. Whilst these symmetry breaking constraints are compatible, they do not break all symmetry. For example, [1, 2, 1, 1, 2] and [1, 2, 2, 1, 2] are symmetric since inverting the first sequence and permuting 1 with 2 gives the second sequence. However, both sequences satisfy all symmetry breaking constraints.

VARIABLE ROTATION SYMMETRY

Suppose we have a sequence of n variables with a rotation symmetry. That is, if we rotate the sequence, we obtain a symmetric solution. We can break all such symmetry with the constraints: $[X_1, \dots, X_n] \leq_{\text{lex}} [X_i, \dots, X_n, X_1, \dots, X_{i-1}]$ for $1 < i \leq n$. If values are also (partially) interchangeable, then we can combine such symmetry breaking constraints with precedence constraints. Whilst these symmetry breaking constraints are compatible, they do not break all symmetry. For example, [1, 1, 2, 1, 2] and [1, 2, 1, 2, 2] are symmetric since rotating the first sequence by 2 elements and permuting 1 with 2 gives the second sequence. However, both sequences satisfy all symmetry breaking constraints.

11 EXPERIMENTAL RESULTS

To test the efficiency and effectiveness of these encodings of value precedence constraints, we ran a range of experiments. We report results here on Schur numbers (prob015 in CSPLib). This problem was used by Law and Lee in the first experimental study of value precedence [9]. We have observed similar results in other domains like the social golfers problem and Ramsey numbers (prob017 in CSPLib).

The Schur number $S(k)$ is the largest integer n for which the interval $[1, n]$ can be partitioned into k sum-free sets. S is sum-free iff $\forall a, b, c \in S : a \neq b + c$. Schur numbers are related to Ramsey numbers, $R(n)$ through the identity: $S(n) \leq R(n) - 2$. Schur numbers were proposed by the famous German mathematician Isaai Schur in 1918. $S(4)$ was open until 1961 when it was first calculated by computer. $S(3)$ is 13, $S(4)$ is 44, and $160 \leq S(5) \leq 315$. We consider the corresponding decision problem, $S(n, k)$ which asks if the interval $[1, n]$ can be partitioned into k sum-free sets. A simple model of this uses n finite domain variables with k interchangeable values.

Results are given in Table 1. The model *all* uses a single global precedence constraint to break all value symmetry. The model *adjacent* uses the method proposed by Law and Lee in [9] which posts $O(k)$ precedence constraints between adjacent interchangeable values. The model *none* use no precedence constraints. We coded the problem using the finite domain library in SICSTUS 3.12.3, and ran it on an AMD Athlon Dual Core 2.2GHz processor with 1 GB RAM.

The results show the benefits of a global value precedence constraint. With a few interchangeable values, we see the same pruning using *adjacent* as *all*. However, we observe better runtimes with the

problem $S(n, k)$	value symmetry breaking								
	none			adjacent values			all values		
	c	b	t	c	b	t	c	b	t
$S(13, 3)$	126	276	0.02	360	46	0.01	243	46	0.01

$S(15, 6)$									

Table 1. Decision problem associated with Schur numbers: constraints posted, backtracks and times to find all solutions in seconds to $S(n, k)$. Blank entries are for problems not solved within the 10 minute cut off. Results are similar to find first solution.

all model as it encodes into fewer ternary constraints ($O(n)$ versus $O(nk)$). With more interchangeable values (e.g. $k > 4$), we observe both better runtimes and more pruning with the single global precedence constraint in the *all* model. The encoding of this global constraint into ternary constraints appears therefore to be an efficient and an effective mechanism to deal with interchangeable values.

12 RELATED WORK

Whilst there has been much work on symmetry breaking constraints for variable symmetries, there has been less on value symmetries. Law and Lee formally defined value precedence [9]. They also gave specialized propagators for breaking value precedence for a pair of interchangeable values. Gent proposed the first encoding of value precedence constraint [6]. However, it is uncertain what consistency is achieved as the encoding indexes with finite domain variables.

A number of methods that modify the underlying solver have been proposed to deal with value symmetry. Van Hentenryck *et al.* gave a labelling schema for breaking all symmetry with interchangeable values [7]. Inspired by this method, Roney-Dougal *et al.* gave a polynomial method to construct a GE-tree, a search tree without value symmetry [12]. Finally, Sellmann and van Hentenryck gave a $O(nd^{3.5} + n^2d^2)$ dominance detection algorithm for breaking all symmetry when both variables and values are interchangeable [13].

There are a number of earlier (and related) results about the tractability of symmetry breaking. Crawford *et al.* prove that breaking all symmetry in propositional problems is NP-hard in general [3]. Bessiere *et al.* prove that the special case of breaking all row and column symmetry for variables in a matrix model is NP-hard [1]. Sellmann and van Hentenryck prove a closely related result that dominance detection for breaking all symmetry with set variables and values that are interchangeable is NP-hard [13].

13 CONCLUSIONS

We have presented a detailed study of the use of value precedence constraints to break value symmetry. We first gave a simple encoding of value precedence into ternary constraints that is both efficient and effective. We then extended value precedence to deal with a number of generalizations like wreath value and partial interchangeability.

We have also shown how value precedence is closely related to lexicographical ordering. Finally, we considered the interaction between value precedence and other symmetry breaking constraints. There are a number of interesting open questions. For example, how does value precedence interact with variable and value ordering heuristics?

Coordination through Inductive Meaning Negotiation

Alessandro Agostini¹

Abstract. This paper is on negotiation, precisely on the negotiation of *meaning*. We advance and discuss a formal paradigm of coordination and variants thereof, wherein meaning negotiation plays a major role in the process of convergence to a common agreement. Our model engages a kind of pairwise, model-theoretic coordination between knowledge-based agents, eventually able to communicate the *complete & local* meaning of their beliefs by expressions taken from the literals of a common first-order language. We focus on the framework of *inductive inference*—sometimes called “formal learning theory,” and argue that it offers a fresh and rigorous perspective on many current debates in Artificial Intelligence in the context of multiple agents in interaction.

1 INTRODUCTION

Following [6], automated negotiation research can be considered to deal with three broad topics, namely: (a) *Negotiation Protocols*: the set of “rules” that govern the interaction among the agents in play. (b) *Negotiation Objects*: the range of issues, or attributes, over which agreement must be reached. (c) *Agents’ Decision Making Models*: the decision making functionality the agents concerned employ to act in line with the negotiation protocol (a) in order to achieve their objectives (b). References to the literature on negotiation protocols and objects are, for instance, [15, 6, 19, 17] and the references cited there. Either negotiation protocols together with negotiation objects or agents’ decision making models is the dominant concern; it depends on the negotiation scenario. In this paper we are interested in a unique negotiation object: *meaning*.

Meaning negotiation is an inductive process that is shaped by multiple elements and that affects these elements. In the process, negotiating meaning entails both interpretation and action. In fact, what we are going to present is a perspective of meaning negotiation that does not imply a fundamental distinction between interpreting and acting, doing and thinking, or understanding and responding. All are part of the ongoing process of the same ‘game’, and the game always generates new circumstances for further negotiation and further meanings. To illustrate, consider the following coordination scenario [7].

Example 1 “Suppose that Frank and Gertrude have to pass one another in the hall every day. On the first day, Frank thinks Gertrude will move to her right, so he does the same. But Gertrude moves to her left. Frank assumes that her convention is to always move to the left, so he moves to his left. But Gertrude draws the symmetrical inference and moves to her right. Thinking that this has gone far enough, Frank moves to his right again, resolving never to move so that Gertrude can get past. But Gertrude, equally exasperated, makes the same decision! The two die of starvation in the hallway.” (p. 267)

¹ Department of Information and Communication Technology, University of Trento, I-38100, Italy. Email: agostini@dit.unitn.it.

Think of the mutual history of Frank and Gertrude as a sequence of successive attempts or trials at passing *at the semantic level*. This means, intuitively, that a sequence of meanings has been generated from previous actions, and that a sequence of actions has been generated from previous meanings. Since they will continue to have “rites of passage” for the unforeseeable future, it would certainly be nice if they could eventually reach a “state of knowledge” in which they always pass on the first attempt. We refer such state of knowledge as the agents’ “common meaning.” How would we model such stable state of knowledge? Can we characterize games like this for which a common meaning exists?

In this paper, we present a formal framework suitable to investigate questions like these. Characterization results, in particular, are as general as important, interesting and, sometimes, difficult to deserve future investigation within the framework we advance in this paper. A main feature of our framework is that the relation between autonomous agents’ actions and preferences leading to actions is made explicit. For doing this, we use inductive logic, as we will see. More precisely, we propose a new approach to the study of coordination between knowledge-based agents, eventually able to explicitly employ the *local* meaning of their beliefs or actions² to solve their coordination problem. In our approach, meaning negotiation plays an important role, as it seems to be a fruitful way to overcome the problem of the local-to-the-agent association between linguistic forms—that represent either physical actions or “speech acts”—and their meaning. We proceed along the model-theoretic tradition of *inductive inference*—say [7, 10] and the references cited there, that descends from the pioneering studies on inductive inference developed by Solomonoff, Putman, Gold, Blum, among others (see for instance [5] for a survey).

This paper is thus structured as follows. Below is an intuitive game-theoretic picture of our basic model of coordination through meaning negotiation, followed (Section 3) by the formal presentation of our model. In Section 4 we illustrate the behavior of a special kind of “self-centered agents,” and give a result on their coordination competence. We conclude with some related work (Section 5), and a summary together with some future work (Sections 6,7).

2 A GAME FOR MEANING NEGOTIATION

We imagine a game of two “knowledge-based” agents, say Alfonso and Barbara, whose knowledge is represented by a nonempty class of structures, **A** and **B**, that interpret (locally) a common (global) lexicon \mathcal{L} . Alfonso and Barbara have preferences and beliefs in the following sense: Barbara believes a sentence θ of \mathcal{L} if there is a structure in **B** where θ holds. Given two sentences θ, ϑ of \mathcal{L} , Barbara prefers

² In this paper we consider beliefs as actions and vice versa. Otherwise, coordination cannot occur, cf. Def. 3ab. This seems true in the passing game.

θ to ϑ if for every structure \mathcal{A} in \mathbf{B} which satisfies θ and every structure \mathcal{B} in \mathbf{B} which satisfies ϑ , the cardinality of \mathcal{A} 's domain is not higher than the cardinality of \mathcal{B} 's domain. Intuitively, under this interpretation of preferences, we say that agents prefer statements which require to employ the most economic structures to convey meaning.

To coordinate, Alfonso and Barbara communicate with each other in order to respectively end up in the limit with a consistent description of a structure, $\mathcal{A} \in \mathbf{A}$ and $\mathcal{B} \in \mathbf{B}$, such that \mathcal{A} is sufficiently close to \mathbf{B} and \mathcal{B} is sufficiently close to \mathbf{A} . We might think that \mathcal{A} is sufficiently close to \mathbf{B} if every finite set of statements expressed by Alfonso (so true in \mathcal{A} , recall footnote 2 on actions as beliefs) is satisfiable in some $\mathcal{B}' \in \mathbf{B}$, and vice versa. Thus, we expect that the more Alfonso is like Barbara, that is, Alfonso and Barbara have similar preferences, the better chance Alfonso and Barbara have to coordinate. The sets of sentences K_A and K_B eventually satisfied by \mathcal{A} and \mathcal{B} , respectively, are Alfonso and Barbara's knowledge base at the specific, temporal point t of their interaction. If satisfied by \mathcal{A} , we say that K_A is the *theory* played by Alfonso up to t . To dramatize, let us suppose that each agent does not know the preferences of the other agent—that is, what structure it will eventually play.

To start the game, Alfonso is conceived as choosing one member from \mathbf{A} to be his “actual world”, namely, the structure that models Alfonso's initial preferences. Alfonso's choice is initially unknown to Barbara. Alfonso then provides a “clue” (Alfonso's action) about his chosen world. At the same time, Barbara does her choice as well, and provides Alfonso with a clue about her actual world. We assume that Alfonso and Barbara are allowed to change their actual world (“mind change” in the terminology of inductive inference [5]) at each step of the game, provided that they remain coherent to the actions shown upon some point and change their mind finitely often. Clearly, it is safe to begin with a sequence of actions (a *behavior*) coherent to the majority of the structures in each class. In this way, if Alfonso realizes that the structure he has in mind, *i.e.* his actual world, is not close enough to Barbara's actual world, he can change it, and this holds for Barbara as well.

Alfonso and Barbara are allowed to start the game again from the beginning whenever some disagreement occurs. Of course, to reach coordination disagreement should happen only finitely often.

Alfonso and Barbara succeed in their coordination game if each player's actual world becomes in the limit sufficiently close to the preferred beliefs played by the other agent, in the sense explained.

Remark 1 It is important to note that, although the game just depicted refers to a first-order setting,—we present it formally in the next section—, our approach to the modeling of coordination may be well generalized to a number of other semantic paradigms, where language \mathcal{L} and structures are not first-order. The central point is that we have to capture (formally) the semantics of the language in use by the agents, and that such language is build upon a common vocabulary. (Otherwise, agents cannot even “understand” each other at the *syntactic* level!) We have used structures in the mathematical sense. Example 3 gives an application scenario where structures are to be thought mostly of “schemas” or ontologies.

Remark 2 By assuming the agents be computable machines, the pair (Alfonso, Barbara) is a kind of *interactive proof system* as defined, for instance, in complexity theory [13]. Moreover, note that the form of interaction between the two agents may differ according to what situation one aims to model. We have chosen a purely alternating interaction with first move by Alfonso and synchronous moves (cf. subsection 3.2.3). Other choices of dynamics are possible with slight technical modifications.

3 THE PARADIGM

In this section we formalize and discuss the foregoing ideas. As we deal with structures, or models, from now on we refer to the resulting formal paradigm as *model-coordination* (*m*-coordination in short).

3.1 Preliminaries and Notation

Sequences. We denote the set $\{0, 1, 2, \dots\}$ of natural numbers by N . Let η be an infinite sequence. For $i \in N$, we write $\eta|_i$ for the proper initial sequence of length i in η . For every finite or infinite sequence ζ of length $n > k$, $k \in N$, we let $\zeta[k]$ denote the finite sequence $\langle \zeta_0 \cdots \zeta_k \rangle$ and $\zeta|k$ denote the sequence obtained from ζ by deleting its first $k + 1$ elements. We write $|\sigma|$ for the length of a finite sequence, and \emptyset for the finite sequence of length zero. Thus, $\zeta[k] = \zeta|_{k+1}$, and $\emptyset|\zeta = \emptyset$ if $|\zeta| = 1$. We write σ_i or also $(\sigma)_i$ for the i th element of σ , $0 \leq i < |\sigma|$. We denote the set of elements in a (finite, infinite) sequence τ by *range*(τ).

A First-Order Framework. We consider a first-order language with equality \mathcal{L} and write \mathcal{L}_{basic} to denote the set of literals of \mathcal{L} . The members of \mathcal{L}_{basic} are called *basic formulas*. Our semantic notions are standard. Let \mathcal{S} be a structure that interprets \mathcal{L} . Let \models denote the model theoretic concept of truth in a structure. Then \mathcal{S} is a *model* of $\Gamma \subseteq \mathcal{L}_{basic}$, and Γ is said to be *satisfiable* in \mathcal{S} , if there is an assignment $h : \text{Var} \rightarrow \text{dom}(\mathcal{S})$ with $\mathcal{S} \models \Gamma[h]$. Γ is *satisfiable* if it is satisfiable in some structure. An assignment h to \mathcal{S} is *complete* if h is a mapping onto $\text{dom}(\mathcal{S})$. The class of models of Γ is denoted by $\text{MOD}(\Gamma)$.

3.2 Basic components

The basic components of model-coordination and the criterion of coordination success are now to be introduced formally.

3.2.1 Environments

Let SEQ denote the collection of all finite sequences over the set \mathcal{L}_{basic} of atomic formulas on vocabulary \mathcal{L} and their negations. We define an *environment* to be any infinite sequence over \mathcal{L}_{basic} . Thus, for all $\sigma \in SEQ$, there is an environment e such that $\sigma = e|_n$ with $n = |\sigma|$. In this technical sense, SEQ then denotes the collection of all proper initial sequences of any environment. To consider consistent data-streams, we need to relate them to a structure. We do this in the next definition.

Definition 1 Let structure \mathcal{S} and complete assignment h to \mathcal{S} be given. An environment e is *for* \mathcal{S} via h just in case $\text{range}(e) = \{\beta \in \mathcal{L}_{basic} \mid \mathcal{S} \models \beta[h]\}$. An environment e is *for* \mathcal{S} just in case e is an environment for \mathcal{S} via some complete assignment.

In other words, an environment for a structure \mathcal{S} via complete assignment h lists the basic diagram of \mathcal{S} under h . (The *basic diagram* of \mathcal{S} under complete assignment h is the subset of \mathcal{L}_{basic} made true in \mathcal{S} via h .)

3.2.2 Agents

An agent in the model-coordination paradigm, or *basic agent*, is a pair (Ψ, \mathbf{A}) , where Ψ is any (computable, total) mapping of SEQ into \mathcal{L}_{basic} , and \mathbf{A} is a nonempty class of countable structures. Faced with data $\sigma \in SEQ$, a basic agent (Ψ, \mathbf{A}) *believes the action* $\Psi(\sigma)$ if there

is $S \in \mathbf{A}$ such that $S \models \Psi(\sigma)[h]$ for some (complete) assignment h to S . If this is the case, we call $\Psi(\sigma)$ a *belief* and the pair S, h a *background knowledge* of $\langle \Psi, \mathbf{A} \rangle$, denoted: $\{\mathcal{S}, h\}_{ag}$ with $ag = \langle \Psi, \mathbf{A} \rangle$. The first component Ψ is called *communication function*, or “ability,” by it the agent generates its actions. The second component \mathbf{A} is called *background world*. We say that $\langle \Psi, \mathbf{A} \rangle$ is *based on* \mathbf{A} . We write Λ^b for the class of all basic agents and $\Lambda^b(\mathbf{A})$ for all basic agents based on \mathbf{A} .

3.2.3 Dynamics

We now consider formally the kind of interaction, or “protocol,” between two basic agents. In this paper, we restrict attention to dynamics based on simultaneous moves, that is, the agents make decisions at the same time, and to pairwise communication only, that is, interactions involve just two agents. Our presentation may be generalized to a number of different protocols—examples are sequential moves, n -person communication, explicit guesses, etcetera. It only depends on what the specific scenario or application requires, cf. Remark 2.

Definition 2 Let basic agents $\langle \Psi, \mathbf{A} \rangle$ and $\langle \Phi, \mathbf{B} \rangle$ be given.

1. The *interaction sequence* (or “play”) of $\langle \Psi, \mathbf{A} \rangle$ and $\langle \Phi, \mathbf{B} \rangle$ is the infinite sequence

$$D_{\Psi, \Phi} = (\langle \overline{\Psi}_i, \overline{\Phi}_i \rangle : i \in N),$$

where $\overline{\Psi}_i$ is the i th move of Ψ and $\overline{\Phi}_i$ is the i th move of Φ , defined by induction as follows.

- i. $\overline{\Psi}_0 = \Psi(\emptyset)$ and $\overline{\Phi}_0 = \Phi(\emptyset)$.
- ii. $\overline{\Psi}_{n+1} = \Psi(\overline{\Phi}[n])$ and $\overline{\Phi}_{n+1} = \Phi(\overline{\Psi}[n])$.
2. The *response sequence*

$$\overline{\Psi} = (\overline{\Psi}_i : i \in N)$$

is the sequence of moves by basic agent Ψ in response to basic agent Φ , and the *response sequence*

$$\overline{\Phi} = (\overline{\Phi}_i : i \in N)$$

is the sequence of moves by Φ in response to Ψ .

3. Let $k \in N$ be given. The *interaction sequence* of $\langle \Psi, \mathbf{A} \rangle$ and $\langle \Phi, \mathbf{B} \rangle$ starting at k is the infinite sequence

$${}^k D_{\Psi, \Phi} = (\langle {}^k \overline{\Psi}_i, {}^k \overline{\Phi}_i \rangle : i \in N),$$

where ${}^k \overline{\Psi}_i$ is the i th element in ${}^k \overline{\Psi}$ and ${}^k \overline{\Phi}_i$ is the i th element in ${}^k \overline{\Phi}$.

We then say that ${}^k \overline{\Psi}_i$ is the i th move of Ψ starting at k and ${}^k \overline{\Phi}_i$ is the i th move of Φ starting at k . Notice that $\overline{\Psi}$ is finite if and only if at any interaction step $i \in N$, $\Phi(\overline{\Psi}|_i)$ or $\Psi(\overline{\Phi}|_i)$ is undefined. If this is the case, it is immediate to verify that also $\overline{\Phi}$ is finite. Observe that $D_{\Psi, \Phi} = \langle \overline{\Psi}_0, \overline{\Phi}_0 \rangle^0 D_{\Psi, \Phi}$.

Remark 3 In our paradigm, the agents make decisions independently at any stage of the coordination process, no agent being fully informed of the choice of the other agent prior to making his own decision. The choice of meaning is always local and hidden to the other agent. Our model of cooperation is a kind of “extensive game with imperfect information and sequential equilibria” [12].

3.2.4 Success

To coordinate agents have to negotiate in the limit a ‘complete and consistent’ description of a structure in their own background world, eventually after a finite number of disagreements. The agents can restart their interaction finitely often, but after the last disagreement they must eventually coordinate. We rely on the following definition.

Definition 3 Let basic agents $\langle \Psi, \mathbf{A} \rangle$ and $\langle \Phi, \mathbf{B} \rangle$ be given. We say that $\langle \Psi, \mathbf{A} \rangle$ *m-coordinates with* $\langle \Phi, \mathbf{B} \rangle$ (written: $\Psi \rightleftharpoons_m \Phi$) just in case for some $s, t \in N$:

- a $_s|\overline{\Psi}$ is an environment for some $\mathcal{A} \in \mathbf{A}$,
- b $_t|\overline{\Phi}$ is an environment for some $\mathcal{B} \in \mathbf{B}$, and
- c for all $n \in N$, $_s|\overline{\Psi}|_n$ is satisfiable in some $\mathcal{B}' \in \mathbf{B}$ and $_t|\overline{\Phi}|_n$ is satisfiable in some $\mathcal{A}' \in \mathbf{A}$.

Clauses a, b fix the relation between actions and beliefs that we call *coherence* (of agents’s behavior). So, there is no coordination without coherence. Note that the definition depends on the interaction sequence $D_{\Psi, \Phi}$, and that structures \mathcal{A}' and \mathcal{B}' depend on n . For simplicity, however, the reader can relax the definition by assuming $\mathcal{A}' = \mathcal{A}$ and $\mathcal{B}' = \mathcal{B}$. In such case, this means that agents coordinate if and only if each agent is able to choose and *enumerate* (cf. Def. 3a,b) a structure among those available, which is a substructure of the structure choosen by the other agent. So, to *m*-coordinate each basic agent outputs in the limit the basic diagram (under some complete assignment) of a structure in his own background world, and such basic diagram must be finitely consistent in some structure of the other agent’s background world—generally different from the structure described by the first agent, but possibly the same.

Example 2 Let us go back to the passing game of Example 1 and compare it with the definition of “success” by *m*-coordination. In the passing game, a stable state of knowledge (equilibrium) is a pair of plays (e.g., (left, left)) such that given Frank has played the first, Gertrude would not be inclined to deviate from the second, and given that Gertrude has played the second, Frank would not be inclined to deviate from the first. Hence, (left, left) and (right, right) are both the equilibria. In our much richer model, we may think of each basic agent with one structure S with domain of two elements, one element interpreting “go left”, the other element interpreting “go right.” Both agents are allowed to use autonomously their background knowledge, respectively $\{\mathcal{S}, h\}_{Frank}$ and $\{\mathcal{S}, g\}_{Gertrude}$ for h, g complete assignments to S . Clearly, the passing game is a special case of model-coordination with $\mathbf{A} = \mathbf{B} = \{\mathcal{S}\}$, where the existence of natural numbers s, t of Definition 3 is not guaranteed, since the players simply do not find out a common assignment $a = h = g$ of their actions. (Frank and Gertrude “die of starvation in the hallway.”)

The next theorem shows that *m*-coordination is indeed possible, and that a game where an “equilibrium” in the sense of the passing game exists. We rely on the following definition of game.

Definition 4 Let nonempty sets $\Sigma(\mathbf{A})$ and $\Sigma(\mathbf{B})$ of basic agents based on, respectively, \mathbf{A} and \mathbf{B} be given. Let $\{D_{\Psi, \Phi}\} = \{D_{\Psi, \Phi} | \langle \Psi, \mathbf{A} \rangle \in \Sigma(\mathbf{A}), \langle \Phi, \mathbf{B} \rangle \in \Sigma(\mathbf{B})\}$. A *meaning negotiation (m-negotiation) game* is a triple $(\Sigma(\mathbf{A}), \Sigma(\mathbf{B}), \{D_{\Psi, \Phi}\})$. An *equilibrium* of a *m*-negotiation game is a pair $(\{\mathcal{A}, h\}_a, \{\mathcal{B}, g\}_b)$ of background knowledges that satisfies conditions a–c of Definition 3 for some $a \in \Sigma(\mathbf{A})$, $b \in \Sigma(\mathbf{B})$. A *partial equilibrium* (of a *m*-negotiation game) is a pair $(\{\mathcal{A}', h\}_a, \{\mathcal{B}', g\}_b)$ of background knowledges that satisfies condition c of the definition.

The basic idea behind the notion of “equilibrium” is that an equilibrium should specify not only the basic agents’ ability in the limit but also their final beliefs about the coordination history that occurred. The notion of partial equilibrium is less stringent; it specifies the agents’ beliefs at *each* stage of the coordination process. Of course, an equilibrium and a partial equilibrium coincide as a special case. Note also that neither an equilibrium nor a partial equilibrium of a m -negotiation game is necessarily unique. But while an equilibrium does not depend on game stages, a partial equilibrium does.

Theorem 1 Suppose that \mathcal{L} is limited to a binary predicate symbol R . Let \mathbf{A} be the class of all countable linear orders with maximum that interpret R , and let \mathbf{B} be the class of all countable linear orders without maximum that interpret R . Then, there are abilities Ψ, Φ such that $\langle \Psi, \mathbf{A} \rangle$ m -coordinates with $\langle \Phi, \mathbf{B} \rangle$.

Proof: Observe that any initial segment of any environment for a linearly ordered structure (with or without maximum) is satisfiable in any infinite linearly ordered structure, since it generates a substructure of the infinite linearly ordered structure and basic formulas are preserved in overstructures [4, Thm. 2.4.1]. Define Ψ and Φ such that Ψ is an environment for some infinite structure in \mathbf{A} and Φ is an environment for some infinite structure in \mathbf{B} . ■

A less abstract example follows.

Example 3 (Schema-Matching Problem) We define a schema a pair of the form (\mathcal{S}, π) , where \mathcal{S} is a structure and π is a set of sentences satisfiable in \mathcal{S} . We can represent the following problem of “schema matching” [9, 3]. Given two schemas (or “classifications”) (\mathcal{A}, π_1) and (\mathcal{B}, π_2) with their associated data, for each $\vartheta \in \pi_1$ (i.e., “concept”), find the most similar $\vartheta' \in \pi_2$, for a predefined similarity measure. Then, m -coordination provides a similarity measure in the strict sense of the existence of two basic agents $\langle \Psi, \mathcal{A} \cup \text{MOD}(\pi_1) \rangle$ and $\langle \Phi, \mathcal{B} \cup \text{MOD}(\pi_2) \rangle$ who m -coordinate. Less strict similarity measures are possible as variants of m -coordination.³

However, not every m -negotiation game has an equilibrium, as shows the following example of a game where players have diametrically opposed interests—it is called ‘strictly competitive’ by game theorists.

Example 4 Suppose that \mathcal{L} is limited to unary predicate symbols H and T [read H “Head” and T “Tail”]. Let $\theta \in \mathcal{L}_{\text{sen}}$ be of the form: $\forall x(Tx \leftrightarrow \neg Hx)$ [read just one between “Head” and “Tail” occurs], $\vartheta \in \mathcal{L}_{\text{sen}}$ be of the form: $\forall x Tx$ [read “Tail” occurs], and $\delta \in \mathcal{L}_{\text{sen}}$ be of the form: $\forall x Hx$ [read “Head” occurs]. Let $\mathbf{A} = \text{MOD}(\{\theta, \vartheta\})$ and let $\mathbf{B} = \text{MOD}(\{\theta, \delta\})$. It is clear that the m -negotiation game $\langle \Lambda^b(\mathbf{A}), \Lambda^b(\mathbf{B}), \{D_{\Psi, \Phi}\} \rangle$ has no equilibrium, since no pair $\langle \Psi, \mathbf{A} \rangle, \langle \Phi, \mathbf{B} \rangle$ of basic agents can m -coordinate.

4 COMPETENCE OF BASIC AGENTS

A general question to ask about coordination concerns the existence of classes of agents such that the coordination competence of each agent in the class cannot be strictly improved. As a kind of evaluation of the representation power of our framework, although somewhat technical, in this section we exhibit a class of “self-centered” basic agents that has the required property for m -coordination.

³ Because of the importance of schema matching in a number of AI-related research areas, we deserve a full study of it as an independent problem to future work. Here we only showed how the problem can be formalized within our paradigm of m -coordination.

Definition 5 We say that basic agent $\langle \Psi, \mathbf{A} \rangle$ is *self-centered* just in case for every $\Phi : \text{SEQ} \rightarrow \mathcal{L}_{\text{basic}}$, there is $\mathcal{A} \in \mathbf{A}$ such that $R(\Psi, \Phi)$ is an environment for \mathcal{A} .

In other words, a self-centered basic agent enumerates with some other basic agent an environment for some structure in the background world the agent is based on.

We now show (Corollary 1) that the negotiation competence of any total, self-centered basic agent cannot be improved by any total basic agent with the same background knowledge. A *total* basic agent is a basic agent with a total communication function. We rely on the following sense of “meaning negotiation competence.”

Definition 6 The *m -negotiation competence* of a basic agent $\langle \Psi, \mathbf{A} \rangle$ is the set

$$m\text{-scope}(\Psi_{\mathbf{A}}) = \{\langle \Phi, \mathbf{B} \rangle \in \Lambda^b \mid \Psi \Rightarrow_m \Phi\}.$$

Definition 7 Basic agents $\langle \Psi, \mathbf{A} \rangle, \langle \Phi, \mathbf{A} \rangle$ are *distinct* just in case $\Psi(\sigma) \neq \Phi(\sigma)$ for some $\sigma \in \text{SEQ}$.

Definition 8 Let $\sigma \in \text{SEQ}$ and basic agent $\langle \Psi, \mathbf{A} \rangle$ be given. We say that $\langle \Psi, \mathbf{A} \rangle$ (or also Ψ) *starts with* σ just in case for all $\tau \in \text{SEQ}$ with $|\tau| < |\sigma|$, $\Psi(\tau) = (\sigma)|_{|\tau|}$.

Theorem 2 For all distinct, self-centered basic agents $\langle \Psi, \mathbf{A} \rangle$ and $\langle \Psi', \mathbf{A} \rangle$, there is a basic agent such that $\langle \Psi, \mathbf{A} \rangle$ m -coordinates with and that $\langle \Psi', \mathbf{A} \rangle$ does not.

The proof is by construction of a basic agent $\langle \Phi, \mathbf{A} \rangle$. We proceed informally. (See [1, Prop. 2.(49)] for a formal proof.) The meaning negotiation between $\langle \Phi, \mathbf{A} \rangle$ and the agents in Theorem 2 runs as follows. At step 0, Φ starts with some $\sigma \in \text{SEQ}$. Then, if there is no previous move by any opponent basic agent to look at, Φ moves “safe”. Otherwise, if an opponent basic agent “agrees” with basic agent $\langle \Psi, \mathbf{A} \rangle$ on σ , then Φ starts copying the opponent’s moves from the first one. If the opponent basic agent “disagrees” with $\langle \Psi, \mathbf{A} \rangle$ on σ , then Φ breaks off coordination and starts producing inconsistent information.

Corollary 1 Let $\langle \Psi, \mathbf{A} \rangle$ be any total self-centered basic agent. Then there is no total basic agent $\langle \Psi', \mathbf{A} \rangle$ such that $m\text{-scope}(\Psi_{\mathbf{A}}) \subset m\text{-scope}(\Psi'_{\mathbf{A}})$.

That is, the meaning negotiation competence of a total, self-centered basic agent cannot be strictly improved.

5 DISCUSSION AND RELATED WORK

Even though our paradigm omits many important aspects of human coordination and computational systems, it helps illuminate a wide range of phenomena. Our paradigm may help analyze design alternative for distributed systems of “peers” [14] and they suggest ways of analyzing the structural changes associated with introducing the inductive approach to coordination into multiagent systems. On the other hand, a limit of our paradigm is the requirement that “to coordinate agents have to negotiate a ‘complete and consistent’ description of a structure.” Can’t there be partial matches, partially consistent descriptions, or even, in fact, totally inconsistent descriptions that lead to coordination? The answer is ‘yes’. Some initial results and comparison thereof can be found in [1, Secs 2.4-2.5]. For an extension of such results to meaning negotiation, see Section 7 on future work.

Even if restricting the study of coordination to a first-order setting—as we did, the variety of coordination paradigms is huge. Related topics, among others, are discussed in the research on coordination, argumentation and dialogue games. We refer to [2, 11] and the references cited there. In particular, our model-coordination seems to capture in a formal way many ideas discussed informally in [11], for instance the notion of “environment,” and the interactions the agents have therein.

Our approach is close in spirit, if not in formal development, to the framework of the *language games* [18], namely, models of language change and language evolution in populations of communicating agents. Some references are be found in [16]. Language games, however, focus much more on language creation and evolution than our models. Moreover, in Remark 1 we have noted that the agents’ language is build upon a common vocabulary. This is not necessarily the case. In [8], for instance, a mapping of differing syntaxes among agents that speak different languages is advanced and discussed, even if within a relatively related technical setting.

A thorough comparison with language games and game theory is possible only when we would enrich our basic paradigm with an explicit system of “pay-offs,” as to control the agent’s actions and preferences, as well as adding the paradigm with a topological space for both meanings and expressions (respectively structures and basic formulas in our setting). As in language games (but in some contrast to game theory), in our paradigm meaning plays an important role.

We deserve a final remark on game theory and an important objection, namely: “What this model-theoretic approach gives us, over say ‘classical’ game theory and equilibria selection in repeated games (apart being novel and rigorous)?” In fact, Nash equilibrium captures a *steady state* of the play of a strategic game [12], similarly to our notion of stable state of knowledge. On the other hand, it is well known that such and similar notions of equilibrium as proposed by classical game theory [12] are not fully satisfactory in dealing with infinitely repeated games. A thorough comparison with game theory, although very interesting and important, is out of the scope of this paper.

6 CONCLUSION

To summarise, we have advanced and discussed a formal paradigm of coordination, wherein meaning negotiation plays a major role in the process of convergence to a common agreement. We have argued, sometimes by examples taken from application or real world, sometimes by more abstract yet illustrative results (Theorem 1 and Theorem 2), that the paradigm has something perhaps fruitful to offer, namely, a novel and rigorous model-theoretic perspective, based on principles of inductive logic, along the important current debates in Artificial Intelligence and related areas, on multiple agents in interaction, including those on the semantic interoperability, the update semantics and belief revision, and the language creation, evolution and learning. We have called such paradigm and the related perspective: model-coordination.

7 FUTURE WORK

The paradigm can be modified in various ways—we mention one.

Data available to the agents can be limited to just atomic (basic) formulas (no negations), or enriched to include universal or other kinds of formulas. Many alternative definitions of an “environment” as in Definition 1 are possible: partial or incomplete, noisy, imperfect, recursive. We have chosen to consider “complete” environments in this paper as it seems the more simple solution. This is, however,

a questionable representation of many natural environments and the majority of computable environments, where software agents usually interact. It is worth noting that “real” environments may suffer omissions, erroneous intrusions, or both omissions and intrusions. Although we can modify our paradigm to model such environments with some additional effort, these important kind of environments have been outside the scope of this paper. We fix them here for future work on coordination through inductive meaning negotiation.

Reaching Agreements for Coalition Formation through Derivation of Agents' Intentions

Samir Aknine¹ and Onn Shehory²

Abstract. This paper addresses the coalition formation problem in multiagent systems. Although several coalition formation models exist today, coalition formation using these models remains costly. As a consequence, applying these models through several iterations when required becomes time-consuming. This paper proposes a new coalition formation mechanism (CFM) to reduce this execution cost. This mechanism is based on four principles: (1) the use of information on task relationships so as to reduce the computational complexity of the coalition formation; (2) the exploitation of the coalition proposals formulated by certain agents in order to derive their intentions, (this principle makes the search for solutions easier, which in turn may result in earlier consensus and agreements-the intention derivation process is performed on a new graph structure introduced in this paper); (3) the use of several strategies for propagating the proposals of the agents in the coalition formation process; and (4) the dynamic reorganization of previous coalitions.

1 INTRODUCTION

The topic of coalition formation has been the subject of much interest over the last few years. Several models have been developed to control the behaviors of the agents involved in the coalition formation process [3,4,5,6]. These models have addressed important issues such as the computational complexity and the use of concessions, to name but two. However, the strategic behaviors of agents during the coalition formation process have not been properly addressed.

This paper tackles this problem and proposes a mechanism based on several strategic behaviors for the agents: (1) concessions as a means of convergence towards the preferred coalitions for the agents with a study of the relationships between tasks in order to facilitate the formation of coalitions according to how compatible the agents' interests are. (2) exploiting the coalition proposals formulated by the agents to derive the underlying intentions. We use these intentions to focus on solutions which lead to earlier consensus. (3) the use of various strategies for propagating the proposals of an agent in order to reinforce its choices. (4) the reorganization of previous coalitions when changes occur in the execution context, or unexpected events tied to the previous coalitions occur.

[1,2] have developed an approach using compromise strategy, but assume that the value for a beneficial compromise is static (fixed or experimentally computed).

In our approach, the aim is to bring agents to identify the compromise point themselves given the context of the coalition formation process they are involved in. Our compromise computation is based on the quid pro quo strategy.

Task relationship analysis can improve coalition search, as we evidenced through the results of our experiments. In particular, the existence of task relationships (e.g. dependencies between tasks) introduces some dependencies between the agents which perform them. When these dependencies exist, it is preferable that agents identify them early on, since such knowledge can promote compromise. Hence, it should be advantageous to identify dependencies between tasks prior to their assignment to agents. Moreover derivation of intentions makes it possible for self-interested agents to adapt their decisions and strategies to the reactions of the other agents while formulating and propagating their proposals for coalitions. A large solution space can make compromises between agents hard to reach, thus making it impossible or quite difficult to explore these solutions with respect to how long the coalition formation process lasts. Therefore agents should inflect their positions with respect to other agents. Our technique for deriving intentions makes it possible to arrive at reciprocal compromises. Based on the principles discussed above we have developed a novel coalition formation mechanism.

The paper is organized as follows. Section 2 introduces the coalition formation problem. Section 3 presents the concepts of the CFM, first the principles of this mechanism for task analysis and the derivation of agents' intentions, then the behaviors of the agents in this mechanism. Section 4 is a brief conclusion.

2 DESCRIPTION AND ILLUSTRATION OF THE PROBLEM

This section defines the coalition formation problem and describes the example we use to illustrate our mechanism.

2.1 Problem Description

Consider a set of agents $N = \{a_1, a_2, \dots, a_n\}$ and a set of tasks $T = \{T_1, T_2, \dots, T_m\}$. The agents in N need to execute the tasks in T and can negotiate their execution. Tasks in T can be combined into sets of tasks, which can be negotiated. Each agent a_i has its own utility function U_i that it tries to maximize. The goal of an agent is to determine the coalitions to join and the task sets to be performed in these coalitions.

2.2 Problem Illustration

In order to illustrate our approach for agent coalition formation and re-formation, let us take the following simple example, to help understand our mechanism (cf. Figure 1).

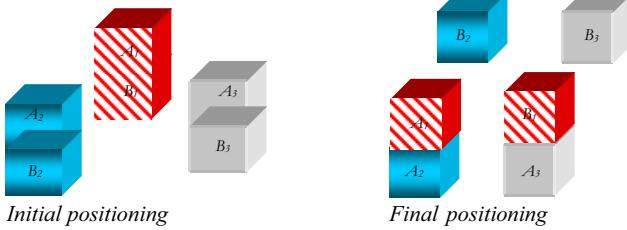

Figure 1. Initial and final block positions

The example concerns agents $a_{i|i=1..n}$ behaving in a world with six blocks initially in a given position. At the end of their execution, agents must have stacked the blocks in a predefined order and at another position (Figure 1). Each agent a_i is responsible for two blocks (A_i, B_i). They have a set of operators for domain actions: $Push(<\{a_i\}>; x; t_k; t_k)$ is the action agent $\{a_i\}$ executes in order to push block x from position t_k to t_k ; $Unstack(<\{a_i\}>; x; y)$ is the action agent $\{a_i\}$ executes in order to unstack block x from y ; $Stack(<\{a_i\}>; x; y)$ is the action agent $\{a_i\}$ executes to stack block x on block y .

3. COALITIONS OF AGENTS

Let us begin by recalling some important definitions.

3.1 Definitions

Definition 1 (Coalition) A tuple $C = \langle A_c, T_c \rangle$ where $A_c = \{a_1, a_2, \dots, a_k\}$ is a set of agents that joined together to perform a task combination $T_c \subseteq T$.

Definition 2 (Coalition structure) A set of coalitions $CS = \{C\}$ such that $\cup A_c \subseteq N$, and $\cup T_c \subseteq T$. A coalition structure which is approved by the agents is considered to be a solution. A solution guarantees that the tasks are executed by the agents. The set $\{T_c\}$ of task combinations that the coalitions in the solution will perform is called the support of the coalition structure.

Definition 3 (Group of coalition structures) A set of coalition structures that, for a specific agent, each provides it with the same utility.

Note that a coalition structure is acceptable for agent a_i if it is preferred over, or equivalent to, the reference structure RS , which corresponds to the minimal guaranteed gain during the negotiation. That is, $U_i(CS) \geq U_i(RS)$.

Definition 4 (Approval set) An approval set $App(CS)$ of a coalition structure CS is the set of agents that have approved the coalition structure CS .

We consider the unacceptable coalition structures as a set of coalition structures $Out(a_i)$ which agent a_i notifies to the others. An unacceptable coalition structure cannot be proposed as a

solution by any agent.

The search for the support of a solution considers relationships between tasks (temporal, causal, etc). Note that complete coverage of the space of task relationship types is beyond the scope of this study. Let us just say that we have to consider task relationships based on the structure of the tasks, then consider relationships based on agents which will perform them. For instance, we have a dependence relationship between $T_1 = Stack(<\{a_1\}>, B_1, A_3)$ and $T_2 = Unstack(<\{a_1\}>, A_1, B_1)$ since the execution of the task T_1 depends on the prior execution of T_2 . Each agent responsible for blocks A_3 and B_1 (respectively a_3 and a_1) is in a relationship (cf. Figure 1). Agent a_1 that is responsible for B_1 may find it very beneficial to satisfy the request of a_3 that is responsible for block A_3 , for instance, for the task $T_3 = Unstack(<\{a_3\}>, A_3, B_3)$, if a_1 wants to reach the requirements for T_1 . However a_1 may also ask for something in exchange, i.e. assistance for $T_4 = stack(<\{a_1\}>, B_1, A_3)$. This cooperation is based on the simple principle of the quid pro quo strategy.

3.2 Coalition formation processing

The coalition formation mechanism requires some processing in addition to the negotiation itself: (1) task analysis prior to negotiation and (2) derivation of agents' intentions during negotiation. The first processing facilitates the concessions on coalitions and the second helps the negotiation converge rapidly.

3.2.1 Task analysis

Task analysis consists of grouping tasks into combinations based on relationships between the tasks, where each combination is to be performed by a coalition. To simplify and optimize the search among those combinations of tasks we construct a binary tree whose nodes are task combinations. The advantage of the suggested method is in directing the search for the support of the solutions towards preferred tasks, thus reducing search complexity.

Definition 5 (Task combination tree) An agent's (binary) task combination tree is built based on the agent's combination preference following a decreasing preference rate for task combinations. Hence, the most preferred combination is the root of the tree. The rest of the nodes are populated in a descending order of preference. Two branches emanate from each node n : an edge labeled (+) and an edge labeled (-). Solutions are placed at the leaves. When inspecting a path from the root to a solution node, (+) on an edge indicates that the node from which the edge emanates is in the support of the solution; (-) indicates that the node from which the edge emanates is not in the support of the solution.

For example, in Figure 3 the support S_3 is only formed from the combinations $\langle T_1, T_2, T_3 \rangle, \langle T_5, T_6 \rangle$ since on the path starting from the root to the leaf S_3 , the node $\langle T_4, T_5 \rangle$ is labeled negatively. Hence, this node does not belong to the support S_3 . The combination tree is built incrementally. To build it, an agent first organizes task combinations in partitions. A partition

is a set of task combinations concerned with one task and containing all the combinations where this task appears. Each task combination belongs to only one partition (cf. Figure 2). For instance, consider a set of agents $\{a_i\}$ and eight tasks T_1, \dots, T_8 . To build its coalition structures, a_i computes some task combinations. This is done with respect to its preferences. For instance, a_i computes the following preferred combinations: $\{T_1, T_2, T_3\}$, $\{T_1, T_2\}$, $\{T_4, T_5\}$, $\{T_5, T_6\}$, $\{T_3, T_4, T_5\}$, $\{T_6, T_7\}$ and $\{T_6, T_7, T_8\}$. To simplify the construction of and the search in the support tree, these combinations are first classified into partitions p_1 , p_2 and p_3 (cf. Figure 2) and ordered in decreasing order of preference. The preference degree of each partition is the average of the preference degrees of the combinations it includes. Here partition p_1 has the highest preference degree and is thus placed at the top.

While building the tree, the preferred combination of agent a_i , $\{T_1, T_2, T_3\}$ is attached to the root of its tree (cf. Figure 3). Then, a_i creates two branches and searches for the next combination to be considered. In the positive branch, the combination must be selected from a partition other than p_1 , because combinations in p_1 share at least T_1 , and a support should have only one instance of each task. The agent selects the combination $\{T_4, T_5\}$ from p_2 . In the negative branch, the agent selects the combination $\{T_1, T_2\}$ from p_1 . The tree is gradually built in the same manner. For instance, the following positive combination is $\{T_6, T_7\}$ from p_3 .

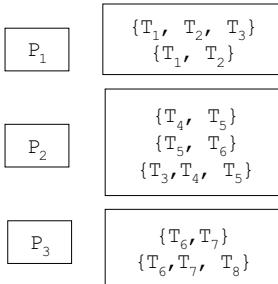

Figure 2. Partitions of task combinations

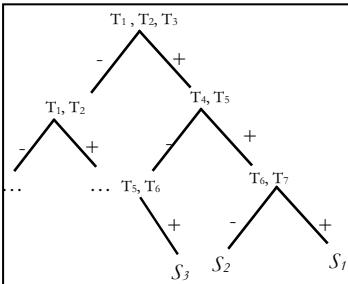

Figure 3. Support tree

Searching the tree and selecting the nodes from which positively labeled branches emanate already gives us several possible supports, S_3 for instance. S_3 is formed from two combinations $\langle\{T_1, T_2, T_3\}, \{T_5, T_6\}\rangle$. In the tree building and search stage each agent autonomously computes its own tree and supports. Each tree may provide several supports of different coalition structures, and supports may vary across trees. This in turn allows several different solutions, as each task combination in each support can be allocated to different coalitions of agents.

3.2.2 Analysis of agent intentions

Each agent applies the same principle of support tree building as well as the generation of the coalition structures to be proposed to the other agents. However, while negotiating, an agent a_i receives several proposals for coalition structures which it must in turn approve, refuse or modify and where appropriate propose new coalition structures to be discussed in later iterations. The construction of these new coalition structures

should not only focus on the choices of a_i but also on the intentions to achieve revealed by the other agents during preceding iterations of the negotiation. This requires a_i to analyze other agents' proposals. To carry out this analysis each agent builds an intention graph relating to the agents which it prefers to approach (possibly all).

3.2.2.1 Building of intention graph

In the previous example, let us assume that agent a_1 received several coalition structures from agent a_2 during the first iterations of the negotiation. Some of the coalition structures are listed below:

$$CS_{21} = \langle \{a_2, a_1\}; \{T_1, T_2, T_3\} \rangle; \langle \{a_2, a_3, a_4\}; \{T_4, T_5\} \rangle;$$

$$\langle \{a_2, a_4\} ; \{T_6\} \rangle$$

$$CS_{22} = \langle \{a_2, a_1\}; \{T_3, T_6\} \rangle; \langle \{a_2, a_3, a_4\}; \{T_2, T_4, T_5\} \rangle$$

$$CS_{23} = \langle \{a_2, a_3\} ; \{T_1, T_2\} \rangle; \langle \{a_2, a_3, a_1\} ; \{T_4, T_5\} \rangle$$

In order to facilitate the convergence of the negotiation, agent a_1 may find it very beneficial to take into account the choices of others, here agent a_2 , in the formulation of the coalition structures. To carry out this processing the agent uses the intention graph to adapt its search for solutions.

Definition 6 (Agent intention graph) An acyclic graph organized in several levels. The nodes of the first level of this graph are the partitions resulting from the classification of the task combinations. The intermediate nodes contain the tasks shared by the nodes they link. The terminal node of the graph is empty.

Using the coalition structure sent by agent a_2 , the agent a_1 builds the set of partitions on the left side of the graph (cf. Figure 4). To build these partitions, a_1 computes the preference of a_2 for each task indicated in the coalition structures. It thus distinguishes the priority and the frequency of a task $\{T_k\}$ in order to compute the preference of a_2 for $\{T_k\}$. The priority of $\{T_k\}$, $P_j(\{T_k\})$, is defined with respect to the group j of coalition structures to which $\{T_k\}$ belongs. A task of the first group of coalition structures obviously has a higher priority than a task appearing in the last group. As for the frequency of $\{T_k\}$ in a group j , $F_j(\{T_k\})$, it depends on the number of occurrences of $\{T_k\}$ in the coalitions structures of this group. The preference of a_2 for $\{T_k\}$, denoted $PREF(\{T_k\})$, is the ratio between its frequency and its priority: $PREF(\{T_k\}) = \sum_{j \geq 1} F_j(\{T_k\}) / P_j(\{T_k\})$.

Based on the preference of each task, a_1 builds the partitions in Figure 4. The first partition p'_1 corresponds to the preferred task T_1 . This partition contains all the combinations where T_1 appears. Therefore, each task combination will belong to only one partition. In each partition described in the left part of Figure 4, a_1 summarizes the combinations of tasks as well as the coalition structures in which they appear. To build the intention graph of agent a_2 , a_1 exploits these task combinations. Using these partitions, a_1 searches first for shared tasks between the combinations in each partition. In Figure 4, note that each partition is attached to a node containing the set of tasks shared by all its combinations. For example, the partition p'_1 , which is initially defined for the task T_1 , is now linked to the node $\langle T_1, T_2 \rangle$. The partition p'_2 , defined for $\langle T_2 \rangle$, is linked to the node $\langle T_2 \rangle$. Once all the nodes of the second level have been built (these nodes indicate the characteristics common to the task combinations of a given partition), a_1 seeks to identify the characteristics common to the partitions, which appear in the

intermediate nodes. To create the nodes of the following level, a_1 analyses the nodes of the current level to check if they share tasks. For each set of common tasks which does not correspond to any node, the agent constructs a new node, which is attached to the nodes which generated it. In the same way, the inclusion of a node in others is also identified in these links, e.g. here the node $\langle T_1, T_2 \rangle$ is attached to the node $\langle T_2 \rangle$ since $\langle T_2 \rangle$ is included in $\langle T_1, T_2 \rangle$.

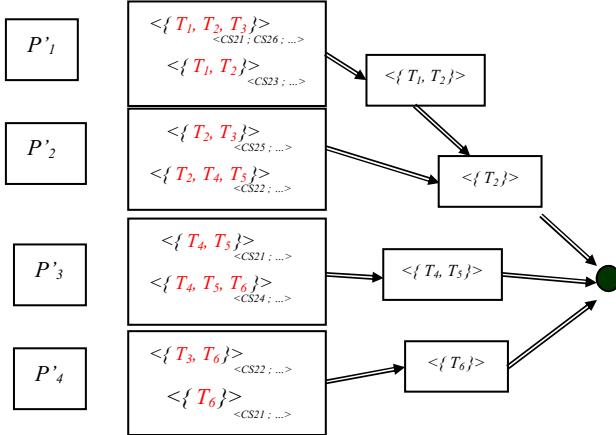

Figure 4. Intention graph for a_2

Note that in this example a_1 builds a graph relating to a_2 , based on the structures that a_2 revealed to a_1 . Depending on the strategy of a_1 , this processing may be repeated: either (1) individually and for all the agents with which a_1 exchanged; or (2) only for the agents which a_1 prefers; or (3) globally by combining in the same intention graph all significant coalition structures for these agents and then computing the preference of these structures. This knowledge is very useful for a_1 since it can use it to deduce the structures these agents prefer to form and accelerate convergence.

3.2.2.2 Intention graph exploration and use

Each agent builds its support tree from which it will propose coalition structures to other agents. These agents will accept or refuse them after negotiation. To build this tree, an agent should also use the knowledge it collected from other agents, i.e. on coalition structures they proposed. These coalition structures and their supports are collected in the intention graph described above. The agent uses this graph in order to find the combinations to insert in its own support tree. While building this tree, each agent analyzes the intention graph it has identified. Remember that each path of the support tree returns a proposal for a coalition structure. Once a task combination has been added to a branch of the support tree, the partition of the intention graph in which this combination appears should be marked with the reference of the branch of the support tree so that it will not be reused in later branches. Thus, in order to avoid the useless exploration of partitions in the intention graph, the agent refers to the following properties:

Property 1 If an ancestor node of a partition p_i in the intention graph contains a task of the path under construction in the support tree, p_i should be marked.

Property 2 Let p_i and p_j be two partitions in the intention graph such that p_i has n_k as a direct ancestor in the intention graph. If p_j is also linked to n_k , marking p_i implies marking p_j too.

To illustrate the use of this intention graph, let's consider again the example presented in section 3.2.1. Recall that agent a_1 computed some task combinations with respect to its preferences: $\{T_1, T_2, T_3\}$, $\{T_1, T_2\}$, $\{T_4, T_5\}$, $\{T_5, T_6\}$, $\{T_3, T_4, T_5\}$, $\{T_6, T_7\}$ and $\{T_6, T_7, T_8\}$. After several rounds of negotiations, agent a_1 received from other agents several proposals which enabled it to build the intention graph shown in Figure 4. To build its first support S_1 , a_1 uses the combinations it has built in its own partitions (cf. Figure 2) as well as the intention graph as explained below.

The first combination of tasks of p_1 is $Comb_1 = \{T_1, T_2, T_3\}$ (cf. Figure 2), which becomes the root of its support tree (cf. Figure 3). a_1 now searches for the combinations which can serve as descendants of $Comb_1$. Of course these combinations should not contain the tasks in $Comb_1$. The exploration of the intention graph is done from right to left and top-down due to the decreasing preferences for the combinations in this graph (cf. section 3.2.2.1). This exploration indicates a first node, $\{T_2\}$ (cf. Figure 4), to which property 1 could be applied. Task T_2 is already in the set of tasks of the branch under construction formed by $Comb_1$. The identification of this node involves marking the first ancestor of this node, i.e. the node $\{T_1, T_2\}$. This ancestor is marked without having to explore it. The first partition p'_1 linked to the node $\{T_1, T_2\}$ is also marked without exploring it (cf. Figure 4). Property 1 implies marking the partition p'_2 of which this node is a direct ancestor. At present, there are only two partitions left in the intention graph which have not been visited (p'_3 and p'_4). a_1 searches for a new combination in order to finish building its branch. It should choose the combination which is the most satisfactory for it and for the other agents. In its partitions, a_1 finds the combination $Comb_2 = \{T_4, T_5\}$ of p_2 (cf. Figure 2). Fortunately in the intention graph the next node to explore is $\{T_4, T_5\}$. This is a favorable situation, since this combination seems to be the best both for a_1 and for the other agents. Again, to finish building its solution, a_1 searches for a combination in the partition p_3 (cf. Figure 2). It has to choose between two combinations and it chooses $\{T_6, T_7\}$. According to the intention graph, this combination also seems to be preferred since the next node to be visited is $\{T_6\}$. The construction of the support tree continues until the agents converge to the same solutions.

3.3 The coalition formation mechanism

The coalition formation mechanism is based on three steps:

(1) The agents initialize the negotiation and transfer their tasks. Each agent asks the other agents to send it their tasks with their explicit priority. Each agent receives the set of tasks and computes the first coalitions to be proposed or agreed to (cf. section 3.2).

(2) An initiator agent computes the first preferred task combinations. For each preferred task combination, the initiator agent finds its preferred agents to perform them. The agent then gathers these coalition structures in groups in order to initiate the negotiation. It then chooses an agent to which these coalition structures will be sent (as proposals for coalition formation). This choice is based on the agent's strategies. The

initiator can behave in three different ways:

- (a) it can send its proposals sequentially to other agents;
- (b) it can send the same proposal to different agents at the same time;
- (c) it can send different proposals to several agents at the same time.

Each strategy involves a particular behavior of the initiator that it should manage. Only strategy (a) is described here. So the initiator initially sends to one agent its preferred coalition structures; it may then send iteratively, in decreasing order of preference, its other coalition structures, until there are no more coalition structures at least equivalent to the reference structure. However, before sending a lower preference coalition structure, the agent may wait until it receives a message from another agent - either a response to its earlier proposal or a new proposal from that agent. These proposals are then used to build the intention graph of these agents (cf. section 3.2.2.1). Each of the other agents also computes its preferred coalition structures. The initiator then computes the second preferred coalition and so on. When an agent r receives a group of coalition structures G from a sender agent s , it only sorts coalition structures that are at least equivalent to the reference structure and the others are not considered. If there is at least one coalition structure CS^* which is preferable or equivalent to r 's best choice, it forwards this CS^* to the next agent that it wishes to include in the negotiation. r approves the CS^* and adds it to $App(CS^*)$. When r finds unacceptable coalition structures in the group it receives, it has to declare them unacceptable to the other agents in $Out(r)$. $Out(r)$ also contains the coalition structures that r itself identified locally as unacceptable. A possible end point of the negotiation occurs when an agent receives a group of coalition structures approved by all the agents concerned in this group. Once the last agent has identified a Pareto optimal solution which is approved by all these agents, it sends them this coalition structure, which they accept as the solution for the negotiation.

(3) The final step of the negotiation consists in validating this solution definitively.

3.4 Coalition formation example

Let us recall the example in section 2.2. Each of a_1 , a_2 and a_3 has identified a set of tasks it has to perform. These tasks are described below.

a_1	a_2	a_3
$T_1 = UnStack (\langle \{a_1, ?\}, A_1, B_1 \rangle)$	$T_6 = UnStack (\langle \{a_2, ?\}, A_2, B_2 \rangle)$	
$T_2 = Stack (\langle \{a_1, ?\}, A_1, A_2 \rangle)$	$T_7 = Push (\langle \{a_2, ?\}, A_2, t_{21}, t_{21} \rangle)$	
$T_3 = Stack (\langle \{a_1, ?\}, B_1, A_3 \rangle)$	$T_8 = Push (\langle \{a_2, ?\}, B_2, t_{22}, t_{22} \rangle)$	
$T_4 = Push (\langle \{a_1, ?\}, A_1, t_{11}, t_{11} \rangle)$	$T_9 = UnStack (\langle \{a_3, ?\}, A_3, B_3 \rangle)$	
$T_5 = Push (\langle \{a_1, ?\}, B_1, t_{12}, t_{12} \rangle)$	$T_{10} = Push (\langle \{a_3, ?\}, A_3, t_{31}, t_{31} \rangle)$	
	$T_{11} = Push (\langle \{a_3, ?\}, B_3, t_{32}, t_{32} \rangle)$	

Once the tasks have been exchanged, each agent tries to find suitable task combinations. Each agent then generates its preferred task combinations and instantiates them. The quid pro quo strategy brings agents a_1 , a_2 and a_3 identify the following combinations after various series of negotiations on feasible combinations: $\{T_1, T_6\}$, $\{T_4, T_7\}$, $\{T_3, T_9\}$, $\{T_2, T_8\}$, $\{T_5, T_{11}\}$.

Consequently agents a_1 , a_2 and a_3 may respectively formulate the following coalition structure proposals:

$$\begin{aligned} SC_1(a_1) &= \langle \{a_1, a_2\} ; \{T_1, T_6\} \rangle ; \langle \{a_1, a_2\} ; \{T_2, T_8\} \rangle ; \langle \{a_1, a_3\} ; \\ &\quad \{T_3, T_9\} \rangle ; \langle \{a_1, a_3\} ; \{T_4, T_7\} \rangle ; \langle \{a_1, a_3\} ; \{T_5, T_{11}\} \rangle ; \langle \dots \rangle \\ SC_2(a_2) &= \langle \{a_1, a_2\} ; \{T_1, T_6\} \rangle ; \langle \{a_1, a_2\} ; \{T_2, T_8\} \rangle ; \langle \{a_1, a_2\} ; \\ &\quad \{T_4, T_7\} \rangle ; \langle \dots \rangle \\ SC_3(a_3) &= \langle \{a_1, a_3\} ; \{T_3, T_9\} \rangle ; \langle \{a_1, a_3\} ; \{T_5, T_{10}, T_{11}\} \rangle ; \langle \dots \rangle \end{aligned}$$

So far each agent has formulated partial solutions considering the tasks it is supposed to carry out. Once the first SC of a_1 is transmitted to a_2 , the latter can immediately approve it since this SC enables it to carry out all its tasks. a_2 may find it beneficial to accept this proposal since it seems completely equitable for it. At this point, only a_1 and a_2 have approved SC_1 . a_1 should now submit a proposal to a_3 . SC_1 is almost satisfactory for a_3 , but unfortunately task T_{10} is not considered in SC_1 . a_3 thus formulates a new coalition structure SC_4 by taking into account the intentions of the agents a_1 and a_2 .

$$SC_4(a_3) = \langle \{a_1, a_2\} ; \{T_1, T_6\} \rangle ; \langle \{a_1, a_2\} ; \{T_2, T_8\} \rangle ; \langle \{a_1, a_3\} ; \\ \{T_3, T_9\} \rangle ; \langle \{a_1, a_3\} ; \{T_4, T_7\} \rangle ; \langle \{a_1, a_3\} ; \{T_5, T_{10}, T_{11}\} \rangle$$

This solution does not weaken the choice of agent a_2 . a_3 can thus consider that it can be approved by a_2 . It only remains for a_1 to approve it, and agree to share task T_{10} with a_3 . The agent that may find it beneficial to yield is a_1 since this solution enables it to carry out all its tasks, unless agent a_2 accepts to carry out T_{10} . SC_4 can thus be approved by all the agents and be used as a solution for the coalition formation.

4 CONCLUSION

This paper has proposed an original coalition formation mechanism, enriched with several essential principles in order to improve the coalition formation: handling relationships between tasks, considering the intentions of the agents during the negotiation of a solution, introducing several strategies for propagating the proposals of the agents in order to reach a solution during the negotiation of the coalitions. This method has been implemented and tested on the application described previously, and compared with the naive method in which these new principles are not studied. The experiments carried out have shown the usefulness of this approach in reducing the time needed for coalition formation and the number of coalition structures evaluated. The approach suggested favors the concessions and allows the agents to converge rapidly towards an acceptable solution.

Cheating is not playing: *Methodological Issues of Computational Game Theory*

Bruno Beaufils¹ and Philippe Mathieu²

Abstract. Computational Game Theory is a way to study and evaluate behaviors using game theory models, via agent-based computer simulations. One of the most known example of this approach is the famous Classical Iterated Prisoner's Dilemma (CIPD). It has been popularized by Axelrod in the beginning of the eighties and had led him to set up a successful Theory of Cooperation.

This use of simulations has always been a challenging application of computer science, and of agent-based approaches, in particular to Social Sciences. It may be viewed as *Empirical Game Theory*. These kind of approach is often necessary since, in the general case, classical analytical ones do not give suitable results. These tools are also often used when full game-theoretic analysis is intractable.

The usual method to evaluate behaviors consists in the collection of strategies, through open contests, and the confrontation of all of them as in a sport championship. Then it becomes, or at least seems to become, easy to evaluate and compare the efficiency of these behaviors.

Evaluating strategies can however not be done efficiently without the insurance that algorithms used are well formed and that they can not introduce bias in their computation. It can not be done without tools able to prevent or, at least, measure deviation from the object of the study. Unfortunately people using such simulations often do not take care seriously about all those aspects, because they are not aware of it, and sometimes because they are. We will try to show effects of bad simulations practice on the simplest example.

We show methodological issues which have to be taken care of, or avoided in order to prevent trouble in simulation results interpretation. Based on some simple illustration, we exhibit two kinds of bias that could be introduced. We classify them as voluntary or involuntary mistakes. The former ones can be explained by poor design of experimentations whereas the latter can defeat the purpose of the evaluation using simple ideas of agreement and cooperation. We also show the implications on interpretations and conclusions that such errors may produce.

We state that scoring/ranking methods are part of the game, and as such have to be described with the game. Many points described may seem to be widely known. We think that with the growth of interest of such methods they have to be detailed and exposed clearly.

1 Introduction

Social sciences generally deal with the study of human beings behavior and their effect on the behavior of groups of humans beings. Studies in this field use two methodologies. The first one consists,

as in *natural science*, in the observation of real life situations in order to try to determine which laws govern the observed groups. The second one, whose adoption is much more recent, consists in the construction of formal models which are then tested and which results are compared to observations. Actually, those two methodologies are not as distinct as one may think. Often the first method is used as first step for the second one in a infinite loop trying to understand the world.

A lot of scientific fields are using this kind of methods to achieve their goal. One may think to economic and management science, trying to understand the behavior of group of people, psychology and artificial intelligence, trying to understand or mimic the behavior of individual. Some mathematical tool have been set up with such a goal in mind. Game Theory has, for instance, been mainly set up in order to understand and explain the behavior of people in parlor game, [8]. It has been used in many political situation, trying to solve conflicts (as this year Economics Nobel Prize winner work) and is still very largely used to understand economic behavior.

With the growth of computer power the testing steps of these approaches are more frequent. The main reason is that purely mathematical tools are sometimes nor powerful nor usable enough when dealing with individual elements and not sets. These tools are very well adapted for a macroscopic view of the world but lose a lot of attractiveness when trying to have a view at a microscopic level. These inappropriate perspectives may be caused by the classical continuous approach of mathematical tool used to explain a world which is a discrete one. On the other side, computers and agent-based models deal very well with discrete computations. Combination of discrete mathematical models and computation power of today is a real chance for *social science* at large.

Another explanation of this proliferation of computer simulations use may be that people think that computer are easier to use than mathematics. The problem is that it is generally not true. We will try to show difficulties involved when using computer agent-based simulations along with some basic solutions which are usable.

We will focus on one particular example which is the study of individual behavior and their effect mainly on the individual fitness but also on the group behavior. This is exactly what computational game theory or *empirical game theory* ([9]), is about. While classical game theory try to solve (or at least to explain) conflictual situations and evolutionary game theory try to explain population dynamics, computational game theory is about evaluating individual behavior. Within this context the purpose of the work is then to find some good behavior, also called strategies. What *good* really means depends on the macroscopic effect studied (cooperation, coalition dynamic, etc.).

The classical way to do is to simulate a big tournament implying a lot of different behavior in a specific game. The more efficient the

¹ LIFL, University of Sciences and Technologies of Lille, beaufils@lifl.fr

² LIFL, University of Sciences and Technologies of Lille, mathieu@lifl.fr

behavior is in this game the better it is considered. Diversity in nature of behavior present in the population of agents implied is then very important. Evaluating an agent in a population where every individuals behave the same way is not interesting, at least most of the time. In order to ensure this needed diversity scientists often use a way which seems efficient : ask other scientists how they will behave in the specified game. That has been successful more than once. One of the main reason is that every participant has not the same representation of the situation modeled by the game. Since background of participants are different, they even do not have the same idea of how to deal well in such situation.

Evaluating strategies can not be done efficiently without testing it more than once. It can not be done without the insurance that algorithms used are well formed and that they can not introduce bias in the result of simulations. It can not be done without tools able to prevent, or at least to measure, deviation from the object of the study.

Unfortunately people using computer simulations does not always take care seriously about all these aspects (CEC'04 contest), because they are not aware of it, and sometimes because they are. We will try to show effects of bad simulations practice on the simplest example.

In a first section we will describe computational game theory methods which will be used to illustrate our ideas. A specific example will be chosen, described, and used in all the rest of the paper. The next section will describe some bias that could be introduced by those methods when they are not used in a proper manner or simply because they are not well designed. That could be summarized as *how to cheat without communication*. Then the third section will described how strategies involved can defeat the purpose of the evaluation using trivial ideas based on agreement and cooperation. That will be summarized as *how to cheat with communication*.

2 Computational Game Theory

Game Theory may be seen as a mathematical tool designed to understand what is a rational behavior in specific situations. More precisely behavior are called strategies. Strategies describe in detail what to do in any possible situation. Possible situations are described by some rules. A definitive definition of what Game Theory is about is still very discussed and two different approaches still coexist. Even the *real life* applicability of Game Theory is still widely discussed. One can refer, among others, to [3, chapter 1] or [7, chapter 5].

We would like to show that evaluating strategies in game theory by computer simulations has to be done with scientific rigor and needs some methodological precautions. One has also to be aware of limits implied by those issues. We focus the demonstration on iterated and repeated games involving two players. The main used evaluation method is based on sport championship. The idea is to evaluate and then order some strategies in a specific game. Evaluation is done pairwise, for every possible pair. In this paper we concentrate, as an example, on the iterated prisoner's dilemma, see [6] for complete history and informal presentation. Remarks made in this context stay however true on any iterated game.

Classically, these kind of evaluations are done during a specific contest where any kind of people are allowed to submit strategies, through a simple description or a more detailed source code implementation in a fixed programming language. The main benefit of using such situation is clarity, since distinction between people being evaluated (*participants*) and people evaluating (*referees*) are obvious.

Two cases are then observable: (i) implementation mistake or design flaws (ii) organized cheating. In both cases we will show that it is almost always possible to get a well-evaluated strategy at the end

of the contest although it is actually a very poor one. In the first case it is often due to a naive software implementation implying edge effect. Referee, and not participants, has then to be blamed. It could be defined as *involuntary cheating*. In the second case an unfair participant is able to profit, for instance, of a design flaw in the contest organization, in order to favor a strategy it has submitted. It could be defined as *voluntary cheating*.

2.1 Iterated games

Iterated games studied here are based on the repetition of a simple game which is defined by a single payoff matrix.

Every iteration of a game is defined by choices made by players. Choices consist of a selection in a fixed list of available moves³. Combination of the move selected by players in a specific iteration defines an outcome of the simple game. The payoff matrix defines payoff obtained by each player for any reachable outcome in an iteration. Iteration will be later called round; the complete sequence of iterations referenced as a meeting, a match or simply a game. The final payoff of a player is simply the sum of all iteration's payoff. The goal of all players is the same: to maximize their final payoff.

A player is identified by predetermined choices following a strategy. This strategy allows, for any given iteration, to know the move a player will use according to previous reached outcomes and in particular according to previously moves played by opponents.

Using computer science terminology a strategy is identified to a program and a behavior during an iterate game to an execution of this program.

In the CIPD there are only two players and two moves available in the simple game. These moves are noted C (for Cooperation) and D (for Defection). For every iteration players choose their moves simultaneously. The payoff matrix is presented in table 1. This matrix is known by both players.

Table 1. Classical Iterated Prisoner's Dilemma payoff matrix.

	C	D
C	3	0
D	5	1

This matrix is a Prisoner's Dilemma payoff matrix. This game involves 2 players and 2 different moves (C and D). Available moves are the same for each player. It is a symmetric matrix: payoff of player A for outcome (C,D), that is when A played C and B played D, is the same as payoff for player B for the outcome (D,C), that is when A played D and B played C; which is 0. Matrix shows thus only the payoff of row player.

In this paper we will only use simple strategies usable in the CIPD:

- a11_c always plays C whatever opponent played.
- a11_d always plays D whatever opponent played.
- tit_for_tat plays C as first move, then plays whatever move opponent played in the previous iteration.
- spiteful plays C until the opponent played D, then always D.
- soft_majo plays the move the opponent has used more often in previous iterations (the majority move). If it played C as many time as D then plays C.
- per_X plays periodically moves in the sequence X. For instance per_CDD, also noted as (CDD)*, plays periodically C,D,D.

³ These moves are the available strategies of the simple game

2.2 Evaluation method

The most used strategy's evaluation method is simply the comparison of its payoff to the one of another strategy. The higher the payoff is, the better the strategy is considered. To evaluate all strategies of a fixed set it is then sufficient to sum scores of each strategies against every other and finally to rank them on the basis of their scores.

For a two-player game, computing such a *round-robin* tournament on set S containing n strategies is simply to fill a $n \times n$ matrix and then to sum value of each lines in order to get the score of each strategy.

It has to be noticed that in such tournament a strategy's score does not necessarily include its score when playing against itself. To the end of the paper and in order not to deal explicitly with the contribution of such inclusion, at least in term of robustness, we will consider that all cells on the diagonal of tournament matrices are nulled. That simplification does not change anything to ideas developed herein and almost nothing to examples chosen as illustrations.

With such a method the higher a strategy is ranked the better its value is considered. Quality of the evaluation depends however essentially in the size of the strategies set.

Classically in order to get a big number of strategies one may organize a contest open to everyone. It is asked to every participant to submit **one** strategy which respects rules of the played game. A big tournament is then computed with all submitted strategies as the set to be evaluated. The basic idea is here to allow the research of new *good* strategies for a specific game. The contest is used as a way to insure diversity and heterogeneity in behaviors.

This method has been regularly used, in particular on the CIPD. One can think to Robert Axelrod contest in the beginning of eighties, see [1], to the French edition of the Scientific American in the beginning of nineties, see [4] for the announcement and [5] for the results, as well as to some scientific conferences such as Artificial Life V in 1996 or the Conference on Evolutionary Computation in 2000. In scientific conferences the goal is often to test new techniques (such as evolutionary computation) when applied to strategies for the iterated prisoner's dilemma.

In all cases *modus operandi* is always the same. Someone asks people to submit strategies. Let us call it the organizer. It has the responsibility to collect strategies and to test them in the most objective way using computer simulations. People submitting strategies are called participants. They submit their proposition by sending the organizer some source code of a computer program, a textual description, or simply by filling a web form, explaining the behavior they want to propose. The organizer generally is in charge of objectivity of the contest. It is the one who runs simulations and thoroughly study their results. The only purpose of such contest is to determine some efficient strategies in a specific situation, not to find a *realistic* mathematical model of a social interactive situation. The organizer insures that all participants are aware of that fact.

3 Cheating without communicating

3.1 Normalization

One of the well known problems with iterated version of prisoner's dilemma is the length of games. If both players know when the meeting will end (last iteration) then an iterated game is equivalent to a simple one. In such situation both players have to play D all the time. It has to be avoided.

One of the chosen solution is to use a discount rate. It allows to give less signification to future moves compared to already played

one. For any formal studies with infinite meeting without any real or computed simulations this make sense. Outside of this context it becomes very difficult to chose a value for this rate and even more difficult to justify this choice. Moreover infinite is not a realizable concept in computer science.

When using simulations it is often preferred to pseudo randomly choose a length at the beginning of every game of a tournament. This pseudo-random number generation is done for a fixed variance. Result of the generation is of course not available to players nor before, nor during the meeting.

It may however be possible for an unfortunate player to always get short meeting compared to the average length. In such conditions it may be badly evaluated whereas, with some luck, evaluation could be completely different. Let us illustrate this using 3 strategies `all_d`, `tit_for_tat`, $(CD)^*$, and consider the following game length:

Players	Game Length
$(CD)^*$ vs <code>all_d</code>	m
<code>all_d</code> vs <code>tit_for_tat</code>	n
<code>tit_for_tat</code> vs $(CD)^*$	p

According to these length, to the CIPD payoff matrix (table 1) and the definition of strategies, payoff obtained by each strategies during a tournament are:

	<code>all_d</code>	$(CD)^*$	<code>tit_for_tat</code>
<code>all_d</code>		$6(m/2)$	$n + 4$
$(CD)^*$	$m/2$		$(5p/2) + 3$
<code>tit_for_tat</code>	$n - 1$	$(5p/2) - 2$	

With $n = 50$, $m = 100$, $p = 60$, which means an average deviation of 20, the obtained rank is:

1. `all_d` with 354 points ;
2. $(CD)^*$ with 203 points ;
3. `tit_for_tat` with 197 points.

On the other hand with $n = 50$, $m = 60$, $p = 100$, which means we stay at a average deviation of 20, the rank becomes:

1. `tit_for_tat` with 297 points ;
2. $(CD)^*$ with 283 points ;
3. `all_d` with 234 points.

It is important to notice that these 2 ranks have completed different head and tail. It is also to be noticed that average deviation and standard deviation stay constant in both cases: 20 and 26.46.

With a normalization of game length to $n = m = p$, we then get the following rank:

1. `all_d` with $4(n + 1)$ points ;
2. $(CD)^*$ with $3(n + 1)$ points ;
3. `tit_for_tat` with $\frac{7n}{2} - 3$ points.

Naturally for the two previous tournament using another normalization process, consisting in the computation of the average score for each iteration, we get a similar rank, which is however different from the two firsts:

1. `all_d` with an average payoff of 4 points ;
2. `tit_for_tat` with an average payoff of 3 points ;
3. $(CD)^*$ with an average payoff of 3.5 points.

Game length has to be unknown by players. Contest organizer has however to choose between using the same pseudo-randomly computed length for every game in the contest, or normalizing scores according to number of rounds played by each strategies. If a tournament is used as an evaluation method player do not have to play against itself.

In the rest of this paper we will use game of 10 rounds for every example and illustration.

3.2 Clones strategies

In some particular context 2 different strategies (program) may produce the same behavior (execution). Let us consider for illustration `tit_for_tat` and `spiteful`. They are different since they use different concepts. They however produce the same behavior against 2 strategies as uncommon as `all_c` and `all_d`.

In a general manner the same case may arise when dealing with genotype and phenotype. Using computer science terminology it is trivial to say that two completely different programs may produce the same results.

That may be viewed from another angle. Many strategies with different names may finally be exactly the same ones. In such case, the use of such a strategy in a contest is a clear bias of the final evaluation and thus devalue the quality of it.

If, for instance, we use n times the same strategy `S1` (by means of same code but different names) in a set of strategies all different when compared by pair (by mean of different code), then it may be possible that `S1` is the best evaluated one. When the same strategy is used only once with the same set of competitors then it may be another strategy than `S1` which is considered the best.

Considering `tit_for_tat` as `S1` as well as `all_d`, and `(CD)*` for the set of competitors it is then easy to see that such situation may arise very clearly, even with tournament composed by game of only 10 rounds:

TOURNAMENT RANK	TOURNAMENT RANK
1 : <code>all_d</code> = 44	1 : <code>tit_for_tat</code> = 62
2 : <code>per_cd</code> = 33	2 : <code>tit_for_tat</code> = 62
3 : <code>tit_for_tat</code> = 32	3 : <code>per_cd</code> = 61
	4 : <code>all_d</code> = 58

We showed how the repeated use of a strategy may influence results of tournament. This frequent bias may arise in 2 cases:

- when 2 strategies have similar implementation code but different names. It is then very easy for a participant of a contest to favor its proposition by flooding it with a very big number of the same strategy using different names each time. In another context (combinatorial auctions, see [10]) a problem close to this one has been identified as *false-name bid*.
- when 2 strategies have different code, different names but produce the same execution due to the simulation context. It is a classical problem in computer science since there is an infinite number of way to write the same thing.

Moreover, it has to be noticed that deciding if two strategies are similar in the general case is impossible. That is a very strong knowledge in theoretical computer science derived from the fact that it is impossible to decide if two programs (Turing machines) have identical behavior (accept the same language). This decision problem is not recursively enumerable. It is however perfectly decidable in some more constraints cases where strategies are defined by filling a predefined structure. This last method is often used on web contest where

participants fill web form in order to define a strategy. This is, however, less interesting since, in such cases, it is often possible to make some tournament involving all possible instances, see work presented in [2] as an example.

4 Cheating with communication

In most cases, players do not know strategies used by their opponents. They may try to deduce it from the behavior of others players. This is a difficulty and one of the major interest of using computational game theory, which we can call *behavioral inference*. At the opposite, let us suppose that you know the strategy of your opponent before playing. In this case it could be easy to determine the best reply to it and thus to maximize your payoff.

Although it is forbidden to communicate *directly* with its opponent, in order for instance to make a deal and agree on the behavior to adopt, it is possible to use the history of played moves to communicate *indirectly*. One of the most trivial idea is then to use some kind of starter succession of moves, used by others to identify you.

Communication can then be established by some coding system fixed in advance by the strategy creator.

With such hypothesis two kind of cases may be considered:

- a unique strategy used by different participants who try to recognize themselves;
- different strategies whose goal of some is to favor the profit of some other.

4.1 Strategies which recognize themselves

We illustrate one such case through a strategy which plays a specific starter succession of moves and then cooperates always after this succession if it observed the same starter played by the opponent and else defects.

If half the population uses the same strategy, then one member of the subpopulation using it has a great chance to be the winner. On the other hand if only one participant uses it in the population then it has a great chance of being a loser since it could no more take advantage from the communication.

Let us consider the `cheater` strategy which plays the `(CDDC)` starter, then observe what the opponent played in the 4 first moves. If opponent played the same succession of moves as the starter then `cheater` cooperates always, else it defects always.

If 3 players using `cheater` are tested against `tit_for_tat`, `spiteful` and `soft_majo` the tournament winner is `cheater`. If the same experiment is done with only one instance of `cheater` then it appears to be the last of the final tournament rank:

TOURNAMENT RANK	TOURNAMENT RANK
1 : <code>cheater2</code> = 109	1 : <code>spiteful</code> = 75
2 : <code>cheater3</code> = 109	2 : <code>tit_for_tat</code> = 74
3 : <code>cheater</code> = 109	3 : <code>soft_majo</code> = 73
4 : <code>spiteful</code> = 105	4 : <code>cheater</code> = 57
5 : <code>tit_for_tat</code> = 102	
6 : <code>soft_majo</code> = 99	

Once 2 players using `cheater` recognizes themselves they win 3 points each and on each round, whereas the rest of time they make others players losing at least 2 points.

Generally this kind of behavior is easily identifiable on tournament results since all strategy using it are grouped at the same level in the final rank (at least when using purely deterministic strategies). This

does not show the same effect as in the previous section where the same strategy is used by more than one player. Here strategies have different behavior adapted to different opponent.

4.2 Master/Slaves

On the same principle as in the previous example it is possible to establish a strategy taking advantage of some others agreeing strategies. The one who benefits is said to be the master and the others to be the slaves.

Compared to the previous example once strategies have recognized themselves then on each round the master win 5 points defecting against its slaves, which agree to be slave by cooperating only with the master. Against others players slaves may use any other aggressive behavior.

Let us consider that the master strategy plays (CDDC), then if it is recognized the same starter played by its opponent always plays D, and if not plays as tit_for_tat.

The slave plays exactly as cheater: it plays (CDDC) then if the opponent did the same starter it cooperates, and else defects.

If master is evaluated against cheater, tit_for_tat and soft_majo it wins the tournament whereas the slave one is ranked last. In the case of no slave the master takes the last position:

TOURNAMENT RANK		TOURNAMENT RANK	
1 :	master = 105	1 :	tit_for_tat = 84
2 :	tit_for_tat = 98	2 :	soft_majo = 83
3 :	soft_majo = 96	3 :	spiteful = 75
4 :	spiteful = 90	4 :	master = 67
5 :	cheater = 65		

Such example could even be refined considering one master but n slaves with completely different starter for each slave. The master job would then only be to recognize the different slaves and to use some other rather *good* strategies against *real* opponent such as tit_for_tat or spiteful.

It has to be noticed that the harmful effect of slaves can be selective. For instance a slight modification of cheater (replacing all_d by tit_for_tat) may harm only aggressive strategies.

In a real contest one has however to find another participant who accepts to be slave, that is using a strategy which have a lot of chance to be badly evaluated. If such coalitions could be identified one solution is then to set the score of each member of the coalition as the average payoff of all member of it. Unfortunately this identification is often difficult to do

Public contest may avoid as far as possible the possibility for one participant to offer more than one strategy. Collusion, such as those shown here, may nevertheless appear since agreement or coalition between different participants before the contest are not avoidable.

The final rank has then to be particularly well studied in all its details, and, at least, strategy of players with the same final payoff have to be investigated.

5 Conclusion

Computational Game Theory deals with the evaluation of heuristic strategies using iterated game. It is some kind of empirical Game Theory. When full game-theoretic analysis is intractable or unuseful, and, as in the general case, it is not possible to prove formally that a strategy is better than another, computer simulations become essential. It generally uses a very specific multi-agent based approach

where agent's behaviors are defined by human participants in public contest. All around the world this method is very often used on different kind of game.

Through the CIPD, we showed in this paper that this kind of evaluation can not be done without any precaution, and that false, or at least biased, results may be found. It is very easy to favor one particular kind of strategy, consciously or not. We described different types of skews one should be aware of and take care about (computation method, repetition of strategies, master/slave effects, etc.).

All along the presentation we tried to give number of examples which we described precisely so that they can be verified and reproduced. We tried to make a short survey of what has to be done or not when using computer simulations for iterated game strategies comparison. Even if you could not present them here, methodological solutions to problem presented here exist. They are mainly based on evolutionary computation ideas and on sets of reference.

In this particular context of strategies evaluation, we basically state that scoring/ranking methods are part of the game. They thus have to be described with the game. All participants must have the same level of information on the contest in order, for instance, to arm themselves against some flaws described here. Changing the purpose of a contest after its start or favoring some participants is cheating.

Many points described here may seem to be widely known or at least trivial. With the rise of contests falling in all traps described here, we fear that finally they are not so well known. We think that with the growth of interest of such methods they have to be detailed and at least exposed clearly.

Computational, as Empirical Game Theory are crossing a major step of its evolution. It may be a very efficient method for evaluating and later constructing new *artificial intelligent* behaviors. In order to achieve this goal, it has to be used seriously.

Mediation in the framework of morpho-logic

Isabelle Bloch¹ and Ramón Pino-Pérez² and Carlos Uzcátegui²

Abstract. In this paper we introduce a median operator between two sets of interpretations (worlds) in a finite propositional language. Our definition is based on morphological operations and Hausdorff distance. It provides a result which lies “halfway” between both sets and accounts for the “extension” or “shape” of the sets. We prove several interesting properties of this operator and compare it with fusion operators. This new operator allows performing mediation between two sets of beliefs, preferences, demands, in an original way, showing an interesting behavior that was not possible to achieve using existing operators.

1 INTRODUCTION

Consider the situation of two agents who are settling the differences between the demands (goals, etc.) of the members of the parties they represent. One of the negotiating conditions is that each demand should receive a fair treatment. The final output of the process should be a new set of demands (for instance, for the merging of the two parties).

This problem reminds the problem faced by fusion [3] where a finite collection of belief sets is merged into another belief set. However, a general fusion operator will not take into account each belief of each party, only consensual beliefs are important. For instance, let X and Y represent respectively the demands of the parties. When X and Y have non empty intersection, any fusion operator will let $X \cap Y$ to be the result of the fusion. The reason is that fusion relies mostly on the parts of X and Y which are the “closest” to each other. The purpose of this paper is to introduce a *median operator* \odot such that $X \odot Y$ lies “halfway” between X and Y and partly satisfies the demands of every member of both parties. This will be achieved by means of the Hausdorff distance which takes into account the “extension” or “shape” of X and Y . The idea of the median is coming from works in Mathematical Morphology about interpolations between compact sets in metric spaces [6]. The idea of Morpho-logic has been already useful for dealing with others operators that naturally appear in AI problems [2].

As it happens with fusion operators, where beliefs are given at the semantical level, we assume that the sets of demands X and Y are given as sets of interpretations (worlds) in a finite propositional language. We use a distance function d between worlds to measure the similitude between worlds (for all practical purposes the reader can assume that d is the Hamming distance). The distance d gives a method to represent the closest worlds to a set X . In fact, let $\delta(X)$ be the collection of all worlds w such that $d(w, X) \leq 1$, where $d(w, X) = \min\{d(w, x) : x \in X\}$. In morphological terms, $\delta(X)$

is called a dilation of X by a ball of radius 1. More generally, the dilation of X of any radius r is the set $\delta_r(X)$ of all w such that $d(w, X) \leq r$.

The Hausdorff distance between X and Y is the smallest integer ρ such that $X \subseteq \delta_\rho(Y)$ and $Y \subseteq \delta_\rho(X)$. Then ρ measures the compromise that both X and Y should make in order to satisfy all demands of the other party. Our median operator satisfies that $d(z, X \odot Y) \leq \rho/2$ for all $z \in X \cup Y$. It is in this sense that $X \odot Y$ lies “halfway” between X and Y . This is a consequence of the fact that \odot has a stronger property: if $x \in X$ and $y \in Y$ then any path from x to y of length at most ρ will meet $X \odot Y$ (the details are given later).

We first recall, in Section 2, the definition of some fusion operators. In Section 3 we introduce a median operator constructed via dilation and Hausdorff distance, study some of its properties and compare it with the fusion operator. In Section 4 we introduce another median operator constructed via dilation, erosion and Hausdorff distance; we compare this operator to the previous one and study some of its properties. In Section 5 we present a procedural approach to compute \odot .

2 FUSION

In this section we recall some previous definitions of fusion [2]. In order to make the exposition more readable, we assume that Ω , the set of worlds, is finite and we fix the distance d as the Hamming distance between worlds. Nevertheless our results hold for all distances $d : \Omega^2 \rightarrow \mathbb{N}$ having the following property (of normality): for all $X \subseteq \Omega$ such that $X \neq \emptyset$ and $X \neq \Omega$, there is a $\omega \in \Omega \setminus X$ such that $d(\omega, X) = 1$.

Let us begin recalling the morphological definition [2] of the Δ^{max} operator [3], denoted here by Δ in order to simplify the notation:

$$X\Delta Y = \delta_n(X) \cap \delta_n(Y) \quad (1)$$

where $n = \min\{k : \delta_k(X) \cap \delta_k(Y) \neq \emptyset\}$.

Since dilations are defined using centered balls of a distance d as structuring elements, they are extensive, i.e. $X \subseteq \delta_r(X)$ (this property will be often used in the following). Other useful properties of dilation are iterativity ($\delta_r(\delta_{r'}(X)) = \delta_{r+r'}(X)$) and monotony ($X \subseteq Y \Rightarrow \delta_r(X) \subseteq \delta_r(Y)$).

Let $m = d_{\min}(X, Y)$ be the minimum distance between X and Y , i.e. $d_{\min}(X, Y) = \min\{d(x, y) : x \in X, y \in Y\}$. Our next definition is a variant of Equation (1):

$$X\Delta' Y = \begin{cases} \delta_{m/2}(X) \cap \delta_{m/2}(Y) & \text{if } m \text{ is even,} \\ (\delta_{\lfloor m/2 \rfloor}(X) \cap \delta_{\lfloor m/2 \rfloor+1}(Y)) \\ \cup (\delta_{\lfloor m/2 \rfloor+1}(X) \cap \delta_{\lfloor m/2 \rfloor}(Y)) & \text{if } m \text{ is odd.} \end{cases} \quad (2)$$

² Departamento de Matemáticas - Facultad de Ciencias - Universidad de Los Andes, Mérida, Venezuela - pino@ula.ve, uzca@ula.ve

Note that if m is even, Δ' and Δ are identical operators. In case m is odd, this new definition avoids dilating “too much”. Then Δ' may be preferred to Δ .

In general, $X\Delta'Y \neq X\Delta Y$ if m is odd (in this case, the value of n in equation (1) is $n = \lfloor m/2 \rfloor + 1$). In general we have:

$$X\Delta'Y \subseteq X\Delta Y \quad (3)$$

(with an equality if m is even). This is illustrated in Figure 1.

Note that $X\Delta Y = X \cap Y$ if $X \cap Y \neq \emptyset$ (in this case $n = 0$).

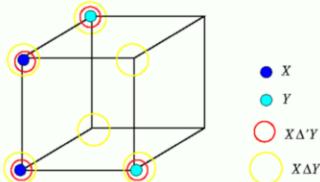

Figure 1. Fusion using Δ and Δ' . The vertices of the cube represent worlds and edges link worlds at distance 1 from each other.

There are some relationships between the two well known fusion operators Δ^{\max} and Δ^Σ ³ [3]. We have, in fact, the following proposition:

Proposition 1 For any X and Y , $X\Delta'Y = \Delta^{\max}(X, Y) \cap \Delta^\Sigma(X, Y)$.

It has been proved in [4] that Δ^Σ is a merging operator and Δ^{\max} is a quasi-merging operator. Thus Δ' satisfies all the common postulates (of merging and quasi-merging) that pass to the intersection. For instance, the consistency axiom: $X \cap Y \neq \emptyset$ entails $X\Delta'Y = X \cap Y$.

Next, we introduce some definitions which will be useful in the following. Namely, they will be helpful to show that the operator Δ' can be characterized as in Proposition 2.

A path α between two elements x and y of Ω is a sequence, x_0, \dots, x_n of points in Ω such that $d(x_i, x_{i+1}) = 1$ for any $i = 0, \dots, n - 1$. The length of such a path α , denoted $|\alpha|$, is n . The set of paths between x and y is denoted $P(x, y)$. If $\alpha = x_0, \dots, x_n$ is a path, we define the set of central points of α , denoted $c(\alpha)$, as $\{x_{n/2}\}$ if n is even and $\{x_{\frac{n-1}{2}}, x_{\frac{n+1}{2}}\}$ otherwise. We will say that an operator Δ_1 is *smaller or equal* than an operator Δ_2 if and only if for any input (X, Y) , $X\Delta_1 Y \subseteq X\Delta_2 Y$.

Proposition 2 The operator Δ' is the smallest operator \diamond having the following property: for all $x \in X$, for all $y \in Y$ and for all path $\alpha \in P(x, y)$, if $|\alpha| \leq m$ then $c(\alpha) \subseteq X \diamond Y$, where $m = d_{\min}(X, Y)$.

Even if this operator enjoys good properties, it is not adequate for some purposes, namely in order to get a global consensus as the following simple example shows:

Example 3 Suppose X and Y represent the political agenda of the Labor Party and the Green Party, respectively. They would like to find an agreement in order to present a common platform for the next elections. As it usually happens, there are several leanings in each of the two parties. In order to simplify, suppose there are two leanings in each party, the left and central. Their positions about ten parameters are encoded by worlds. The parameters are the following: nationalization of big private companies; increasing the taxes

³ $\Delta^\Sigma(X, Y) = \{w : d(w, X) + d(w, Y) = \min_{w' \in \Omega} d(w', X) + d(w', Y)\}$

for the rich people; reducing the taxes for the poor people; increasing the budget of public health; increasing the budget for public education; creating a subvention for the unemployed persons; increasing the budget of research programs; reducing the subsidies for the big agriculture exploitations; creating subsidies for organic agriculture; fostering the public transports. The encoding is made in the following manner: $X = \{w_1, w_2\}$, $Y = \{w_1, w_3\}$, where $w_1 = (1, 1, 1, 1, 1, 1, 1, 1, 1, 1)$ is the encoding of the left wing in both parties, the central wing in the Labor Party is encoded by $w_2 = (0, 0, 0, 1, 1, 1, 0, 0, 0)$ and the central wing in the Green Party by $w_3 = (0, 0, 0, 0, 0, 0, 1, 1, 1)$. If the policy adopted for merging these leanings is a classical fusion, in which the result is $\{w_1\}$ (the intersection of both groups), they run the risk of the splitting of both political parties. Thus they have to adopt a different policy in order to reach an agreement more fair to all leanings.

The rest of the paper is dedicated to study some operators proposed as an alternative to classical merging operators. These operators are called median operators and take inspiration from Mathematical Morphology [5], in particular [6].

3 MEDIAN FROM HAUSDORFF DISTANCE

One of the main features of the morphological setting is that it offers different ways of talking about closeness. One of them has already been evoked in the previous section when we defined the minimum distance m between X and Y . Actually this notion does not define a distance⁴ between elements of $\mathcal{P}^*(\Omega)$, the set of nonempty subsets of Ω (because $m = 0$ iff $X \cap Y \neq \emptyset$). However, there is a true distance between elements of $\mathcal{P}^*(\Omega)$. This distance, d_H , is the so called Hausdorff distance, defined from d in the following way:

$$d_H(X, Y) = \max\{\max\{d(x, Y) : x \in X\}, \max\{d(y, X) : y \in Y\}\} \quad (4)$$

where $d(w, Z) = \min\{d(w, z) : z \in Z\}$, for $w \in \Omega$, $Z \in \mathcal{P}^*(\Omega)$.

It is easy to check that d_H is indeed a distance. In order to simplify the notation, when X and Y are fixed, we put $\rho = d_H(X, Y)$.

Note that, by definition, ρ can be viewed as a measure of the degree of global disagreement between X and Y : among the distances between an element of X and Y and between an element of Y and X , ρ is the largest one. Another way to understand the meaning of ρ is given by the following identity:

$$\rho = \min\{n : X \subseteq \delta_n(Y) \wedge Y \subseteq \delta_n(X)\} \quad (5)$$

Thus, the set $\delta_\rho(X) \cup \delta_\rho(Y)$ has a natural “fairness property”, but it is in general too big. We propose a better solution guided by the notion of interpolation.

The notion of interpolating set in our discrete case is:

$$Z_n = \delta_n(X) \cap \delta_{\rho-n}(Y) \quad (6)$$

for $n = 0, 1, \dots, \rho$. When n is roughly $\rho/2$, then the interpolating set Z_n “lies half way between” X and Y . Thus, the definition of our median operator is as follows:

$$X \odot Y = \begin{cases} \delta_{\rho/2}(X) \cap \delta_{\rho/2}(Y) & \text{if } \rho \text{ is even,} \\ (\delta_{\lfloor \rho/2 \rfloor}(X) \cap \delta_{\lfloor \rho/2 \rfloor+1}(Y)) \cup (\delta_{\lfloor \rho/2 \rfloor+1}(X) \cap \delta_{\lfloor \rho/2 \rfloor}(Y)) & \text{if } \rho \text{ is odd.} \end{cases} \quad (7)$$

Note that $\lfloor \rho/2 \rfloor + 1 = \rho - \lfloor \rho/2 \rfloor$.

We will show next that \odot is indeed a well defined operator and then show some of its properties.

⁴ Remember that a distance have to satisfy $d(X, Y) = 0 \Leftrightarrow X = Y$; $d(X, Y) = d(Y, X)$ and triangle inequality.

Properties

1. Let $Z_{\rho'} = \delta_{\rho'}(X) \cap \delta_{\rho-\rho'}(Y)$ for $\rho' \in \{0, \dots, \rho\}$. Then $Z_{\rho'} \neq \emptyset$.

Proof: since the Hausdorff distance is ρ , there exists x in X and y in Y and a path $x_0 = x, \dots, x_\rho = y$ of length ρ such that $d(x_i, x_{i+1}) = 1$. For $i = \rho'$, we have $x_{\rho'} \in \delta_{\rho'}(X)$. Since $d(x_{\rho'}, y) \leq \rho - \rho'$, we have also $x_{\rho'} \in \delta_{\rho-\rho'}(Y)$. (The path can be decomposed into a path $x = x_0 \dots x_{\rho'}$ of length ρ' and a path $x_{\rho'} \dots x_\rho = y$ of length $\rho - \rho'$). Hence $x_{\rho'} \in Z_{\rho'}$. ■

This results proves that the definition of $X \odot Y$ is consistent:

$$X \odot Y \neq \emptyset \quad (8)$$

2. Since the dilations are extensive, we have:

$$X \cap Y \subseteq X \odot Y \quad (9)$$

3. Link between median and fusion:

- if $m < \rho$, then $X \Delta Y \subseteq X \odot Y$ (see Figure 2);
- if $m = \rho$ and is an even number, then $X \Delta Y = X \odot Y$ (see Figure 3);
- if $m = \rho = 1$, then $X \odot Y = X \cup Y \subseteq X \Delta Y$.
- if $m = \rho$ and is an odd number, then $X \odot Y = X \Delta' Y$ and therefore (by Proposition 1) $X \odot Y \subseteq X \Delta Y$.

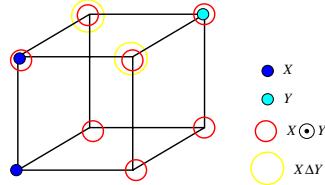

Figure 2. An example where $\rho = 3$ and $m = 2$ and $X \Delta Y \subseteq X \odot Y$.

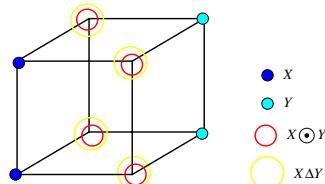

Figure 3. An example where $\rho = m = 2$ and $X \Delta Y = X \odot Y$.

Proof:

- $m < \rho$, ρ and m even: then $n = m/2$, and $X \Delta Y = \delta_{m/2}(X) \cap \delta_{m/2}(Y)$, which is included in $\delta_{\rho/2}(X) \cap \delta_{\rho/2}(Y)$ since $m < \rho$ and dilation is increasing with respect to the size of the structuring element.

- $m < \rho$, ρ odd and m even: then $m < \rho - 1$ hence $2n \leq \rho - 1$ and $n \leq \lfloor \rho/2 \rfloor$. Therefore we have $\delta_n(X) \subseteq \delta_{\lfloor \rho/2 \rfloor}(X) \subseteq \delta_{\lfloor \rho/2 \rfloor + 1}(X)$ and the same for Y , from which we deduce $\delta_n(X) \cap \delta_n(Y) \subseteq X \odot Y$.

- $m < \rho$, m odd: then $n = \lfloor m/2 \rfloor + 1$ ($2n = m + 1$), hence $m + 1 \leq \rho$ and $2n \leq \rho$. If ρ is even, then $n \leq \rho/2$ and $X \Delta Y \subseteq X \odot Y$ (as for the first case). If ρ is odd, since $2n$ is even, we have $2n \leq \rho - 1$ and $n \leq \lfloor \rho/2 \rfloor$. Therefore $X \Delta Y \subseteq X \odot Y$ (as for the second case).

- $m = \rho$ and even: then $n = m/2 = \rho/2$ and $\delta_n(X) \cap \delta_n(Y) = \delta_{\rho/2}(X) \cap \delta_{\rho/2}(Y)$.

- $m = \rho = 1$: then $n = 1$ and $\lfloor \rho/2 \rfloor = 0$. Therefore we have $X \subseteq \delta_1(Y)$ and $Y \subseteq \delta_1(X)$ (from the definition of Hausdorff distance) and $X \odot Y = X \cup Y$. Moreover, $X \cup Y \subseteq \delta_1(X)$ and $X \cup Y \subseteq \delta_1(Y)$, so $X \cup Y \subseteq \delta_1(X) \cap \delta_1(Y) = X \Delta Y$. ■

The last case is illustrated in Figures 4 and 5 in two different situations.

A consequence of this result is that if ω is in $X \Delta Y$ and if $d_{\min}(X, Y) = m$, this does not imply that there is x in X and y in Y such that $d(x, \omega) + d(\omega, y) = m$. An example of ω is shown in Figure 5 for which $d(x, \omega) + d(\omega, y) \geq 2$.

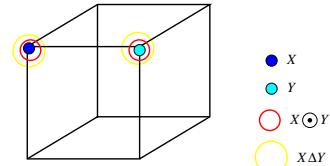

Figure 4. An example where $\rho = m = 1$ and $X \Delta Y = X \odot Y$.

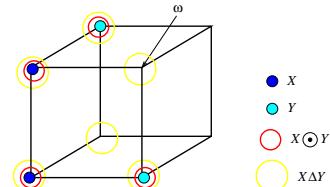

Figure 5. An example where $\rho = m = 1$ and $X \odot Y \subset X \Delta Y$.

Note that this property tells that when $m < \rho$, then $X \Delta Y \subseteq X \odot Y$ and when $m = \rho$, then $X \odot Y \subseteq X \Delta Y$.

4. Commutativity: $X \odot Y = Y \odot X$ (by construction).
5. Since $d_H(X, X) = 0$, we have $X \odot X = X = X \Delta X$.
6. \odot is not associative. A counter-example is shown in Figure 6.

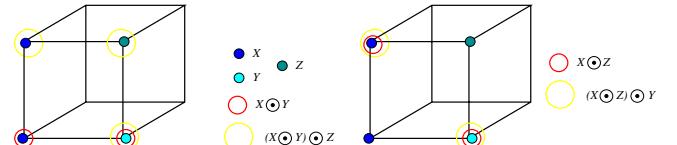

Figure 6. An counter-example of associativity.

7. \odot is not monotone, i.e. $X \subseteq X'$ does not entail generally $X \odot Y \subseteq X' \odot Y$.

Example 3 (continued) In this example we have $\rho = 7$. The point $w = (0, 0, 0, 1, 1, 1, 1, 1, 1) \in X \odot Y$ and it is a distance 3 from w_2 and a distance 4 from w_3 . Notice that, unlike the Δ operator, \odot does not forget w_2 and w_3 . In fact, for every $z \in X \cup Y$, we can find a point $t \in X \odot Y$ such that $d(z, t) \leq 3$: for $z = w_1$ take $t = w_1$; for $z = w_2$ take $t = w$; for $z = w_3$ take $t = (0, 0, 0, 1, 1, 1, 1, 1, 1)$.

Now we present the definition of a median operator. It is motivated by the properties of \odot . We will show that this notion captures the idea of getting a set that lies halfway between X and Y (see proposition 6).

Definition 4 An operator $\diamond : \mathcal{P}^*(\Omega) \times \mathcal{P}^*(\Omega) \rightarrow \mathcal{P}^*(\Omega)$ is said to be a median operator if \diamond satisfies the following condition:

$$\forall x \in X, \forall y \in Y, \forall \alpha \in P(x, y) \quad (|\alpha| \leq \rho \Rightarrow c(\alpha) \subseteq X \diamond Y) \quad (10)$$

Theorem 5 \odot is the smallest median operator, i.e. \odot satisfies Equation (10) and for all $X, Y \in \mathcal{P}^*(\Omega)$ and all operator \diamond satisfying Equation (10), $X \odot Y \subseteq X \diamond Y$.

Proof: It is enough to see that $z \in X \odot Y$ iff $\exists x \in X, \exists y \in Y$ and $\exists \alpha \in P(x, y)$ such that $|\alpha| \leq \rho$ and $z \in c(\alpha)$. The *if* part is easy to show: suppose $\alpha = x_0, x_1, \dots, x_n$ and n is even. Since $z = x_{\frac{n}{2}}$, z is in $\delta_{\frac{\rho}{2}}(X) \cap \delta_{\frac{\rho}{2}}(Y)$ and since $n \leq \rho$ and dilations are increasing we have $z \in \delta_{\frac{\rho}{2}}(X) \cap \delta_{\frac{\rho}{2}}(Y)$ (in case ρ is even) or $z \in (\delta_{\lfloor \rho/2 \rfloor}(X) \cap \delta_{\lfloor \rho/2 \rfloor+1}(Y)) \cup (\delta_{\lfloor \rho/2 \rfloor+1}(X) \cap \delta_{\lfloor \rho/2 \rfloor}(Y))$ (in case ρ is odd). A similar argument works when n is odd.

For the *only if* part, suppose ρ is even and that $z \in \delta_{\frac{\rho}{2}}(X) \cap \delta_{\frac{\rho}{2}}(Y)$. Thus there are two paths $x_0, x_1, \dots, x_k = z$ and $z = y_0, y_1, \dots, y_p$ with $x_0 \in X, y_p \in Y, k \leq \frac{\rho}{2}$ and $p \leq \frac{\rho}{2}$. So $\alpha = x_0, x_1, \dots, x_k, y_1, \dots, y_p$ is a path of length $k + p$. Note that $k + p \leq \rho$. We consider two cases. First, if $|k - p| \leq 1$, $z \in c(\alpha)$. Second, if $|k - p| \geq 2$ the path can be extended, via loops, to a path α' with $|\alpha'| \leq \rho$, $z \in c(\alpha')$ and $\alpha' \in P(x_0, y_p)$ (for instance if $k = p - 2$, $\alpha' = x_0, x_1, x_0, x_1, \dots, x_k, y_1, \dots, y_p$). The case ρ odd is similar. ■

Proposition 6 Suppose \diamond satisfies Equation (10), then the following holds:

$$d(z, X \diamond Y) \leq \rho/2, \text{ for all } z \in X \cup Y.$$

In particular, this is true for \odot . Note that the operator Δ' (which satisfies Proposition 2) does not enjoy a property analogous to Proposition 6, namely, there are X and Y and $z \in X \cup Y$ such that $d(z, X \Delta' Y) > m/2$.

4 MEDIAN FROM DILATION AND EROSION

In this section we present a different median operator. We first recall the definition of the erosion $\varepsilon_k(X)$ of size k of a set X : $w \in \varepsilon_k(X)$ if $\delta_k(w) \subseteq X$.

The idea for the new median operator is to use any parameter $\nu \geq m$ in Equation (7) instead of ρ . This method provides a whole family of operators \odot_ν as follows:

$$X \odot_\nu Y = \begin{cases} \delta_{\nu/2}(X) \cap \delta_{\nu/2}(Y) & \text{if } \nu \text{ is even,} \\ (\delta_{\lfloor \nu/2 \rfloor}(X) \cap \delta_{\lfloor \nu/2 \rfloor+1}(Y)) \\ \cup (\delta_{\lfloor \nu/2 \rfloor+1}(X) \cap \delta_{\lfloor \nu/2 \rfloor}(Y)) & \text{if } \nu \text{ is odd.} \end{cases} \quad (11)$$

Note that if $\nu > \rho$, then \odot_ν is a median operator. For instance, when $\nu = 2\rho$, then $X \cup Y \subseteq \delta_\rho(X) \cap \delta_\rho(Y)$. But the dilations can be very large, and therefore an erosion is applied on the result, leading to the following definition:

$$M'(X, Y) = \varepsilon_k(\delta_\rho(X) \cap \delta_\rho(Y)) \quad (12)$$

This definition is particularly interesting if we take:

$$k = \begin{cases} \rho/2 & \text{if } \rho \text{ is even,} \\ \lfloor \rho/2 \rfloor & \text{if } \rho \text{ is odd.} \end{cases} \quad (13)$$

From the next result and Theorem 2 it follows that M' is indeed a median operator, i.e. it satisfies the condition (10).

Theorem 7

$$X \odot Y \subseteq M'(X, Y) \quad (14)$$

Moreover, if $m < \rho$, then $X \Delta Y \subseteq X \odot Y \subseteq M'(X, Y)$.

Proof:

- ρ even, $k = \rho/2$:

$$X \odot Y \subseteq \varepsilon_{\rho/2}\delta_{\rho/2}(X \odot Y)$$

since $\varepsilon_{\rho/2}\delta_{\rho/2}$ is a closing, hence extensive. Since $\delta(A \cap B) \subseteq \delta(A) \cap \delta(B)$ for any dilation, we have:

$$X \odot Y \subseteq \varepsilon_{\rho/2}(\delta_{\rho/2}\delta_{\rho/2}(X) \cap \delta_{\rho/2}\delta_{\rho/2}(Y))$$

Since $\delta_{\rho/2}\delta_{\rho/2} = \delta_\rho$, we have $X \odot Y \subseteq M'(X, Y)$.

- ρ odd, $k = \lfloor \rho/2 \rfloor$:

$$X \odot Y \subseteq \varepsilon_{\lfloor \rho/2 \rfloor}\delta_{\lfloor \rho/2 \rfloor}(X \odot Y)$$

Since δ commutes with \cup , we have:

$$\begin{aligned} \varepsilon_{\lfloor \rho/2 \rfloor}\delta_{\lfloor \rho/2 \rfloor}(X \odot Y) &= \varepsilon_{\lfloor \rho/2 \rfloor}(\delta_{\lfloor \rho/2 \rfloor}(\delta_{\lfloor \rho/2 \rfloor}(X) \cap \delta_{\lfloor \rho/2 \rfloor+1}(Y)) \\ &\quad \cup \delta_{\lfloor \rho/2 \rfloor}(\delta_{\lfloor \rho/2 \rfloor+1}(X), \delta_{\lfloor \rho/2 \rfloor}(Y))) \end{aligned}$$

Therefore (with $\lfloor \rho/2 \rfloor + \lfloor \rho/2 \rfloor = \rho - 1$):

$$\begin{aligned} X \odot Y &\subseteq \varepsilon_{\lfloor \rho/2 \rfloor}((\delta_{\rho-1}(X) \cap \delta_\rho(Y)) \cup (\delta_\rho(X) \cap \delta_{\rho-1}(Y))) \\ &\subseteq \varepsilon_{\lfloor \rho/2 \rfloor}(\delta_\rho(X) \cap \delta_\rho(Y)) \end{aligned}$$

Indeed:

$$\begin{aligned} (\delta_{\rho-1}(X) \cap \delta_\rho(Y)) \cup (\delta_\rho(X) \cap \delta_{\rho-1}(Y)) &= \\ (\delta_{\rho-1}(X) \cup \delta_\rho(X)) \cap (\delta_{\rho-1}(Y) \cup \delta_\rho(Y)) \cap \dots &= \\ \delta_\rho(X) \cap \delta_\rho(Y) \cap \dots & \end{aligned}$$

which is included in $\delta_\rho(X) \cap \delta_\rho(Y)$. ■

Several examples are shown in Figure 7.

5 ORDERINGS AND PROCEDURAL APPROACH

A procedural approach can be derived from the following table ($\Sigma = d(\omega, X) + d(\omega, Y)$ and $\text{Max} = \max\{d(\omega, X), d(\omega, Y)\}$):

	X	Y	Σ	Max
ω_1	$d(\omega_1, X)$	$d(\omega_1, Y)$	Σ_1	Max_1
ω_2	$d(\omega_2, X)$	$d(\omega_2, Y)$	Σ_2	Max_2
...				
ω_n	$d(\omega_n, X)$	$d(\omega_n, Y)$	Σ_n	Max_n

The procedures for different operators are as follows:

- Δ -fusion (Δ^{max}): take ω_i having the smallest Max_i . This corresponds to the following total pre-order: $(d_1, d_2) \leq (d'_1, d'_2) \Leftrightarrow \max\{d_1, d_2\} \leq \max\{d'_1, d'_2\}$.
- Σ -fusion (Δ^Σ): take ω_i having the smallest Σ_i . This corresponds to the following total pre-order: $(d_1, d_2) \leq (d'_1, d'_2) \Leftrightarrow d_1 + d_2 \leq d'_1 + d'_2$.
- $\Delta' \subseteq \Delta^\Sigma \cap \Delta^{max}$ corresponds to the following order: $(d_1, d_2) \leq (d'_1, d'_2) \Leftrightarrow d_1 \leq d'_1$ and $d_2 \leq d'_2$. Δ' can be obtained from Σ -fusion and a second filter: $|d(\omega, X) - d(\omega, Y)| \leq 1$ (or minimizing the Max_i).

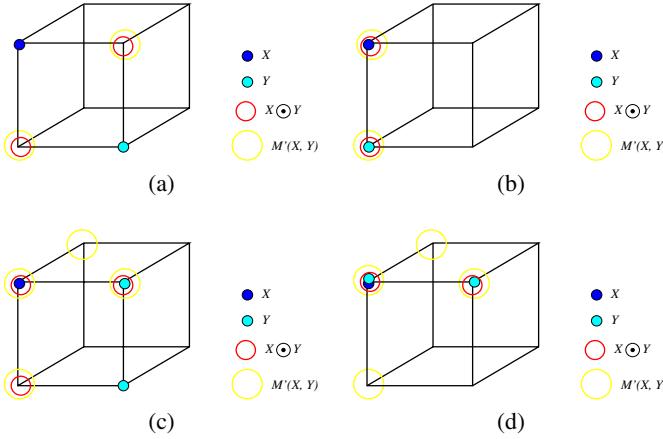

Figure 7. (a) An example with $\rho = m = 2$ and $M'(X, Y) = X \odot Y = X\Delta Y$. (b) An example with $\rho = m = 1$ ($k = 0$) and $M'(X, Y) = X \odot Y = X\Delta Y = X \cup Y$. (c) An example with $\rho = 2$, $m = 1$ ($k = 1$) and $X \odot Y = X\Delta Y$, $X \odot Y \subset M'(X, Y)$. (d) An example with $\rho = 1$, $m = 0$ ($k = 0$), $X\Delta Y = X$, $X \odot Y = X \cup Y$, and $X\Delta Y \subset X \odot Y \subset M'(X, Y)$.

- \odot can be obtained from the table in the following way: first take the set of ω such that $\Sigma \leq \rho$ then among these worlds take those satisfying $|d(\omega, X) - d(\omega, Y)| \leq 1$.
- Note that ρ can be calculated using the table: ρ is the maximum in the column of *Max* for the rows corresponding to worlds of $X \cup Y$.

One of the main features of this procedural approach is that it suggests very precise manners to extend the median operators to more than two elements.

Extensions to more than two elements $X_1 \dots X_k$: We propose three possible extensions:

1. Based on Proposition 1, we extend Δ' using the following procedure: minimize the column of Σ and then minimize the *Max*.
2. ρ can be generalized as follows:

$$\rho = \max_i \{d(\omega, X_i) : \omega \in X_1 \cup \dots \cup X_k\} \quad (15)$$

This number corresponds to the maximum of the columns of *Max* among the rows coming from worlds in $X_1 \cup \dots \cup X_k$.

Let $\bar{\rho} = (k-1)\rho$. First, take all ω such that $\Sigma \leq \bar{\rho}$. For the second step we have two alternatives: (i) keep only those ω such that the sum of $|d(\omega, X_i) - d(\omega, X_j)|$ is minimal; (ii) keep only those ω such that $|d(\omega, X_i) - d(\omega, X_j)| \leq k-1$.

Examples are shown in Figures 8 and 9.

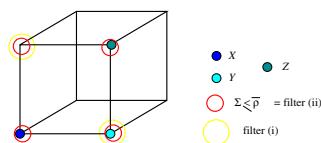

Figure 8. An example of extension to three elements.

3. First compute:

$$A_{ij} = X_i \odot_{2\rho} X_j = \delta_\rho(X_i) \cap \delta_\rho(X_j) \quad (16)$$

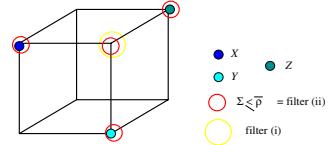

Figure 9. Another example of extension to three elements.

where ρ is given by Equation 15. The proposed operator is $\bigcap_{i \neq j} A_{ij}$. It is easy to show that this intersection is non empty. Notice also that if we take $X_i \odot_\rho X_j$ in (16) the intersection could be empty. Since the intersection could be very large, we can then take the most central part (the last non empty erosion). This is similar to the idea of barycenter. An example is shown in Figure 10.

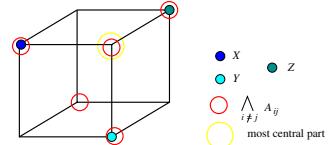

Figure 10. Extension to three elements using the last approach.

6 CONCLUSION

We have proposed the notion of median operator. The minimal of all median operators is denoted by \odot . The operator \odot is useful for computing the “middle interpolators” between two sets of beliefs, preferences or demands. This provides an original way to perform mediation or negotiation, showing interesting results which were not possible to achieve using existing operators. In particular we have shown that all parts of the two input sets are taken into account in the final decision, as opposed to classical fusion operators which account only for the parts that are the closest to each other.

Future work aims at further exploring the proposed extensions to more than two sets. Other definitions could also be developed, based on different morphological approaches, such as influence zones [1, 7]. Further applications to negotiations problems are also foreseen.

Strengthening Admissible Coalitions

Guido Boella and Luigi Sauro¹ and Leendert van der Torre²

Abstract. We develop a criterion for coalition formation among goal-directed agents, the indecomposable do-ut-des property. The indecomposable do-ut-des property refines the do-ut-des property (literally *give to get*) by considering the fact that agents prefer to form coalitions whose components cannot be formed independently. A formal description of this property is provided as well as an analysis of algorithms and their complexity.

1 Introduction

In this work we study the formation of coalitions among goal-directed agents. We start from a theory of social power and dependence introduced by Castelfranchi et al. [3]. In this context a coalition is intended as a group of agents which agree to cooperate for the achievement of a shared goal or to exchange with each other the achievement of their own goals. The second case is of particular interest as different networks of exchanges can be considered but not all of them are realizable.

We assume that the formation of a coalition is supported by unanimous and enforced agreements, i.e. a coalition is effectively formed only when all its members agree to it (unanimousness) and they cannot deviate from what established in the agreement, once they decide to enter it (enforcement). Under these assumptions, we develop a criterion of admissibility, the indecomposable do-ut-des property (i-dud in the following), establishing which coalitions cannot be formed under the assumption that the agents are self-interested. The i-dud property is a refinement of the do-ut-des property [2] which describes a condition of reciprocity: an agent *gives* a goal only if this fact enables it to *obtain*, directly or indirectly, the satisfaction of one of its own goals. The i-dud property refines the do-ut-des property by taking into account also the fact that a coalition formation process can itself be costly and usually the costs involved in a coalition formation process increase with the number of agents involved. Furthermore, being a coalition agreed unanimously, the more agents are involved in it, the larger is the risk of defections which can jeopardize the formation of the coalition. Thus, agents prefer to form coalitions which are as small as possible.

In Section 2 we define the i-dud property and provide some examples of this notion. In Section 3, we provide an algorithm to search all the sub-coalitions of a given coalition which satisfies the i-dud property. Even if this problem is not computationally tractable, we show in Section 4 that the problem to verify if a single coalition satisfies the i-dud property is tractable and, in several cases, also the complexity of the first problem may decrease considerably. Conclusions end the paper.

2 From do-ut-des to i-dud coalitions

Depending on the problem, a multiagent system can be represented at different levels of abstraction. For example, if you want to study how agents have to coordinate in order to achieve a goal or how agents should optimally use their resources, then a multiagent system can involve resources, actions, plans [1, 6]. Instead, if you want to study which coalitions are strategically admissible to be formed, you usually do not need such fine-grained descriptions of a multiagent system, coalitions are directly described by means of the consequences that they can attain collaborating, without any description about which joint plans agents have to perform [7, 10]. Following this idea, we describe potential coalitions abstracting from actions, plans or resources. However, in contrast with these approaches, we do not represent a coalition just indicating the set of goals that it can attain. We want to use the topology of goal exchanges inside a coalition to define our admissibility criterion.

Thus, inspired by Conte and Sichman [4] we represent a (potential) coalition as a labeled AND-graph of dependencies among agents. A labeled AND-graph consists of a set of nodes \mathcal{V} - which denotes the agents involved in the coalition - and a set \mathcal{E} of labeled AND-arcs. Denoting with Gl the goals exchanged in the coalition, a labeled AND-arc connects an agent ag_i to a nonempty set of agents Q and it is labelled with a goal $g \in Gl$, so it can be represented as a triple (ag_i, Q, g) . The meaning of such an arc is that the agent ag_i desires the goal g and the achievement of g is delegated to the set of agents Q . In order to represent a coalition a labeled AND-graph has to satisfy two further conditions. Since a coalition is intended as the result of an agreement process, the first condition is that only those agents that contribute to the achievement of some goals are admitted in this process. The second condition establishes that a coalition formation process does not involve private commitments that do not require any form of collaboration.

Definition 1 A coalition is represented as a labeled AND-graph which is a tuple $C = \langle \mathcal{V}, \mathcal{E} \rangle$, where \mathcal{V} is a finite set of nodes and $\mathcal{E} \subseteq \mathcal{V} \times (2^{\mathcal{V}} \setminus \{\emptyset\}) \times Gl$ is a set of labeled AND-arcs.

C satisfies two conditions: (1) for each node $ag_j \in \mathcal{V}$, there exists at least an AND-arc (ag_i, Q, g) such that $ag_j \in Q$ and (2) \mathcal{E} does not contain an AND-arc in the form $(ag_i, \{ag_i\}, g)$.

With an abuse of notation we mean with $(Q, g) \in C$ that there exists a $(ag_i, Q, g) \in \mathcal{E}$. Following [8] we call (Q, g) a commitment of C . A sub-coalition C' is intended a subgraph of C where some commitments are suppressed, $(Q, g) \notin C'$, for some $(Q, g) \in C$.

We want to restrict the notion of coalitions assuring, first, reciprocity, and, second, that no sub-coalitions of a coalition can be formed independently. The former property is called do-ut-des [2, 8], and we refine it to match the second requirement called indecomposability.

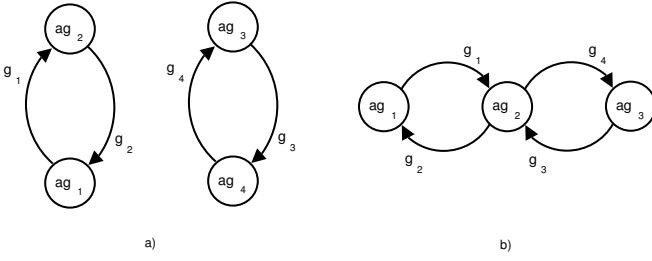

Figure 1. Two coalitions that satisfy the do-ut-des property but that do not satisfy the i-dud property.

The do-ut-des property assures that each chain of exchanges involved in a coalition returns something back to each agent involved in it. This property has been characterized in [2, 8] by means of a qualitative preference relation and a notion of dominance similar to those used in Game Theory, such as the notion of core. Here, instead, we propose a version of the do-ut-des property which is grounded on topological property of chains of exchanges; the equivalence with the dominance-based approach is shown in [8]. In [8] a goal is meant as a state of affairs that, once attained by a group of agents, benefits one or, in case, more agents. To simplify our formalism, we consider that there do not exist two agents which desire the same goal.

We introduce some preliminary notions. A finite sequence of AND-arcs $\mathcal{P} = (ag_{i_1}, Q_1, g_1), \dots, (ag_{i_n}, Q_n, g_n)$ is a path if for all $2 \leq h \leq n$, $ag_{i_h} \in Q_{h-1}$. Paths formalize possible *chains of exchanges* among the agents. We denote with $out(ag_i)$ the set of labeled AND-arcs outgoing the agent ag_i , i.e. $out(ag_i) = \{(ag_j, Q, g)\}$. Given $\mathcal{O} \subseteq out(ag_i)$, we call \mathcal{O}^* the propagation of \mathcal{O} , i.e. the set of AND-arcs containing all the paths $\mathcal{P} = (ag_{i_1}, Q_1, g_1), \dots, (ag_{i_n}, Q_n, g_n)$ such that (1) $(ag_{i_1}, Q_1, g_1) \in \mathcal{O}$ and \mathcal{P} does not contain an arc in $out(ag_i) \setminus \mathcal{O}$. We notice that $out^*(ag_i)$ contains all (and only) the paths starting from ag_i .

The do-ut-des property consists of two conditions. The first condition is an efficiency condition: there do not exist two distinct sets of agents in a coalition which are committed to the achievement of the same goal. The second condition expresses the notion of reciprocity: given an AND-arc $(ag_i, Q, g) \in \mathcal{E}$, each agent ag_j involved in Q agrees to provide the goal g to ag_i , only in the case this commitment returns the satisfaction of some of its goals by means of a path \mathcal{P} .

Definition 2 A coalition $\langle \mathcal{V}, \mathcal{E} \rangle$ satisfies the do-ut-des property iff (1) there do not exist two commitments $(Q, g), (Q', g) \in \mathcal{C}$ such that $Q \neq Q'$ and (2) for all $(ag_i, Q, g) \in \mathcal{E}$ and for all $ag_j \in Q$, $(ag_i, Q, g) \in out^*(ag_j)$.

It can be seen that both the coalitions in Figure 1 (a) and (b) satisfy Definition 2.

However, the do-ut-des property does not consider the possibility that a coalition can be decomposed in smaller sub-coalitions which can be formed independently. Forming smaller coalitions can be preferred by agents because, e.g., involving less agents they reduce the risk of defections, are easier to monitor, less expensive to form by means of agreements, less trust is required among all the agents, etc. The coalitions in Figure 1 (a) and (b) show two cases of this fact. Consider in Figure 1 (a) the sub-coalitions C_1 , involving only agents ag_1 and ag_2 and the relative arcs, and C_2 , involving only agents ag_3 and ag_4 and the relative arcs. As the agents involved in C_1 are not interested in the goals achieved in C_2 and vice versa, the two sub-

coalitions can be formed independently.

Concerning Figure 1 (b), C denotes the whole coalition, C_1 the coalition consisting of the nodes ag_1 and ag_2 and the two arcs labelled with the goals g_1 and g_2 . C_2 denotes the coalition consisting of the nodes ag_3 and ag_4 and the remaining arcs labelled with the goals g_3 and g_4 . The difference is that in Figure 1 (a) both ag_1 and ag_2 are indifferent between C_1 and the whole coalition, while in Figure 1 (b) ag_2 is not indifferent between C_1 and C since in C it receives the goal g_4 which is not provided in C_1 .

However, ag_1 is indifferent between C_1 and C and ag_3 is indifferent between C_2 and C as they receive and have to obtain the same goals in both coalitions. Thus, if they agree to C , then they would agree respectively to C_1 and C_2 . When agent ag_2 wants to propose to ag_1 and ag_3 to form coalitions, it has to decide whether to propose C to both agents or C_1 and C_2 separately. It knows that if they agree to C , then they would also agree respectively to C_1 and C_2 . Agent ag_2 chooses C_1 or C_2 since forming one of them does not affect the possibility for ag_2 to reach an agreement on the other sub-coalition, and C_1 and C_2 are individually more reliable to succeed with respect to the whole C - as they involve individually less agents.

The i-dud property consists of three conditions. Given a coalition C , the first condition is the condition (1) of the do-ut-des property. The second condition strengthens the condition (2) of do-ut-des property by imposing that for each agent ag_i in C , $out^*(ag_i) = \mathcal{E}$. Thus, a coalition cannot be decomposed in two subgraphs which are disconnected as in Figure 1 (a). Finally, the third condition takes into account the case shown in Figure 1 (b): there does not exist an agent ag_i and a bi-partition $\mathcal{O}_1, \mathcal{O}_2$ of $out(ag_i)$ - where we assume that bi-partitions are composed by nonempty sets - such that $\mathcal{O}_1^* \cap \mathcal{O}_2^* = \emptyset$. The idea underlying this third condition is that if $\mathcal{O}_1^* \cap \mathcal{O}_2^* = \emptyset$, then no agent $ag_j \neq ag_i$ involved in \mathcal{O}_1^* would be interested in one of the goals achieved in \mathcal{O}_2^* and vice versa. So, ag_i can deal separately with the formation of these two sub-coalitions.

Definition 3 A coalition $\langle \mathcal{V}, \mathcal{E} \rangle$ satisfies the i-dud property iff for all the agents $ag_i \in \mathcal{V}$, (cond1) there do not exist two commitments $(Q, g), (Q', g) \in C$ such that $Q \neq Q'$, (cond2) $out^*(ag_i) = \mathcal{E}$ and (cond3) there does not exist a bi-partition $\mathcal{O}_1, \mathcal{O}_2$ of $out(ag_i)$ such that $\mathcal{O}_1^* \cap \mathcal{O}_2^* = \emptyset$.

Considering again the coalitions in Figure 1 (a) and (b), as expected, they both do not satisfy the i-dud property. In Figure 1 (a), the first condition of Definition 3 is not satisfied as, for example, $out^*(ag_1) = \{(ag_1, \{ag_2\}, g_1), (ag_2, \{ag_1\}, g_2)\} \subset \mathcal{E}$. In Figure 1 (b), the third condition of Definition 3 is not satisfied. Indeed, considering the bi-partition of ag_2 composed by $\mathcal{O}_1 = \{(ag_2, \{ag_1\}, g_2)\}$ and $\mathcal{O}_2 = \{(ag_2, \{ag_3\}, g_4)\}$, we have that $\mathcal{O}_1^* = \{(ag_2, \{ag_1\}, g_2), (ag_1, \{ag_2\}, g_1)\}$ and $\mathcal{O}_2^* = \{(ag_2, \{ag_3\}, g_4), (ag_3, \{ag_2\}, g_3)\}$. Thus, $\mathcal{O}_1^* \cap \mathcal{O}_2^* = \emptyset$.

A labeled AND-graph can represent a potential coalition consisting of all, or a large part of, the opportunities of collaboration in a multiagent system. So we would like to establish not only if the whole coalition is admissible or not, but also which of its sub-coalitions are admissible to be formed. Figure 2 (a) shows a quite complex coalition that does not satisfy the i-dud property. Indeed, given the bi-partition of $out(ag_1)$ $\mathcal{O}_1 = \{(ag_1, \{ag_4, ag_5\}, g_1)\}$ and $\mathcal{O}_2 = \{(ag_1, \{ag_3\}, g_6)\}$, it can be verified that $\mathcal{O}_1^* \cap \mathcal{O}_2^* = \emptyset$. Figure 2 (b), (c), (d) and (e) show all the sub-coalitions of Figure 2 (a) which satisfy the i-dud property. These coalitions clearly satisfy also the do-ut-des property. However, since the do-ut-des property seeks only the reciprocity in a coalition, any composition of coalition (e) with one of the coalitions (b), (c) and (d) satisfies the do-ut-des

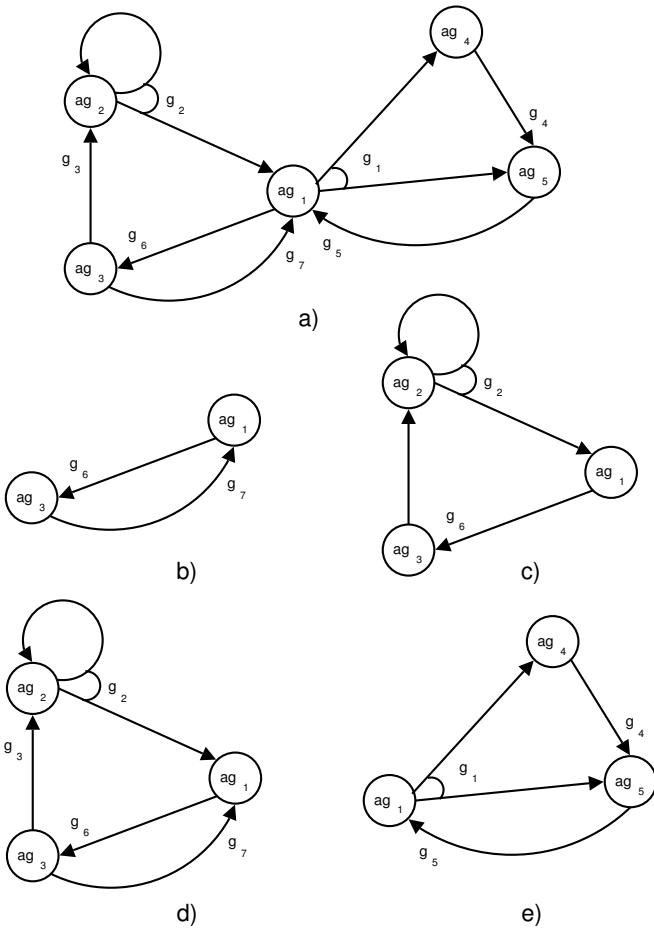

Figure 2. A complex coalition (a) and the sub-coalitions which satisfy the i-dud property (b), (c), (d) and (e).

property as well.

Given a coalition C , Definition 3 could be used *tout court* in order to design an algorithm which find all the sub-coalitions satisfying the i-dud property (C included). However, Definition 3 requires to verify, for each agent ag_i involved in C , a condition on the set of bi-partitions of $out(ag_i)$. The number of bi-partitions of a set A is equal to the Stirling number $S(n, 2) = 2^{n-1} - 1$, where n is the cardinality of A . Therefore, the problem to verify if just C satisfies the i-dud property would increase in complexity exponentially with the cardinality of $out(ag_i)$. For this reason we consider an alternative approach in order to make at least the verification of a single coalition tractable.

We reformulate cond2 as a property of strong connectivity of a directed graph. We define a direct graph $\mathbf{G}[C] = \langle \mathbf{V}, \mathbf{E} \rangle$ relative to the coalition $C = \langle \mathcal{V}, \mathcal{E} \rangle$ as follows: the set of nodes \mathbf{V} is equal to the set \mathcal{V} of agents involved in C and $(ag_i, ag_j) \in \mathbf{E}$ if and only if there exist a goal g and a group of agents Q such that $(ag_i, Q, g) \in \mathcal{E}$ and $ag_j \in Q$. It is easy to see that if $(ag_j, Q, g) \in out^*(ag_i)$, then there exists a path in $\mathbf{G}[C]$ from ag_i to ag_j . So, since each agent is involved in the achievement of at least a goal, the condition that $out^*(ag_i) = \mathcal{E}$ is equivalent to say that $\mathbf{G}[C]$ is strongly connected, i.e. for each pair of nodes ag_i and ag_j there exists a path from ag_i to ag_j . Given a generic directed graph \mathbf{G} , we call the strongly con-

nected components of \mathbf{G} the maximal strongly connected sub-graphs which contains at least one arc.

Now we consider how to reformulate cond3. Under the assumption that $\mathbf{G}[C]$ is strongly connected, cond3 is closely related to the notion of biconnectivity for undirected graphs. An undirected graph G is biconnected if and only if it is connected and for all triples of distinct nodes ag_i, ag_j and ag_k , there exists a path p connecting ag_j and ag_k such that ag_i is not in p . In the contrary case, ag_i is called an articulation node [9]. As for strongly connected components of a directed graph, the biconnected components of an undirected graph G are the maximal biconnected subgraphs of G which contain at least one arc. It is easy to see that two distinct biconnected components share at most one node and, if so, this node is an articulation node.

Starting from the directed graph $\mathbf{G}[C] = \langle \mathbf{V}, \mathbf{E} \rangle$, we define an undirected graph $G[C] = \langle V, E \rangle$ as follows: $V = \mathbf{V}$ and, for $ag_i \neq ag_j$, $\{ag_i, ag_j\} \in E$ if and only if (ag_i, ag_j) or (ag_j, ag_i) are in \mathbf{E} . The following theorem shows that the fact that cond3 is not satisfied is indicated by the presence of an articulation node ag_i .

Theorem 1 Let $C = \langle \mathcal{V}, \mathcal{E} \rangle$ be coalition such that $\mathbf{G}[C]$ is strongly connected, if there exists an agent $ag_i \in \mathcal{V}$ and a bipartition $\mathcal{O}_1, \mathcal{O}_2$ of $out(ag_i)$ such that $\mathcal{O}_1^* \cap \mathcal{O}_2^* = \emptyset$, then ag_i is an articulation node of $G[C]$.

proof: Assume that there exists an agent $ag_i \in \mathcal{V}$ and a bipartition $\mathcal{O}_1, \mathcal{O}_2$ of $out(ag_i)$ such that $\mathcal{O}_1^* \cap \mathcal{O}_2^* = \emptyset$ and, per absurdum, ag_i is not an articulation node.

Strong connectivity of $\mathbf{G}[C]$ assures that (ass1) there exist two agents, say ag_1 and ag_2 , such that ag_i, ag_1 and ag_2 are distinct and ag_1 is involved in \mathcal{O}_1^* and ag_2 is involved in \mathcal{O}_2^* , and (ass2) $\mathcal{O}_1^* \cup \mathcal{O}_2^* = \mathcal{E}$. Since ag_i is not an articulation node, there exists an undirected path p connecting ag_1 and ag_2 such that ag_i is not a node of p . For (ass2) and condition (1) of Definition 1, each node in the path is an agent in \mathcal{O}_1^* or \mathcal{O}_2^* . Thus, starting from ag_1 it is possible to walk through p until an agent ag_h is in \mathcal{O}_1^* and the successor ag_k is in \mathcal{O}_2^* . The presence of an undirected arc connecting ag_h to ag_k means that one of them is involved in set out of the other one. Without loss of generality we assume that there exists a set of agents Q and a goal g such that $ag_h \in Q$ and $(ag_k, Q, g) \in \mathcal{E}$. This means that $out(ag_h)$ is contained in both \mathcal{O}_1^* and \mathcal{O}_2^* . For strong connectivity of $\mathbf{G}[C]$, we also have that $out^*(ag_h) = \mathcal{E}$ and hence $out(ag_h)$ is not empty, then $\mathcal{O}_1^* \cap \mathcal{O}_2^* \neq \emptyset$ against the hypothesis. \square

So, if $\mathbf{G}[C]$ is biconnected (i.e. it does not have articulation points), then it satisfies cond3. However, the inverse implication of Theorem 1 does not hold and cond3 can be satisfied even if $\mathbf{G}[C]$ has an articulation point ag_i . This is due to the fact that the undirected graph $G[C]$ breaks an AND-arc in several undirected arcs, so the biconnected components sharing ag_i may not correspond to any bipartition of $out(ag_i)$. Figure 3 considers this fact. Figure 3 (b) represents the undirected graph $G[C]$ of the coalition C in Figure 3 (a). There exist two biconnected components of $G[C]$, one for each arc, sharing ag_1 as articulation node. However, both arcs $\{ag_1, ag_2\}$ and $\{ag_1, ag_3\}$ correspond to the AND-arc $(ag_1, \{ag_2, ag_3\}, g_1)$, thus they have to be considered as a single component because $\{(ag_1, \{ag_2, ag_3\}, g_1)\}^*$ contains both of them. Being $out(ag_1)$ equal to $\{(ag_1, \{ag_2, ag_3\}, g_1)\}$, there does not exist a bi-partition $\mathcal{O}_1, \mathcal{O}_2$ of $out(ag_1)$ such that $\mathcal{O}_1^* \cap \mathcal{O}_2^* = \emptyset$. Thus, C satisfies cond3.

This property holds in general, when some biconnected components of $G[C]$ contain some arcs which correspond to the same AND-arc of C , they are considered as a single component. If this grouping process ends with a single component consisting of the whole undirected graph $G[C]$, then no bi-partitions of $out(ag_1)$ falsify cond3.

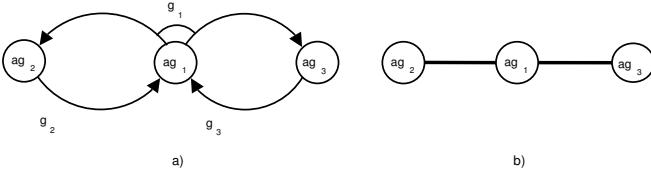

Figure 3. A labeled AND-graph and the corresponding undirected graph.

Algorithm 1: FIND-I-DUD

Data: $C = \langle \mathcal{V}, \mathcal{E} \rangle$.
Result: I_DUD , the set of sub-coalitions of C that satisfy the i-dud property

```

1  $I\_DUD \leftarrow \emptyset;$ 
2  $NDC = \text{NO-DUPL-COMMITMENTS}(C);$ 
3 forall  $C' \in NDC$  do
4    $I\_DUD \leftarrow I\_DUD \cup \text{FIND-2-3}(C');$ 
```

3 The algorithm for finding coalitions

In this section we design a procedure FIND-I-DUD (see Algorithm 1) which finds all the sub-coalitions of a coalition C satisfying the i-dud property (C included). We use the reformulation of cond2 and cond3 in Definition 3 in terms of strong connectivity of directed graphs and biconnectivity of undirected graphs. By doing so, we also decompose our problem as much as possible in well known problems in graph theory.

The variable I_DUD in line 1 stores the set of sub-coalitions of C which satisfy the i-dud property. In line 2 NO-DUPL-COMMITMENTS checks in \mathcal{E} the presence of commitments with the same goal but assigned to different sets of agents (cond1) and it returns the set NDC of all combinations C' obtained from C by deleting all the duplicated commitments except one. This way, the sub-coalitions in NDC are the maximal sub-coalitions which satisfy cond1. Since all their sub-coalitions satisfy this condition as well, we do not need to check recursively this condition on them, i.e. NO-DUPL-COMMITMENTS can be run only once.

For each coalition in NDC the procedure FIND-2-3 is run (lines 3-4). FIND-2-3 (Algorithm 2) takes as input a coalition C - which satisfies cond1 - and it returns the set of sub-coalitions of C , C included, that satisfy cond2 and cond3. As we already have checked cond1, we can add the results of FIND-2-3 to the set I_DUD .

The variable S stores the subsets of C that satisfy cond2 and cond3, in line 1 this variable is initialized to the empty set.

In line 2 SC-COMPONENTS calculates the strongly connected components SCC of $G[C]$ - algorithms for this procedure are well known [5, 9]. Three cases are distinguished.

Case 1: $G[C]$ has no strongly connected components. Since strong connectivity is a necessary condition for the satisfaction of cond2, no sub-coalitions of C satisfy the i-dud property. Therefore, S is empty.

Case 2: $G[C]$ is not strongly connected, but there exist some strongly connected components. In this case only the sub-coalitions of C such that the relative directed graphs are subgraphs of a strongly connected component can satisfy cond2. Therefore, in lines 7-10, for each strongly connected component, the maximal labeled AND-graph $\langle \mathcal{V}', \mathcal{E}' \rangle$, included in the component, is constructed. The func-

Algorithm 2: FIND-2-3

Data: $C = \langle \mathcal{V}, \mathcal{E} \rangle$.
Result: S , the set of sub-coalitions of C that satisfy cond2 and cond3.

```

1  $S \leftarrow \emptyset;$ 
2  $SCC \leftarrow \text{SC-COMPONENTS}(G[C]);$ 
3 switch do
4   case  $G[C]$  has no strongly connected components
5      $S \leftarrow \emptyset;$ 
6   case  $G[C]$  is not strongly connected, but it has some
7     strongly connected components
8     forall  $\langle \mathcal{V}, \mathcal{E} \rangle \in SCC$  do
9        $\mathcal{V}' \leftarrow \mathcal{V};$ 
10       $\mathcal{E}' \leftarrow \{(ag_i, Q, g) \in \mathcal{E} \mid ag_i \in \mathcal{V} \wedge Q \subseteq \mathcal{V}\};$ 
11       $S \leftarrow S \cup \text{FIND-2-3}(\langle \mathcal{V}', \mathcal{E}' \rangle);$ 
12   case  $G[C]$  is strongly connected
13      $(BC, A\_NODES) \leftarrow \text{BC-COMPONENTS}(G[C]);$ 
14     forall  $(ag_i, Q, g) \in \mathcal{E}$  s.t.  $ag_i \in A\_NODES$  do
15        $BC' \leftarrow \{\langle \mathcal{V}', \mathcal{E}' \rangle \in BC \mid \{ag_i, ag_j\} \in \mathcal{E}' \text{ with } ag_j \in Q\};$ 
16        $BC \leftarrow [BC \setminus BC'] \cup \{\bigcup BC'\};$ 
17     if  $|BC| = 1$  then
18        $S \leftarrow \{C\};$ 
19       forall  $(Q, g) \in C$  do
20          $C' \leftarrow C \setminus \{(Q, g)\};$ 
21          $S \leftarrow S \cup \text{FIND-2-3}(C');$ 
22     else
23       forall  $\langle \mathcal{V}, \mathcal{E} \rangle \in BC$  do
24          $\mathcal{E}' \leftarrow \{(ag_i, Q, g) \in \mathcal{E} \mid ag_i \in \mathcal{V} \wedge Q \subseteq \mathcal{V}\};$ 
25          $\mathcal{V}' \leftarrow \mathcal{V};$ 
26          $S \leftarrow S \cup \text{FIND-2-3}(\langle \mathcal{V}', \mathcal{E}' \rangle);$ 
27 return  $S;$ 
```

tion FIND-2-3 is recursively called on $\langle \mathcal{V}', \mathcal{E}' \rangle$ and its output is added to S .

Case 3: $G[C]$ is strongly connected, therefore, cond2 is satisfied. It remains to check cond3 and for complexity reasons we use the characterization by means of the biconnected components of $G[C]$ (see Section 2).

In line 12 the set of biconnected components BC and the set of articulation points A_NODES are calculated. In lines 13-15 FIND-2-3 checks, for each articulation node ag_i , if there exists an AND-arc (ag_i, Q, g) such that the other agents in Q are involved in two, or more, biconnected components, then these biconnected components replaced with their union (see Figure 3). In the case we end with a single component, $|BC| = 1$, C satisfies also cond3 and it is added to S . Then, in lines 18-20, the sub-coalitions C' obtained removing a single commitment (Q, g) from C are constructed and FIND-2-3 is recursively called on them. If $|BC| > 1$, then C does not satisfy cond3. Also all the subsets C' of C such that $G[C']$ is not included in a component of BC cannot satisfy cond3, therefore for each component $\langle \mathcal{V}, \mathcal{E} \rangle$ in BC , the maximal subgraph of C included in $\langle \mathcal{V}, \mathcal{E} \rangle$ is selected. FIND-2-3 is recursively called on C' and the output is added to S (lines 22-25). Finally, S is returned, line 27.

4 Complexity of the algorithm

In this section we discuss the complexity of FIND-I-DUD. First of all, we show that the problem of checking if a coalition satisfies the i-dud property is tractable. Algorithms FIND-I-DUD and FIND-2-3 can be easily modified to simply check if a given coalition satisfies the i-dud property. First, in FIND-I-DUD we replace the FOR statement with an IF-THEN-ELSE statement which returns false if C does not satisfy cond1, it calls FIND-2-3 on C , otherwise. In FIND-2-3 we replace lines 5,7-10, 22-25 with an instruction returning false, and lines 17-20 with an instruction returning true. We denote with m the number of agents involved in C and with l the number of arcs in $G[C]$. The procedure SC-COMPONENTS takes a time proportional to l [5]. In the case $G[C]$ is not strongly connected, C does not satisfy the i-dud property and FIND-2-3 returns false. In the contrary case, the procedure BC-COMPONENTS is called on the undirected graph $G[C]$.

Also BC-COMPONENTS can be executed in a time that is proportional to $|E|$ and, since $|E| \leq l$, so far Algorithm 2 has a complexity that is proportional to l . We have to consider now the complexity of the cycle corresponding to the lines 13-15. The number of iterations of the cycle 13-15 is less than l . The instruction in line 14 has as upper bound m , assuming that, during the execution of BC-COMPONENTS, a data structure is stored associating each arc with the biconnected component in which it is included. Since the sets of arcs of two distinct biconnected components are disjoint, also the instruction in line 15 can be performed in time proportional to the set of distinct biconnected components found in line 12, which has an upper bound in m . Therefore, the cycle 13-15 has an upper bound in $O(l \cdot m)$. Since $O(l \cdot m)$ is an upper bound also to check cond1, it is an upper bound for the problem to verify if a coalition satisfies the i-dud property.

With respect to the original problem to find all the sub-coalitions of C that satisfy the i-dud property, consider that C satisfies cond1 and it contains only AND-arcs as $(ag_i, \{ag_j\}, g)$. In this case we can represent C as a directed graph $G[C]$, where each arc (u, v) univocally corresponds to a goal. We show that a single run of FIND-2-3 is not computationally tractable. FIND-2-3 finds all the sub-coalitions of a coalition $G[C]$ that satisfy cond2 and cond3. This requires to find in particular all the subgraphs of $G[C]$ that are the strongly connected subgraphs and such that the relative undirected graph, $G[C]$, is biconnected. Since an hamiltonian cycle in $G[C]$ - if any exists - satisfies the previous two conditions, FIND-2-3 has to find a set of subgraphs which contains all the hamiltonian cycles of $G[C]$. Thus, this problem is exponential with respect to the number of arcs l . In contrast, since checking if a subgraph of $G[C]$ is an hamiltonian cycle is linear with the cardinality of the nodes V , also the problem of finding an hamiltonian cycle would be polynomial with respect to number of arcs.

In the case a coalition C can be represented by the corresponding directed graph $G[C]$, the set of subgraphs to check is equal to 2^l . However, if C does not satisfy the i-dud property, then, either $G[C]$ is not strongly connected or $G[C]$ has more than one component as calculated in the lines 12-15. In both cases FIND-2-3 is called directly on the subgraphs calculated respectively in lines 8-9 and 23-24. So, if there are k of these subgraphs, each of them with l_i arcs, we have that the number of the graph which remain to be verified is $2^{l_1} + \dots + 2^{l_k}$ instead of (approximately from below) $2^{l_1+\dots+l_k} - 1$. In the worst case $G[C]$ is not strongly connected and it has one strongly component with $l-1$ arcs. In this case 2^{l-1} graphs remain to be verified instead of $2^l - 1$.

We note that this fact occurs not only once, but every time a sub-coalition of C does not satisfy the i-dud property. Moreover, if C is a proper AND-graph this phenomenon can be amplified by the fact that when an AND-arc is removed in line 8, it may disconnect a strongly connected component of $G[C]$.

Returning to the coalition C in Figure 2 (a), the number of AND-arcs is 7, so *a priori* $2^7 = 128$ sub-coalitions should be checked by the algorithm FIND-I-DUD. However, C does not satisfy cond3 and, after BC results to be greater than 1 in line 16 of FIND-2-3, FIND-2-3 is called on the sub-coalitions in Figure 2 (d) and (e). The first sub-coalition has 4 AND-arcs and the second one has just 3 arcs. So after a single call of FIND-2-3, it remains $2^4 + 2^3 = 24$ sub-coalitions instead of 127. It can be shown that the total number of sub-coalitions checked is equal to 16, i.e. only the 12,5% of the number of all sub-coalitions of C .

5 Conclusion

In this work we define a criterion of admissibility for coalition formation which is based on the representation of a coalition as a net of exchanges [4]: the i-dud property. This property refines the do-ut-des property [2] by taking into account the fact that two distinct coalitions cannot be considered a whole coalition if they can be formed independently. This condition arises from the fact that agents prefer to form small coalitions because, as coalitions spring from unanimously agreements, the more are the agents involved in a coalition the more is the risk that one of them gives up joining it.

The i-dud property inherits from the do-ut-des property the fact that it uses only the internal topology of exchanges to check the admissibility of a coalition. Approaches based on Cooperative Game Theory, as [7, 10], abstract from this internal structure, and hence they need to compare a coalition with the other possible coalitions in order to establish its admissibility. This way, also the problem to see if a coalition is admissible, applying for example the notion of core, is intractable.

Advanced Policy Explanations on the Web¹

P. A. Bonatti and D. Olmedilla and J. Peer²

Abstract. The frameworks for protecting security and privacy can be effective only if common users—with no training in computer science or logic—increase their awareness and control over the policy applied by the systems they interact with. Towards this end, we introduce a mechanism for answering *why*, *why-not*, *how-to*, and *what-if* queries on rule-based policies for trust negotiation. Our framework is *lightweight* and *scalable* but it fulfills the main goals of modern explanation facilities. We adopt a novel *tabled explanation structure*, that simultaneously shows local and global (intra-proof and inter-proof) information, thereby facilitating navigation. Answers are focussed by removing irrelevant parts with suitable heuristics.

1 Introduction

The area of trust management—and in particular trust negotiation (TN)—is intersecting semantic web issues. In recent approaches [2, 5], software agents communicate their security and privacy requirements by exchanging policies formulated as rules, that is, simple ontologies. In this case, semantic descriptions concern the semantics of access control and information disclosure, which constitutes part of service and user agent semantics.

There is increasing awareness that advanced security and privacy techniques cannot be effective unless users are able to understand and possibly personalize the policy enforced by the systems they interact with (cf. [3] and the CUPS project on <http://cups.cs.cmu.edu/>). In order to enhance user awareness and control on policies, researchers are advocating a form of *cooperative policy enforcement* where policy decisions can be inspected by non-specialized users, and negative responses are enriched with suggestions and explanations.

In this paper, we describe an *advanced explanation mechanism* designed to help users understand what rule-based policies prescribe and control. Our first contribution consists in a requirements analysis for explanations in the context of trust negotiation. Moreover, we define explanation mechanisms for *why*, *why-not*, *how-to*, and *what-if* queries. There are several novel aspects in our approach:

- We adopt a *tabled explanation structure* as opposed to more traditional approaches based on single proof trees. The tabled approach makes it possible to describe infinite failures (which is essential for *why not* queries).
- Our explanations show the outcome of different possible proof attempts and let users see both local and global proof details at the same time. Such combination of intra-proof and inter-proof information is expected to facilitate navigation across the explanation structures.

- We introduce suitable heuristics for focussing explanations by removing irrelevant parts of the proof attempts. Any-way, we provide a second level of explanations where all the missing details can be recovered, if desired.
- Our heuristics are *generic*, i.e. domain independent. This means that they require no manual configuration.
- The combination of tabling techniques and heuristics yields a completely novel method for explaining failure. In the past, the problem has been ignored or formulated differently (e.g., by suggesting how to complete proofs by introducing new facts [4]).

Moreover, we aim at a *lightweight* and *scalable* explanation mechanism, that fits the requirements of web applications.

This paper is structured as follows. First, in Section 2, we recall the latest developments on explanations for expert systems. Then we outline in Section 3 the requirements for explanations in the context of trust negotiation, and briefly compare the two frameworks. Section 4 briefly introduces trust negotiation in our context and anticipates the functionalities of the explanation modules by means of a reference scenario. Then the explanation mechanisms are formally defined in two steps: First, the internal structures are defined (Section 5), then we describe how to render the explanation in natural language (Section 6). Section 7 concludes the paper with a final discussion of the results.

2 State of the Art

Integrated Explanation Facilities (IEFs) have been a goal for the development of intelligent systems early on. During the last fifteen years, a variety of design approaches for explanation facilities have been proposed, often classified as *second generation* frameworks by the literature [14, 6]. Examples of second generation IEFs include EES, the Explainable Expert System [11], the Mission Planning Assistant (MPA) [13, 12], the Reconstructive Explainer Rex [14]. These frameworks manage to decouple reasoning and explanation, whith the purpose of creating high quality explanations, at the cost of producing and synchronizing two versions of knowledge, one for reasoning and one for explaining. This is one of the main reasons that forced us to depart from these approaches (see next section).

From the Semantic Web perspective, the most comprehensive work on this new frontier is Inference Web (IW) [9, 10], a toolkit that aims at providing generic explanation tools for (Semantic) Web based systems. We could not use IW's facilities for our purposes because there is no support for explaining infinitely failed derivations. To navigate why-not queries we found it useful to explore multiple proof attempts simultaneously, while IW APIs are designed to manipulate single proofs. Moreover, IW's approach at removing the parts of the proof irrelevant to explanations (based on derived inference rules)

¹ Partially supported by REWERSE, IST-2004-506779.

² Universities of Naples, Hannover, and St. Gallen, respectively. D. Olmedilla is also a member of L3S. Contact: bonatti@na.infn.it

is not suitable for the kind of ellipsis and focussing we need, that we had to achieve by introducing a notion of *cluster* (see Section 5) and by exploiting predicate dependency graphs.

Finally, in the context of security, the KNOW system [7] focusses on the provision of feedback after a request is denied. However, KNOW does not return an explanation but a set of changes to the policy that would make it fulfilled. Similarly, the WhyNot system [4] suggests which sets of facts might be added to the system to make a given goal succeed, based on some heuristic weights calculated on proofs.

3 Requirements

Since TN frameworks can be applied in many application domains, rule-based policies almost always refer to domain specific concepts and application specific information sources. So a TN framework has to be suitably instantiated for each application by defining the set of application specific predicates, and interfacing them with legacy software and data. *Almost no further effort should be added to the framework instantiation phase.*

A second requirement is related to scalability: *explanations should not increase significantly the computational load of the servers* which is already increased by rule manipulation.

The first requirement is incompatible with the methodology of [1], that prescribes an actor and five distinct phases entirely devoted to the development of an independent explanation module equipped with an ad-hoc domain ontology and special rules for creating explanation-related data structures.

The second requirement is incompatible with the methodology of [1], too. The special rules for creating explanation-related data structures are meant to be executed during the reasoning process and may potentially affect performance.

A third requirement, instead, is shared with second generation explanation systems: explanations should be closer to the users' problem solving strategies than the system's automated reasoning strategy. The reason is that policy explanation systems should be understood by any user.

According to modern explanation approaches, the support for explanation presentation is characterized by the following features [9]:

- **Methods for asking for explanations.** We have identified the following kinds of queries: *why/why not, how to, what if*, that may be asked before, during, and after a negotiation to understand which pieces of information are actually used (some information may be unnecessarily released), what remains to be done. The same queries can be used to inspect and monitor policies.
- **Methods for breaking up proofs into manageable pieces.** The local view (the rules that directly apply to a given goal), should be enriched with global information such as the different answer substitutions of each subgoal, to help users in deciding which proof and which proof branches should be visited next.
- **Methods for pruning proofs and explanations to highlight relevant information.** The negotiation protocol determines what is relevant: Peers fulfil conditions by submitting credentials and other information, so the pieces of information that have been submitted and those that have not determine the focus of attention. State predicates constitute another kind of crucial information in TN, be-

cause their semantics is often *blurred* [2], i.e. it is not communicated to the client (either for privacy reasons or for efficiency). This raises the need for special explanations.

- **Methods and user interfaces for proof and explanation navigation:** We see a proof as a (potentially cyclic) hypertext, whose links help the user in exploring single as well as alternative proofs and proof attempts.
- **Different presentation formats.** Natural language is an appealing, user-friendly format. It can be complemented by graphical representations.
- **Methods for obtaining justifications for conflicting answers.** Today the languages involved in TN are not expressive enough to derive contradictions, so this aspect is currently marginal but this may change in the future.

Finally, the entities referred by the policies should be denoted in a user-friendly way. Their internal encoding (XML, object handles, etc.) is generally not suitable because it is meaningless to most users.

4 TN and Explanations

We apply our techniques to PROTUNE [2], one of the most recent trust negotiation frameworks. In summary, each party makes decisions on access control and information disclosure according to a set of rules that entail decision atoms such as `allow(X)`. The rule language extends Datalog with syntactic sugar. Policy rules are extended with a time-dependent set of facts, including currently available credentials and declarations (sent by the other party), other negotiation-related information, user profiles, etc. The argument of `allow(X)` may refer to a service or it may denote a credential release, declaration release or the execution of some specified action. To explain its disclosure requirements to the other peers, each peer sends out the *rules* themselves, as a compact representation of all the possible ways of fulfilling the request. First, however, the rules are suitably filtered to protect the sensitive parts of the policy (the policy itself may be confidential). Explanations are built from filtered policies (so they can be built on the clients). The following scenario illustrates some of the explanations that our method produces from the filtered rules.

A digital library protects its resources according to the policy partially illustrated in Figure 1. John Smith tries to download a paper with file name "paper01234.pdf" and authenticates himself by providing an id credential. He receives the answer "permission denied" from the library service. To understand why, he sends a *why-not* query to the service. His personal assistant gathers the policies provided for why-not explanations and filters them highlighting the parts most relevant to the user, i.e. those requirements the user did not fulfill, and hiding some other aspects of the policy (e.g., those that do not depend on the user). The first output is:

I can't prove that it is allowed to download paper01234.pdf **because:**

- Rule [r₃] is not applicable:
there is no User such that
User is authenticated [details]
- and
rule [r₄] is not applicable:
there is no User such that
User is authenticated [details]

```

...
[r2] : allow(download(Resource)) ←
    public(Resource).
[r3] : allow(download(Resource)) ←
    authenticated(User),
    has.subscription(User, Subscription),
    available_for(Resource, Subscription).
[r4] : allow(download(Resource)) ←
    authenticated(User),
    paid(User, Resource).
...
[r6] : authenticated(User) ←
    id(Credential),
    Credential.name : User,
    Credential.public_key : K,
    challenge(K).
[r7] : authenticated(User) ←
    declaration([username = User, password = P]),
    passwd(User, P).
...

```

Figure 1. Digital Library Policy

moreover
there is no User such that
User has paid for paper01234.pdf [details]

Concise explanations (like the one presented above) do not show all the details and focus primarily on those conditions that depend on the user, giving him the opportunity to fulfill the conditions quickly. For example rule r_3 talks about subscriptions, but these details are omitted in the explanation above because if John is not authenticated it makes no sense to inspect his subscription. However, John could still request the full explanation by clicking on the [details] link.

John did disclose his id credential and wonders why the authentication failed. By clicking on that condition he eventually finds why (the definition of $\text{id}/1$ is not shown in Figure 1):

I can't find any Cred such that Cred is an id because:
c012 is a credential with
 type student-id and issuer Open University [details]
student-id is an id-type [details]
but
it is not the case that
Open University is trusted for id [details]

This explains why John's request has not been accepted: the certification authority (CA) 'Open University' on his credential is not among the trusted CAs for id credentials at the library service. Note that the above explanations anticipate the results of each subgoal (e.g. a failure, or the answer substitution fixing the credential's identifier, type and issuer). In case of multiple answer substitutions, the user can inspect the list of all answers of a subgoals and apply some, to focus on a subset of all proof attempts (see *refinement links* in the following sections).

John might ask for a complete explanation of the possible ways of obtaining the paper by issuing a *how-to* query. The result would be:

to make sure that it is allowed to download Resource
nothing needs to be done if
Resource is public [details]
alternatively
please make sure that for some User

User is authenticated	[details]
where, for some Subscription,	
User has subscription Subscription	
and	
Resource is available for Subscription	[details]
alternatively	
please make sure that for some User	
User is authenticated	[details]
and	
User has paid for Resource	[details]

Again, John can get a specific how-to explanation for each of the above conditions by clicking on it. The "make sure" part contains predicates that depend on user actions (including `credential`); they are identified via a standard *predicate dependency graph*. Due to space constraints, *what-if* queries, *why* queries, and "technical" (level 2) explanations that provide full proof details are not discussed in this paper.

5 Explanation Structures

To meet page limitations, we present here slightly simplified explanation structures that do not support blurred predicates (which involve notions similar to abductive explanations and verbalizations such as: "it might be the case that...").

We assume the reader to be familiar with the basics of logic programming, including the notions of *most general unifier* (mgu) and *(computed) answer substitution*. The reader is referred to [8] for these matters. There are some delicate technical aspects in handling substitutions, related to standardization apart. So we assume a function $\text{ans}_P^E(G)$ that for all programs P , all goals G , and all expressions E returns a complete (up to variable renaming) set of answer substitutions whose range does not contain any variable occurring in P, E, G .

Before formalizing explanations we tackle the problem of referring to structured objects, such as credentials, that are typically denoted by means of internal identifiers (*handles*) that have no meaning to the common user. We noted that the attribute atoms $obj.attr:val$ in a rule body are typically the relevant, characterizing attributes of the complex object whose handle is obj —see for instance the why-not explanation referring to credential c012 in Section 4. In a given negotiation, these attributes almost always identify a unique object when their values are fixed. So our idea is using these attributes as a key to identify the object. For this purpose, we look for subsets of the body called *clusters* that correspond to concepts with attributes (a sort of terminological expression) and treat them as a description of the complex object.

Definition 1 (Clusters) Let $L = p(t)$ where p is a unary predicate and t is a term. If $L \in \text{body}(r)$, then a cluster of L (in r) is a set containing L and some attribute subgoals $(u.a : v) \in \text{body}(r)$ with $u = t$. A cluster is complete if it contains all such subgoals. If t is a variable, then it is called the main variable of the cluster; L and p are called the main literal and the main predicate of the cluster, respectively.

Example 1 The policy rule instance r_6 in Figure 1 contains one complete cluster (the first three literals in the body) whose main literal is $\text{id}(\text{Credential})$. The cluster denotes "the id with name User and public key K". \square

Remark 1 Clusters are more flexible than key attributes because they can be applied also to those classes of objects that

have no key attributes. Moreover, clusters reduce the framework instantiation effort, because they need no manual intervention (while key attributes must be specified by knowledge engineers). Clusters are very useful in *why not* queries, where incomplete clusters allow to explain situations such as: “*there is an id with name J. Smith, but the public key is not k012*”.

While a single atom like `credential(X)` may have multiple solutions, often its cluster has just one answer (in this sense the attributes of X characterize X). By applying this substitution, we specify the credential we are talking about. The process of exhaustively applying substitutions when they are the unique answer of a cluster or a subgoal is formalized as a binary (rewrite) relation \rightarrow_U over annotated rules (r, θ) . The precise definition and the heuristics for the cases where different rewrite sequences yield different results³ are in the full report. The framework can be adapted to different heuristics simply by changing the definition of \rightarrow_U .

We are ready to formalize explanations. They are graphs (abstracting a hypertext) where each node illustrates: (i) the local context for a goal, that is, the rules whose head unifies with that goal; (ii) a global view of all the proof attempts, consisting in the answers of each rule body and subgoal thereof. Such answers provide a sort of *lookahead* on proof outcomes that may help the user in navigating the proof. We proceed by defining the explanation graph, starting with its nodes and entry points.

Definition 2 An explanation node for a program P is a finite set of pairs (r, θ) where $r \in P$ and θ is a substitution.

The explanation entry point for an atom A w.r.t. P , denoted by $\text{entry}_P(A)$, is the (unique) explanation node X for P such that

$$X = \{(r, \theta) \mid r \in P, A \text{ is unifiable with } \text{head}(r), \\ \text{and } (r, \text{mgu}(A, \text{head}(r))) \rightarrow_U (r, \theta)\}.$$

There are two kinds of navigation links: *detail links* and *refinement links*. Informally, the former expand the proof details by showing the rules that can be used to prove a subgoal; the latter apply answer substitutions locally to the rule to see the effects on the other subgoals and focus on a subset of all the possible proofs.

Now we can proceed with the formalization of navigation links. They lead directly to nodes where unique answers have been propagated, and consider only maximally general answer substitutions to reduce redundancy. So we need a function $\text{mg}(S)$ that for all sets of substitutions S returns the maximally general elements of S . In the following we extend \rightarrow_U to explanation nodes as follows:

$$X_1 \rightarrow_U X_2 \text{ iff } X_2 = \{(r, \theta') \mid \\ \text{for some } (r, \theta) \in X_1, (r, \theta) \rightarrow_U (r, \theta')\}.$$

Definition 3 (Level 1 navigation link) For all explanation nodes X_1 and X_2 for P we define:

detail links: $X_1 \xrightarrow{L} X_2$ iff for some $(r, \theta) \in X_1$ and some $L \in \text{body}(r)$, $\text{entry}_P(L\theta) \rightarrow_U X_2$;

refinement links: $X_1 \xrightarrow{\sigma} X_2$ iff for some $(r, \theta) \in X_1$ and some $L \in \text{body}(r)$, $\sigma \in \text{mg}(\text{ans}_P^r(L\theta))$ and $\{(r, \theta\sigma)\} \rightarrow_U X_2$

³ This may happen if $\text{body}(r)$ fails.

Example 2 Let P be the program illustrated in Figure 1 extended with time-dependent facts, and $A = \text{allow}(\text{'paper0123.pdf'})$. If the body literals of r_2 , r_3 , and r_4 have no solutions, then $\text{entry}_P(A) = \{(r_2, \theta), (r_3, \theta), (r_4, \theta)\}$ where $\theta = [\text{Resource} = \text{'paper0123.pdf'}$]. If only $\text{authenticated}(\text{User})$ has a unique solution, say, $[\text{User} = \text{'John'}]$, then $\text{entry}_P(A) = \{(r_2, \theta), (r_3, \theta'), (r_4, \theta')\}$ where $\theta' = [\text{Resource} = \text{'paper0123.pdf'}, \text{User} = \text{'John'}]$. Now suppose that the subgoal $\text{has.subscription}(\text{John}, \text{Subscription})$ of $r_3\theta'$ has two answer substitutions σ, σ' . The action of selecting and applying σ to r_3 is formalized by crossing the refinement link $\text{entry}_P(A) \xrightarrow{\sigma} \{(r_2, \theta), (r_3, \theta'\sigma), (r_4, \theta')\}$. Otherwise, the action of expanding the details of the subgoal $L = \text{authenticated}(\text{User})$ of $r_3\theta'$ is formalized by the detail link $\text{entry}_P(A) \xrightarrow{\sigma} \{(r_6, \gamma), (r_7, \gamma')\}$, where γ, γ' result from applying the unique answers of the subgoals of r_6 and r_7 . \square

Definition 4 A level 1 explanation graph for an atom A w.r.t. a partially specified program P is a minimal structure (V, E^D, E^R) closed under the following properties:

1. V contains $\text{entry}_P(A)$;
2. if for some $X_1 \in V$, $X_1 \xrightarrow{L} X_2$ then V contains exactly one variant \tilde{X}_2 of X_2 , and E^D contains an edge (X_1, L, \tilde{X}_2) ;
3. if for some $X_1 \in V$, $X_1 \xrightarrow{\sigma} X_2$ then V contains exactly one variant \tilde{X}_2 of X_2 , and E^R contains an edge $(X_1, \sigma, \tilde{X}_2)$.

Since our programs are basically Datalog programs, it can be shown that the explanation graph is always finite. It is cyclic in the presence of infinitely failed proofs, and the browser can highlight loops by marking the nodes that have already been visited. In the full paper, *explanation structures* are defined as explanation graphs labelled with suitably filtered answer substitutions (the *global*, possibly *inter-proof* information).

6 Verbalization

Explanation structures are translated into natural language sentences by instantiating text patterns. The verbalization patterns for application dependent literals must be supplied during the framework instantiation phase. They are typically formulated with simple PROTUNE metafacts like:

`is_authenticated(X).explanation : [X, is_authenticated]`

If necessary, proper rules (with nonempty body) can be used and it is also possible to define text patterns for negative literals. By default, variable names are taken from the original rule—which is the first element of the current node (r, θ) .

A cluster $C = \{L, t.a_1 : v_1, \dots, t.a_n : v_n\}$ of (r, θ) with main literal L is verbalized as a single condition:

`verb(L1\theta) with a1 v1, a2 v2, ..., and an vn.`

The rest of this section is implicitly formulated w.r.t. the following context:

- a node $X = \{(r_1, \theta_1), \dots, (r_z, \theta_z)\}$ of XG (the current node);
- an atom A (the one being currently explained), more general than $\text{head}(r_i\theta_i)$ for $1 \leq i \leq z$.

For all clusters or literals Y and for all substitutions θ , the verbalization of $Y\theta$ will be denoted by $\text{verb}(Y, \theta)$. For the sake of simplicity, the navigation links will not be shown.

We show the verbalization details for *why-not* queries (the details for the other queries are in the full paper). They start with:

I can't prove that $\text{verb}(A, \varepsilon)$ because: (if A is ground)

I can't find any <var list> such that $\text{verb}(A, \varepsilon)$ because: (if A is not ground).

The above *incipit* is followed by the verbalization of all $(r_i, \theta_i) \in X$. Each pair (r_i, θ_i) is formatted according to the following pattern:

Rule <rule identifier> is not applicable:
<Success Slot> but <Failure Slot>

where **but** is omitted if any of the two slots is missing. The Success Slot in its most complete version is verbalized as:

<quantification>
verb(Y_1, θ_i) and ...and verb(Y_m, θ_i) and verb(L_1, θ_i)
and ...and verb(L_n, θ_i)

where $Y_1 \dots Y_m$ are all the \subseteq -maximal clusters in $\text{body}(r_i \theta_i)$ with a single answer (i.e. $|\text{ans}_P(Y_i)| = 1$), and $L_1 \dots L_n$ are all the literals with a single answer (i.e. $|\text{ans}_P(L_j)| = 1$) that do not occur in $Y_1 \dots Y_m$.

If $\text{body}(r_i \theta_i)$ contains some failed clusters or literals (with zero answers), then the Failure Slot is verbalized as⁴

verb(not Z_1, θ_i) moreover...moreover
verb(not Z_j, θ_i) moreover verb(not L'_1, θ_i) more-
over...moreover verb(not L'_k, θ_i)

where $\{Z_1 \dots Z_j\}$, denoted by **minfailed**, consists of the \subseteq -minimal failed clusters in $\text{body}(r_i \theta_i)$, and $L'_1 \dots L'_k$ are the failed literals in $\text{body}(r_i \theta_i)$ that neither occur in **minfailed** nor belong to the set of attribute atoms $t.a:v$ such that t is the main variable of a singleton cluster in **minfailed**. With the latter condition, the attributes of non-existing objects are ignored.

Example 3 If no id has been provided, then (with this condition) the *why not* verbalization of r_6 is simply: “**there is no Credential such that Credential is an id**” as expected. A naive approach would have produced something like “**there is no Credential such that Credential is an id with name User and public.key K**”, which is misleading. □

If no clusters or literals fail, the Failure Slot is verbalized as

each of the following facts has some solution
<quantification> verb(L'_1) ... <quantification> verb(L'_k)
but there is no common solution

where $L'_1 \dots L'_k$ are the literals with two or more solutions in $\text{body}(r_i \theta_i)$. Via refinement links, the user may apply a chosen answer substitution and explore why it eventually fails (i.e. which other subgoals become failed after applying that substitution).

7 Conclusions

In TN it is possible to construct good explanations in response to *why*, *why not*, *how to*, and *what if* queries, using simple generic explanation strategies based on the intended meaning of a few core predicates with a special role in negotiations. The

only extra workload needed during the framework instantiation phase to support explanations consists in writing literal verbalization patterns. Moreover, the extra computational burden on the server can be limited to adding a few more rules to the filtered policies (the literal verbalization rules) because the explanations can be independently produced on the clients. Despite its simplicity, our explanation mechanism supports most of the advanced features of second generation explanation systems.

Another contribution of our work is a novel explanation structure combining local and global information about single and multiple proof attempts. The new explanation structures are analogous to the tables of tabled logic programming engines, so our work might be applied to execution tracing in tabled Prolog implementations like XSB. Our method provides an effective way of explaining infinitely failed proofs. Global proof information and heuristics help in focussing the explanation strictly on relevant details. The resulting explanations have no counterpart in previous literature.

Prevention of harmful behaviors within cognitive and autonomous agents

Caroline Chopinaud¹ and Amal El Fallah Seghrouchni² and Patrick Taillibert³

Abstract. Being able to ensure that a multiagent system will not generate undesirable behaviors is essential within the context of critical applications (embedded systems or real-time systems). The emergence of behaviors from the agents interaction can generate situations incompatible with the expected system execution. The standard methods to validate a multiagent system do not prevent the occurrence of undesirable behaviors during its execution in real condition. We propose a complementary approach of dynamic self-monitoring and self-regulation allowing the agents to control their own behavior. This paper goes on to present the automatic generation of self-controlled agents. We use the observer approach to verify that the agents behavior respects a set of laws throughout the system execution.

1 Introduction

The behavior of a multiagent system (MAS) emerges from the agents' interaction. Some emergent behaviors can lead the system to fail: these are **undesirable behaviors**. In our study, the autonomy is an essential specificity of cognitive agents. We consider the autonomy as the capacity of an agent to take its decision alone, without the help of another entity [1]. From the developer point of view, the agent autonomy requires to take into account the unpredictability of the agents' behavior. This view increases the possibilities of occurrence of undesirable behaviors.

The potential occurrence of undesirable behaviors could be critical for the MAS execution, especially in the context of embedded or real-time applications. To ensure the reliability of the multiagent systems, our work aims to provide a mechanism allowing the detection and the prevention of the occurrence of these undesirable behaviors, harmful to the system execution. A first approach could be the application to multiagent systems of widely used validation methods like: tests, model-checking and automatic demonstration. But, these methods cannot find all the errors in a system: the model-checking works on an abstraction of the system and its environment; the automatic demonstration is complex and heavy; tests cannot be exhaustive [3]. So, in order to detect the remaining errors, we propose to verify the system at runtime. From this perspective, the recent work of R. Paes & al. [12] proposes the use of laws to control the emergence of wrong behaviors in the context of open MAS. Their approach consists in monitoring the interaction of the agents thanks to an external entity and in describing the interaction protocols to detect violation. Similarly, the work of Klein and Dellarocas [7] proposes an approach of the exception handling thanks to a description of the

exceptions and external entities filtering the agents' communication. In the work of S. Hagg [6], sentinels are used to monitor the communication between the agents, build models of other agents and intervene according to given guidelines. To our knowledge, works about the surveillance of agents behaviors use external entities to monitor the agents and detect inconsistencies, particularly with respect to their communications and interactions. Moreover, most of the verification steps are done manually. The main advantage of our approach consists in the automatic creation of agents which are able to verify their behaviors from laws. This verification is based on the dynamic self-monitoring and self-regulation of each agent in order to prevent the system failure. We call this verification, the **agent control**.

The section 2 presents the agent control. The section 3 describes the laws and their use to control the agents by themselves. The section 4 details the whole process of the generation of a self-controlled agent. The section 5 describes the working of our approach and the section 6 introduces the multiagent case. Finally, the section 7 introduces a prototype implementing our approach while the section 8 concludes our paper.

2 Control of autonomous agents

The agent control is divided in three stages :

- The monitoring of the behavior of an agent or a group of agents.
- The detection of undesirable behaviors that could emerge from the execution of an agent or a group of agents.
- The regulation of the problematical agent(s).

2.1 Monitoring of an agent behavior

Monitoring the behavior of each agent in MAS in order to observe relevant events, allows to detect or prevent the occurrence of undesirable behaviors in the system [4]. Our work focuses on the observation of the MAS behavior at runtime. To observe the behavior of an agent, it is necessary to insert event detectors in the agent program. Although it is possible for a developer to insert manually the probes into the agent program, this kind of instrumentation is hard, time-consuming and prone to error [9]. We propose an automatic instrumentation of the programs of the agents, *i.e.* to insert a code of control to detect some events from the specification of *hooks* provided by the developers. The main interest of this automation is to simplify the work of the developer and to reduce the risk of errors during the instrumentation.

2.2 Detection of undesirable behaviors

Making an exhaustive model of all the MAS behaviors is difficult and costly because of its complexity (indeterminism, state explosion, distributed nature, interleaving between the autonomous agents behaviors). So we propose to abstract this model thanks to the definition of properties about the agents' behavior. These properties are expressed using norms [13], usually defined as constraints on the agents' behavior in order to guarantee a collective order. An autonomous agent decides to respect or not a norm depending on the actions it chooses to perform. We use **laws** to describe desired or dreaded behaviors or situations ; these laws represent significant or critical requirements on the system execution and could be specified by the customer. At the opposite of norms, laws are defined independently of the agents' design and are not taken into account by the agents during the decision process. In other words, the agents can act autonomously while our approach consists in verifying afterwards if the chosen action respects the laws. Consequently the agents' implementation and the laws/control description are distinguished. The detection of undesirable behaviors can be viewed as the detection of laws transgression.

2.3 Self-regulation of agents behaviors

When an occurrence of (a potential) undesirable behavior is (to be) detected, (*i.e.* when a law is transgressed), the agents concerned by the law must regulate their behavior by themselves thanks to their capacity of reasoning. The developer provides the agents with a set of strategies of regulation associated with the transgression of laws and, at runtime, the agents deduce the behavior to follow when they are informed of a law transgression. This behavior of regulation takes the transgression into account but also the main behavior of the agent, its current state, or even the other agents. Then, it seems quite complex to define these strategies independently of the agents' implementation, as for the laws. It is the reason why, to date, the strategies are defined directly in the agent program.

3 The control description

In our approach, the description of the control applied to a multiagent system comes down to the description of laws associated with the agents.

3.1 Level of description

For a sake of generality, we would like to provide a mechanism of control which is not specific to one agent model. Hence, the laws concern abstract concepts representing the application and the model(s) of agent(s) used. We propose an ontology composed of the following concepts: AGENT, FEATURES and ACTION. The FEATURES concept has the sub-concept of Object, Message, Goal, Plan and Knowledge. The ACTION concept has the sub-concepts of Creation_Agent, Sending_Message, Receipt_Message and Migration.

The designers of the system may freely extend this set of basic concepts to refine and to enrich the description of the model(s) of the agent(s) and the application. Moreover, in order to monitor the agent behavior, we have introduced previously that the developers can describe hooks (cf 2.1). These hooks define the relation between the concepts describing the agent model(s) and its (their) implementation (for more details see [2]).

3.2 A language of Law

To express the laws, we propose a language based on deontic operators, which are widely used in the context of norms. Our language applies to events and states about the agents, corresponding to the general basic concepts of FEATURES and ACTION, introduced in the previous part. An **event** can be the execution of an action or the change of a features value. A **state** represents the resulting state of an event. The expression of time or temporal relation between the events and states is crucial in our framework and it is taken into account in our language as we will see below. Our language distinguishes two kinds of law: prohibition and obligation. A prohibition law represents the unwanted states or events of an agent. It allows the detection of situations where an event or a state which must never occur, is going to happen. An obligation law represents the expected states or events of an agent. It allows the detection of situations where an expected event or state does not occur. In our approach a law is composed of three parts:

- **CONCERNED AGENT (CA):** the statement of agents concerned by the law, *i.e.* the agents subject to the law and agents used to describe the law application context.
- **DEONTIC ASSERTION (DA):** the description of what is obligatory or forbidden. It is a set of relationships between an agent and an event or a state.
- **APPLICATION CONDITIONS (APC):** the description of the law context. It is an expression describing when the DA must be respected relatively to a set of events or states.

The description of our language is as follows:

<i>LAW</i>	$::= (CA) (DA \langle APC \rangle)$
<i>CA</i>	$::= agent : AGENT \langle \text{and } PROP \rangle$
<i>DA</i>	$::= DEON_OP EXP$
<i>APC</i>	$::= TEMP_OP EXP \mid TEMP_OP EXP APC$
<i>DEON_OP</i>	$::= FORBIDDEN \mid OBLIGED$
<i>TEMP_OP</i>	$::= AFTER \mid BEFORE \mid IF$
<i>EXP</i>	$::= TERM \mid TERM AND EXP \mid TERM THEN EXP$
<i>TERM</i>	$::= EVENT \mid NOT EVENT \mid EVENT TIME$
<i>EVENT</i>	$::= agent do SMTM \langle \text{and } PROP \rangle \mid agent be SMTM \langle \text{and } PROP \rangle$
<i>TIME</i>	$::= -second \mid +second$

where SMTM represents a concept like ACTION or FEATURES; AGENT represents the concept of agent; PROP is a common attribute representing the properties on these concepts.

The laws are, actually, deontic formula expressed in dynamic deontic logic[10]. Knowingly, the language limits the possibilities of laws expressiveness to a sub-set of the dynamic deontic logic, allowing the description of behaviors which can be monitored. For example, a law can be expressed in this way: “(L1): *It is forbidden for an agent A1 to do an action ACT2 after an action ACT1 and before a time Sec*” and by using the language :

(L1): (A1 : Agent)
FORBIDDEN (A1 do ACT2) **AFTER** (A1 do ACT1) - Sec.

4 Self-controlled Agents

A main interest of our approach is the generation of agents being able to control their own behaviors. A self-controlled agent is obtained automatically from:

- the agent behavior program,
- the set of laws associated with the agent,
- the hooks between the concepts used in the laws and the agent model implementation.

A generated agent has a specific architecture of control allowing its monitoring and the detection of laws transgression thanks to the **observer mechanism** [5].

4.1 The observer

The observer mechanism is used in the context of real-time systems testing, on-line validation of parallel, or even distributed systems. The observer consists in a parallel execution of a program and a model of properties applied to the program execution. The model and the program are connected with control points. A controller checks on the model and the program execution are consistent. If the system execution does not match the model, the verification fails.

We propose to put this approach in place into the agents in order to provide them with the means to control their own behavior. A law is modeled by means of a Petri net [11] whose transitions are bound to the program with control points. The Petri nets representing each law are automatically generated (c.f. 4.3). We insert into the agent behavior program the control points and we generate a runnable agent with a specific architecture, using the observer approach. When the program execution meets a control point, the controller makes sure the tokens are in the right place at the right time in the corresponding net, and brings about some change in the model, accordingly.

4.2 The agent architecture

A target generated agent has a specific architecture divided into two parts, the *behavior part* and the *control part*. The behavior part includes the real agent behavior and strategies of regulation defined by the developer. Indeed, we would like not only that the verification fails when an inconsistency is detected, but that the agent regulates its behavior whenever a law is transgressed. The control part includes the set of Petri nets representing the laws associated with the agent and makes sure of the detection of the laws violation. The connections between the program and the models are effective thanks to a sending of information from the behavior part to the control part. To allow this sending of information, we instrument the behavior part by inserting automatically some control points associated with the events and states contained in the laws. The control part receives the information and verifies the respect of the laws.

4.3 The generation

The generation of a self-controlled agent comes down to the generation of the Petri nets representing the laws concerning the agent and the instrumentation of the agent behavior to detect the occurrence of events and states expressed in the laws.

4.3.1 The instrumentation

We propose an automatic instrumentation of the agent behavior program to monitor the occurrence of the events and states, defined in the laws, by means of **control points**. This instrumentation is done thanks to the hooks defined by the developer, between the concepts describing the model and its implementation. In order to do that, we draw our inspiration from the principle of weaving. The **weaving** is an important part of aspect programming [14]. The latter uses the weaving to inject aspects in classes of an application, at the methods level, to modify the system execution after the compilation. An aspect is a module representing crosscutting concerns. The interest of aspect programming to integrate the monitoring in an application

was demonstrated in another light by [8]. So, our approach could be summarize as follows:

1. Extracting the events or states to be detected.
2. For each event or state, searching for the hook that has been provided by the developer.
3. Injecting, before or after that hook, the piece of code allowing to send the information to the control part and to recover of possible information of transgression. The latest enables the agent to start a strategy of regulation.

4.3.2 The generation of Petri nets

The generation of a Petri net representing a law is divided into three stages:

1. The translation of the law in a logic expression L , in order to point out a set of atomic expressions, $\{e_1, \dots, e_n\}$.
2. Incrementally:
 - (a) The deduction of a set of Petri nets, $\{p_1, \dots, p_n\}$ representative of each expression in $\{e_1, \dots, e_n\}$.
 - (b) The merging of all the nets in $\{p_1, \dots, p_n\}$ from the relations between e_1, \dots, e_n to obtain a final Petri net, P , representing the law.

To perform the step (1), each operator in the language has a meaning in dynamic deontic logic. We use a set of translation rules to obtain the logic expression representing the law (cf. Set of Rules 1). For the step (2), we propose to represent atomic expression by means of a Petri net, as in the set of rules 2; and merging rules, as described in the set of rules 3. To express a prohibition we use an *inhibitor arc* and to express a time, we use a *temporal Petri net*. The final Petri net P representing the law, is embedded into the control part of each agent submitted to the law.

Set of Rules 1

- Let Act be a set of actions.
 Let $Assert$ be a set of assertions.
 Let $State$ be a set of states included in $Assert$.
 $\forall \alpha \in Act, \phi \in Assert, \beta \in State$.
- (1) $FORBIDDEN \alpha \equiv F\alpha$
 - (2) $OBLIGED \alpha \equiv O\alpha$
 - (3) $\phi AFTER \alpha \equiv [\alpha]\phi$
 - (4) $FORBIDDEN \alpha_1 BEFORE \alpha_2 \equiv done(\alpha_2) \vee F\alpha_1$
 - (5) $OBLIGED \alpha_1 BEFORE \alpha_2 \equiv \neg done(\alpha) \vee O\alpha_1$
 - (6) $\alpha_1 AND \alpha_2 \equiv (\alpha_1; \alpha_2) \cup (\alpha_2; \alpha_1)$
 - (7) $\alpha_1 THEN \alpha_2 \equiv \alpha_1; \alpha_2$
 - (8) $\phi IF \beta \equiv \beta \supset \phi$
 - (9) $FORBIDDEN \alpha - Sec \equiv done(time(Sec)) \vee F\alpha$
 - (10) $OBLIGED \alpha - Sec \equiv \neg done(time(Sec)) \vee O\alpha$
 - (11) $\phi + Sec \equiv [time(Sec)]\phi$

Set of Rules 2

- Let $PN = \langle P, T, Pre, Post \rangle$ be a Petri net, where:
 P : a set of places, $P = (p_1, p_2, \dots, p_n)$,
 T : a set of transitions, $T = (t_1, t_2, \dots, t_n)$,
 Pre : a function, $P \times T \rightarrow N$, which defines directed arcs from places to transitions. (Note Pre^* , when the directed arc is an inhibitor arc)
 $Post$: a function, $P \times T \rightarrow N$, which defines directed arcs from transitions to places
 t_α be the transition associated with the action α .
 In the following, the rule $X \Rightarrow Y$ means that X is a logical assertion and Y the corresponding Petri net.
 $\forall \alpha \in Act, \beta \in State$
- (1) $F\alpha \Rightarrow \langle (p_i, p_j), t_\alpha, Pre^*(p_i, t_\alpha), Post(p_j, t_\alpha) \rangle$
 - (2) $O\alpha \Rightarrow \langle (p_i, p_j), t_\alpha, Pre(p_i, t_\alpha), Post(p_j, t_\alpha) \rangle$
 - (3) $done\alpha \Rightarrow \langle (p_i, p_j), t_\alpha, Pre(p_i, t_\alpha), Post(p_j, t_\alpha) \rangle$

- (4) $\neg done\alpha \Rightarrow < p_i, p_j, t_\alpha, Pre^*(p_i, t_\alpha), Post(p_j, t_\alpha) >$
- (5) $\beta \Rightarrow < (p_i, \beta, p_j), t_i, t_j, (Pre(p_i, t_i), Pre(\beta, t_j)), (Post(\beta, t_i), Post(p_j, t_j)) >$
- (6) $\alpha \Rightarrow < (p_i, p_j), t_\alpha, Pre(p_i, t_\alpha), Post(p_j, t_\alpha) >$

Set of Rules 3

Let t_α be the transition associated with the event α .
 Let t_ϕ be the transition associated with the event used in ϕ .
 Let $Pre(p,t)$ be the function which returns the input place p of a transition t .
 Let $Post(p,t)$ be the function which returns the output place p of a transition t .
 Let $merge_p(p_1, p_2)$ be the operator of fusion of two places p_1 and p_2 .
 $\forall \alpha \in Act, \phi \in Assert, \beta \in State$
 (1) $[\alpha]\phi \Rightarrow merge_p(Pre(p, t_\alpha), Pre(p, t_\phi))$.
 (2) $\phi_1 \vee \phi_2 \Rightarrow merge_p(Pre(p, t_{\phi_1}), Pre(p, t_{\phi_2}))$.
 (3) $\phi_1 \wedge \phi_2 \Rightarrow separation$ in two Petri nets : PN_{ϕ_1} and PN_{ϕ_2}
 (4) $\beta \supset \phi \Rightarrow merge_p(Pre(p, t_\phi), \beta)$

5 The detection of transgression

We remind that the behavior part sends information about its states and events to the control part. From this information, the control part must verify if the laws associated with the agent are respected. To detect the laws violation, the control part uses the two following algorithms:

Algorithm 1 In the main part of the control part

- 1: Let I be an information about the agent behavior.
 - 2: Let $\{t_1, \dots, t_n\}$ be the set of transitions associated with I .
 - 3: Let $\{P_1, \dots, P_m\}$ be the set of Petri nets associated with the agent.
 - 4: Let $\{Pact_1, \dots, Pact_p\}$ be the set of activated Petri nets (i.e. associated with the laws to be manage)
 - 5: Let t_{ij} be the transition i of the net j .
 - 6: **for all** $P_k \in \{P_1, \dots, P_m\}$ with $t_{1k} \in \{t_1, \dots, t_n\}$ **do**
 - 7: $Pact_{p+1} \leftarrow$ create an instance of P_k
 - 8: add $Pact_{p+1}$ in $\{Pact_1, \dots, Pact_p\}$
 - 9: **end for**
 - 10: Let $\{Pact_1, \dots, Pact_l\}$ be the set of the activated Petri nets including a $t_{ij} \in \{t_1, \dots, t_n\}, j \in \{1, \dots, l\}$
 - 11: **for all** $Pact_j \in \{Pact_1, \dots, Pact_l\}$ **do**
 - 12: inform $Pact_j$ of the information associated with t_{ij}
 - 13: **end for**
-

Algorithm 2 Within the instances of Petri net

- 1: Let $\{t_1, t_n\}$ be the set of transitions of the Petri net.
 - 2: Let I be the sent information.
 - 3: Let t_I be the transition associated with the information $I \in t_1, \dots, t_n$.
 - 4: A transition t_i is **activated** if a token stands in all the previous places of t_i (in our Petri net the arcs are one-valuated).
 - 5: **if** t_I is activated **then**
 - 6: **if** t_I is fireable **then**
 - 7: fire the transition t_I
 - 8: **else**
 - 9: throw exception
 - 10: **end if**
 - 11: **end if**
-

The control part receives the information and generates a new instances of each Petri net beginning by the transition associated with the information. The monitoring of the law, i.e. the associated Petri net, is **activated**. Then, the control part forwards the information to all the instances where the information is expected. If the transition associated with the information is activated, the instance verifies if the transition is fireable (according to the line 6, algo 2) and changes the Petri net. When an inconsistency is detected, the instance throws an exception and the control part warns the behavior part by sending

information of transgression. An instance is destroyed when the net is in a final state, so when the law is respected or when the delay of the law observation is elapsed.

When the behavior part sends an information to the control part, it is stopped until the control part permits its restarting. The temporary deadlock is essential if we want to prevent the execution of forbidden actions.

6 About the multiagent behaviors

In the previous parts, we have presented the whole functioning of the self-controlled agents. Particularly, we tackle a single agent view, that is when a law affects only one agent. Even if this first part solves a set of problems related to individual agent behavior, we think that shifting to the multiagent behaviors rises other problems. Indeed, the question is the control of the multiagent system behavior when several agents, individually correct, are put together. A first step to answer this question is the handling of the control when a law is applied to several agents.

Our aim is to distribute as much as possible the control into each agent involved in the law. We would like to avoid a centralized solution. We emphasize three points to put forward in that case:

- How is the distribution of the Petri net done among all the agents concerned by the law?
- How do the control parts of the agents collaborate to detect a law transgression?
- How is the regulation done? Who is the culprit?

6.1 The net distribution

The Petri net representing a law applied to several agents is deduced as in a single agent context. Then, the net is distributed into the control parts of the agents concerned by the law. This distribution is done by following the algorithm 3.

Algorithm 3 Petri net Distribution

- 1: Let L be a law.
 - 2: Let P be the Petri net representing L .
 - 3: Let $Nbagent$ be the number of agents concerned by L .
 - 4: Let $\{T_{m1}, \dots, T_{mn}\}$ be the set of transitions where the information associated with t_{mi} comes from the agent $AG_m, m \in \{1, \dots, Nbagent\}$.
 - 5: Let $Ppre_{mt}$ be the input place of the transition t of the agent AG_m .
 - 6: Let $Ppost_{mt}$ be the output place of the transition t of the agent AG_m .
 - 7: **for all** $T \in \{T_{m1}, \dots, T_{mn}\}$ **do**
 - 8: put T in the control part of the agent AG_m .
 - 9: **end for**
 - 10: **if** $Ppost_{mt} \equiv Ppre_{(m+1)t'}$ **then**
 - 11: put $Ppost_{mt}$ in the control part of the agent $AG_{(m+1)}$.
 - 12: **end if**
 - 13: **if** $Ppre_{(m+1)t'} \equiv Ppre_{mt}$ **then**
 - 14: put $Ppre_{mt}$ in the control part of the agent AG_m .
 - 15: **end if**
 - 16: **for all** $t' \in \{1, \dots, n\}, m' \in \{1, \dots, Nbagent\}$ **do**
 - 17: **if** $Ppost_{mt} \neq Ppre_{m't'}$ **then**
 - 18: put $Ppost_{mt}$ in the control part of the agent AG_m .
 - 19: **end if**
 - 20: **if** $Ppre_{mt} \neq Ppost_{m't'}$ **then**
 - 21: put $Ppre_{mt}$ in the control part of the agent AG_m .
 - 22: **end if**
 - 23: **end for**
-

Let us note that the control parts are only linked through the arcs between places and transitions (themselves distributed over the control parts of agents). These links represent the information flow between the control parts (i.e. the flow of the token).

6.2 The collaboration

A control part is willing to listen to the behavior part of its agent and to the control part of the other agents. Indeed, when a law is distributed into several agents, the control parts of these agents are able to exchange information about the occurrence of events and states. We have seen that the net distribution between the control parts is in such a way that only branches $Transition \rightarrow Place$ or $Place \rightarrow Transition$ link every pieces of the net. These arcs represent the flow of an information between the agents. In order to explain the collaboration between the control parts, we propose to use an example.

So, when a control part, C_A , receives an information from its agent, if this information is associated with a transition T whose the next place is in the control part of another agent, C_B , then C_A sends information about the firing of this transition, (actually, it sends the token) to the control part C_B and waits for an acknowledgment of receipt. During this waiting, the execution of the agent is temporarily stopped and the information associated with T is considered as always available. The control part C_B receives the information, sends the acknowledgment to the control part C_A and executes the algorithm 1, as if the information comes to its associated behavior part. When C_A receives the acknowledgment, the transition can be really fired, the information associated with T is consumed and the agent behavior can continue.

6.3 The regulation

The detection of a law transgression generates an exception in the control part. This exception generates the transmission of information of transgression from the control part to the behavior part of the agent. In the context of a law applied to several agents, the mechanism remains the same. All the control parts detecting a transgression, send the exception to the associated behavior part. So, we suppose that the strategies of regulation solve the problem of who is the culprit. Putting such strategy in place in the agents is not trivial and will be treated in our future work.

7 Implementation

Our approach is implemented in a framework: SCAAR. This framework provides the means to describe laws, concepts... and to generate self-controlled agents. A prototype of SCAAR has been implemented in SICStus Prolog. This first version provides a part of the language, to describe single agent laws and the generation, from the laws description, of the Petri nets. The net distribution into several agents is in progress. The behavior of the control part has been implemented using the algorithms described in the section 5. The generated self-controlled agents are made up of two Prolog processes, one executing the real agent behavior, one executing the control part behavior. These two parts communicate by TCP/IP channel for the messages passing about the occurrence of events in the agent behavior and the detection of laws transgression.

Our approach has been applied to a multiagent application of mobile naval targets localization, developed in our service: *Interloc*. In Interloc, planes seek to detect boats, in a passive way. The system is implemented in Prolog. In order to demonstrate the robustness of MAS application, Interloc provides a set of wrong agent behaviors, like:

- Dumb: The agent sends no message.
- Deaf: The agent reads no message.

- Selfish: The agent always refuses the requested services.
- Absurd: The agent accepts the services but sends absurd results.
- Latecomer: The agent is always late replying.

Therefore, Interloc is an interesting testbed to validate our approach. We have expressed laws to detect wrong behaviors and the application has been executed with modified agents in order to detect these “undesirable behaviors”, by using the generator provided by SCAAR.

8 Conclusion

We have presented the principles of the autonomous agent control. Particularly, we have described the mechanisms and the architecture of the self-controlled agents, agents able to monitor their own behaviors. This monitoring is done from the specification of the laws that the agents must respect during their execution. A distributed solution to control multiagent behaviors has been proposed. An advantage of our approach is the possibility to define laws at a high level, allowing its application to several models of agents. Another point is the automatic generation of the agents and the simplification of the developer’s work to take the control into account. The framework SCAAR, allowing the generation of self-controlled agents has been introduced. Our future work is essentially to enhance the implementation and treat more carefully the regulation part.

Coalition Structure Generation in Task-Based Settings

Viet Dung Dang and Nicholas R. Jennings¹

Abstract. The coalition formation process, in which a number of independent, autonomous agents come together to act as a collective, is an important form of interaction in multi-agent systems. However, one of the main problems that hinders the wide spread adoption of coalition formation technologies is the computational complexity of *coalition structure generation*. That is, once a group of agents has been identified, how can it be partitioned in order to maximise the social payoff? To date, most work on this problem has concentrated on simple *characteristic function games*. However, this lacks the notion of tasks which makes it more difficult to apply it in many applications. Against this background, this paper studies coalition structure generation in a general task-based setting. Specifically, we show that this problem is NP-hard and that the minimum number of coalition structures that need to be searched through in order to establish a solution within a bound from the optimal is exponential to the number of agents. We then go onto develop an anytime algorithm that can establish a solution within a bound from the optimal with a minimal search and can reduce the bound further if time permits.

1 Introduction

The coming together of a number of distinct, autonomous agents in order to act as a coherent grouping is an important form of interaction in multi-agent systems. It has been long studied in game theory [3] and has recently become an important topic in multi-agent systems (where buyer agents may pool their requirements in order to obtain bigger group discounts), in grid computing (where multi-institution virtual organisations are viewed as being central to coordinated resource sharing and problem solving), and in e-business (where agile groupings of agents need to be formed in order to satisfy particular market niches). In all of these cases, the formation of coalitions aims to increase the agents' abilities to satisfy goals and to maximise their personal and/or the system's outcomes.

In this context, the coalition formation process can be viewed as being composed of three main activities [5]:

1. *Coalition structure generation*: forming coalitions of agents such that those within a coalition coordinate their activities, but those in different coalitions do not. This primarily involves partitioning the set of all agents in the system into exhaustive and disjoint coalitions². Such a partition is called a coalition structure. For example, in a multi-agent system composed of three agents $\{a_1, a_2, a_3\}$, there exist seven possible coalitions: $\{a_1\}, \{a_2\}, \{a_3\}, \{a_1, a_2\}, \{a_1, a_3\}, \{a_2, a_3\}, \{a_1, a_2, a_3\}$ and five possible coalition structures: $\{\{a_1, a_2, a_3\}\}, \{\{a_1\},$

$\{a_2, a_3\}\}, \{\{a_2\}, \{a_3, a_1\}\}, \{\{a_3\}, \{a_1, a_2\}\}$ and $\{\{a_1\}, \{a_2\}, \{a_3\}\}$.

2. *Optimising the value of each coalition*: pooling the resources and tasks of the agents in a given coalition to maximise the coalition value. For example, given the coalition structure $\{\{a_1\}, \{a_2, a_3\}\}$, each of the two coalitions $\{a_1\}$ and $\{a_2, a_3\}$ will try to optimise its value.
3. *Payoff distribution*: dividing each coalition's value among its members. For example, if the coalition $\{a_2, a_3\}$ produces a payoff of X then this value needs to be divided between a_2 and a_3 according to some scheme (e.g. equality or stability).

Although these activities are distinct and, in a sense, conceptually sequential, it is also clear that they interact. For example, in a competitive environment, the coalition that an agent wants to join depends on the payoff that it is likely to receive (activities 1 and 3). However, in cooperative environments, where the agents work together to maximise the social welfare, payoff distribution is less important, and coalition structure generation that maximises the social welfare is the dominant concern. Here, our focus is on the first of these activities.

To date, most work on coalition structure generation has focused on simple *characteristic function games* (CFGs) (see section 6). In such settings, there is a value $v(S)$ for each and every subset S of A, known as the value of coalition S, which is the utility that members of S can jointly attain. However, in many practical applications, it is often the case that a coalition is formed in order to perform some task from a pool of potential tasks that the agent system has to perform [2] [6]. But in CFGs this connection between coalitions and tasks is absent; it is simply assumed that a coalition's value is attained when its agents pool their resources and tasks together somehow. The notion of tasks generally increases the complexity of the problem as there are typically many ways to map coalitions to tasks (as will be shown in more detail in section 2). Also, the assumption of CFGs that a coalition value is not affected by the actions of non-members is no longer valid, as a coalition's value now depends on the tasks that it performs and this set of tasks are accessible by all agents. Recently, there have been some work on such task-based coalition formations [2] [6]. However, the authors typically made some limiting assumptions about either the coalition values or the maximum size of a coalition (see section 6 for more details). In this paper we don't make such assumptions, as we deal with a general case.

Against this background, this paper advances the state-of-the-art in the following ways. First, we analyse the complexity of the coalition structure generation problem in task-based coalition formation settings. We show that the problem is NP-hard and, moreover, the minimum number of coalition structures that need to be searched through in order to establish a solution within a bound from the optimal is exponential to the number of agents. Second, we develop an anytime algorithm that can establish a solution within a bound from

¹ School of Electronics and Computer Science, University of Southampton, Southampton SO17 1BJ, UK, email: {vdd, nrj}@ecs.soton.ac.uk.

² Some research also considers non-disjoint coalitions (see section 5 for details).

the optimal and can reduce the bound further if time permits. We also consider a special case where each coalition carries out at most one task (referred as single-task coalitions in our paper) and show that in this case, the minimum number of coalition structures that need to be searched through in order to establish a bound from the optimal is much smaller than the general case.

The rest of the paper is structured as follows. Section 2 introduces our task-based coalition formation model. Section 3 analyses the complexity of the coalition structure generation problem and presents a minimal search to establish a bound from the optimal. Section 4 presents our anytime algorithm. Section 5 deals with the case of single-task coalitions. Finally, section 6 covers related work and section 7 concludes.

2 Task-Based Coalition Formation

This section formalises coalition structure generation in task-based settings, an extension of coalition formation in CFGs. Let A be the set of agents, and n be the number of agents in A (i.e. $|A| = n$). Let T be the set of tasks and m be the number of tasks: $T = \{t_1, t_2, \dots, t_m\}$. As an extension of coalition formation in CFGs, we consider settings where for each subset $C \subseteq A$ and each set of tasks $V \subseteq T$ there is a coalition value $v(C, V)$ for the coalition (C, V) . The coalition value $v(C, V)$ can be considered as the utility that agents in coalition C can attain by performing the tasks in V .³ Thus, while in traditional CFG the coalition value is a function $v : 2^A \rightarrow R$, in our case it is a function $v : 2^A \times 2^T \rightarrow R$. It can be seen that for each CFG coalition C there are $(2^m - 1)$ corresponding task-based coalitions (C, V) as there are $(2^m - 1)$ possible set of tasks. As there are $(2^n - 1)$ CFG coalitions C , there are $(2^n - 1)(2^m - 1)$ task-based coalitions.

As in [3], we assume that every coalition value is non-negative:

$$v(C, V) \geq 0, \forall C \subseteq A, V \subseteq T \quad (1)$$

Definition 1 A coalition structure CS is a partition of A into exhaustive disjoint (non-empty) coalitions, each of which will do a different set of tasks such as: i) these sets of tasks are disjoint, ii) at most one of them can be empty (that is, at most one coalition will do nothing, because if two or more of them do nothing then we can merge them together into one)⁴. Thus, $CS = \{(C_1, V_1), (C_2, V_2), \dots, (C_k, V_k)\}$, $1 \leq k \leq n$, coalition C_i , $1 \leq i \leq k$, will do the set of tasks V_i such that the following conditions are satisfied:

- $C_i \subseteq A, C_i \neq \emptyset, \forall 1 \leq i \leq k$
- $C_i \cap C_j = \emptyset, \forall 1 \leq i, j \leq k, i \neq j$
- $\bigcup_{i=1}^k C_i = A$
- $V_i \subseteq T, \forall 1 \leq i \leq k$
- $V_i \cap V_j = \emptyset, \forall 1 \leq i, j \leq k, i \neq j$
- $|\{V_i | V_i = \emptyset\}| \leq 1$

For example, for $A = \{a_1, a_2, a_3, a_4, a_5, a_6\}$ and $T = \{t_1, t_2, t_3, t_4, t_5, t_6\}$, the following is a coalition structure: $\{\{\{a_1, a_2\}, \{t_1\}\}, \{\{a_3\}, \{t_2, t_3\}\}, \{\{a_4, a_5\}, \{t_4, t_5\}\}\}$. In the above coalition structure, coalition $\{a_1, a_2\}$ does task t_1 , coalition $\{a_3\}$ does tasks t_2 and t_3 , coalition $\{a_4, a_5\}$ carries out tasks t_4 and t_5 , and agent a_6 does nothing (also task t_6 is not carried out by any coalition).

³ In this paper, we use the word *coalition* to refer to both a group of agents (e.g. coalition C) and a group of agents with a set of tasks to perform (e.g. coalition (C, V)).

⁴ The value of a coalition that does nothing is 0, that is, $v(C, \emptyset) = 0$.

Proposition 1 Let the size of a coalition structure be the number of coalitions that it contains. Then the size of any task-based coalition structure will be less than the number of tasks plus 1. That is, for any coalition structure $CS = \{(C_1, V_1), (C_2, V_2), \dots, (C_k, V_k)\}$, we have:

$$k \leq m + 1 \quad (2)$$

PROOF. From definition 1 we have: the sets V_i are disjoint and at most one of them is empty. Thus the union of the sets V_1, V_2, \dots, V_k must have at least $k - 1$ elements. But this union is a subset of T and T has m elements. Thus we have $k - 1 \leq m$ or $k \leq m + 1$. \square

Proposition 2 For each CFG coalition structure (C_1, C_2, \dots, C_k) ($k \leq m + 1$), there are $(k + 1)^m$ corresponding task-based coalition structures.

PROOF. For each task $t \in T$, there are $k + 1$ possibilities: t is carried out by a coalition C_i , $1 \leq i \leq k$ or is not carried out by any coalition. As there are m tasks, there are $(k + 1)^m$ combinations of possibilities to form a task-based coalition structure from that CFG coalition structure. \square

As in traditional CFG, we consider the *value* of a coalition structure $V(CS)$ in terms of its social welfare. That is, the value of a coalition structure is the sum of the values of its coalitions:

$$V(CS) = \sum_{i=1}^k v(C_i, V_i)$$

for $CS = \{(C_1, V_1), (C_2, V_2), \dots, (C_k, V_k)\}$.

Also let L be the set of all coalition structures.

Given the above terms, the problem of coalition structure generation for task-based coalition formation is then to find a coalition structure CS^* that maximises the social welfare. That is:

$$CS^* = \operatorname{argmax}_{CS \in L} V(CS)$$

Moreover, a solution CS' is said to be *within a bound b from the optimal solution* iff: $V(CS^*)/V(CS') \leq b$.

Having presented the settings in this section, the next section analyses the complexity of the problem.

3 Complexity Analysis

In this section, we analyse the complexity of the problem and discuss the smallest number of coalition structures that need to be searched through in order to establish a solution that is within a bound from the optimal one.

First, we investigate the size of the search space. Just as in the case of CFGs, the set of all coalition structures can be partitioned into a number of layers, each layer L_k , $1 \leq k \leq n$ holds all coalition structures with size k .

In CFG settings, the number of coalition structures in L_k is $S(n, k)$, widely known in Mathematics as *the Stirling number of the Second Kind* [4]. The value of $S(n, k)$ can be computed by the following standard formula:

$$S(n, k) = \frac{1}{k!} \sum_{i=0}^{k-1} (-1)^i \binom{k}{i} (k-i)^n$$

In task-based settings, the number of coalition structures in L_k can be calculated as follows.

Proposition 3 *The number of coalition structures with size k ($1 \leq k \leq m+1$) can be computed by the following formula:*

$$|L_k| = (k+1)^m \cdot S(n, k)$$

PROOF. As for each CFG coalition structure (C_1, C_2, \dots, C_k) ($k \leq m+1$), there are $(k+1)^m$ corresponding task-based coalition structures (proposition 2) and there are $S(n, k)$ CFG coalition structures with size k , the number of coalition structures with size k is $(k+1)^m \cdot S(n, k)$. \square

Theorem 1 *The total number of coalition structures is $\sum_{k=1}^{\min(n, m+1)} (k+1)^m$.*

PROOF. As the number of coalition structures with size k ($1 \leq k \leq m+1$) is $(k+1)^m \cdot S(n, k)$ (proposition 3) and $k \leq n$ (as each coalition has at least one agent), thus the total number of coalition structures is $\sum_{k=1}^{\min(n, m+1)} (k+1)^m$. \square

With this knowledge, we now discuss how a bound from the optimal can be established while searching as little of the space as possible. In CFG settings, it has been shown that searching two CFG layers L_1 and L_2 is the quickest way to ensure a bound from the optimal [5] (quickest here means searching the smallest number of coalition structures). In our task-based settings, however, we will show that we only need to search a portion of the corresponding layers L_1 and L_2 in order to establish a bound.

Theorem 2 *The smallest number of coalition structures that need to be searched in order to establish a bound from the optimal is at least $(2^{m+n-1} - 1)$.*

PROOF. Suppose K^* is the smallest set of coalition structures that need to be searched in order to establish a bound from the optimal. That is, K^* contains the smallest number of coalition structures to be searched in order to establish a bound from the optimal. Because the value of a coalition $v(C, V)$ can be arbitrarily big, in order to establish a bound from the optimal, every coalition (C, V) ($V \neq \emptyset$) needs to be included in one of the coalition structures in K^* .

First, we can see that for any coalition (C, V) such that $C = A$ or $V = T$, the coalition structure that contains it cannot contain any other coalition, as there is either no agent or no task left. Thus the number of coalition structures that need to be searched through to cover these coalitions (and only them) is the number of these coalitions.

Now let us count the number of coalitions (C, V) such that $C = A$ or $V = T$. There are $(2^m - 1)$ coalitions (A, V) as there are $(2^m - 1)$ non-empty subsets of T . Similarly, there are $(2^n - 1)$ coalitions (C, T) . However, the coalition (A, T) is counted twice, so we have the number of coalitions (C, V) such that $C = A$ or $V = T$ is: $(2^m - 1) + (2^n - 1) - 1 = 2^m + 2^n - 3$. Thus the number of coalition structures that need to be searched through to cover these coalitions (and only them) is $2^m + 2^n - 3$.

Now, consider the coalitions (C, V) such that $C \subset A$ and $V \subset T$ (that is, C is a strict subset of A and V is a strict subset of T). Let us count the number of agent occurrences in every coalition⁵. For every

$1 \leq i \leq n-1$, as there are $\binom{n}{i}$ subsets⁶ of size i of A and $(2^m - 2)$ non-empty strict subsets of T , there are $\binom{n}{i} \cdot (2^m - 2)$ coalitions (C, V) where C is of size i .

Thus the number of agent occurrences in all coalitions (C, V) such that $C \subset A$ and $V \subset T$ is:

$$\sum_{i=1}^{n-1} (2^m - 2) \cdot \binom{n}{i} \cdot i = (2^m - 2) \cdot \sum_{i=1}^{n-1} \binom{n}{i} \cdot i \quad (3)$$

$$= (2^m - 2)n \cdot \sum_{i=1}^{n-1} C_{n-1}^{i-1} = (2^m - 2)n \cdot (2^{n-1} - 1) \quad (4)$$

As in each coalition structure, the number of agent occurrences is at most n , we need to search through at least $\frac{(2^m - 2)n \cdot (2^{n-1} - 1)}{n} = (2^m - 2) \cdot (2^{n-1} - 1)$ coalition structures to cover all coalitions (C, V) such that $C \subset A$ and $V \subset T$.

From the above results, we have the smallest number of coalition structures that need to be searched through in order to establish any bound from the optimal is $2^m + 2^n - 3 + (2^m - 2) \cdot (2^{n-1} - 1) = 2^{m+n-1} - 1$. \square

Theorem 1 trivially leads to the following corollary.

Corollary 1 *The problem of coalition structure generation for task-based settings is NP-hard.*

Now, the following question naturally arises: is there a set of exactly $2^{m+n-1} - 1$ coalition structures that after searching through all of its coalition structures, a bound from the optimal can be established? We will show that there does indeed exist such a set in the theorem below.

Theorem 3 *The smallest number of coalition structures that need to be searched in order to establish a bound from the optimal is $2^{m+n-1} - 1$.*

PROOF. As we have proved in Theorem 1 that we need to search at least $2^{m+n-1} - 1$ coalition structures in order to establish a bound from the optimal, we just need to show that there exists a set of $2^{m+n-1} - 1$ coalition structures that after searching through this set, a bound from the optimal will be established. Thus we will construct such set of coalition structures below.

Consider the following set of coalition structures: $K = K_1 \cup K_2$ where K_1 is the set of coalition structures $\{(A, V)\}$ in which V is a non-empty subset of T and K_2 is the set of coalition structures $\{(C, V), (A \setminus C, T \setminus V)\}$ where C is a strict subset of A and V is a subset of T .

First, we will show that the number of coalition structures in K is exactly $(2^{m+n-1} - 1)$. As there are $2^m - 1$ non-empty subsets of T , K_1 contains $2^m - 1$ coalition structures. For the set K_2 : there are $2^n - 2$ non-empty strict subsets C of A and 2^m subsets V of T , so there are $2^m(2^n - 2) = 2^{m+1}(2^{n-1} - 1)$ (C, V) coalitions. However, each coalition structure in K_2 contains two such (C, V) coalitions and each coalition (C, V) appears exactly once in a coalition structure in K_2 , thus the number of coalition structures in K_2 is $2^{m+1}(2^{n-1} - 1)/2 = 2^m(2^{n-1} - 1)$. Thus we can count the number of coalition structures by summing up the number of coalition structures in K_1 and K_2 together:

$$2^m - 1 + 2^m(2^{n-1} - 1) = 2^{m+n-1} - 1$$

⁵ When we count the number of agent occurrences, we take into account the repetition of agent occurrence. For example, in coalitions $\{a_1, a_2\}$ and $\{a_1, a_3\}$ the number of agents is 3, but the number of agent occurrences is 4.

⁶ $\binom{n}{k}$, or nC_k , is the standard mathematical notation to denote the number of different (unordered) combinations of k objects, taken from a pool of n objects and is calculated using the following formula: $\binom{n}{k} = \frac{n!}{k!(n-k)!}$.

Now we will show that after searching through all the coalition structures in K , a bound from the optimal can be established. Let $v(C^*, V^*) = \max_{C \subseteq A, V \subseteq T} v(C, V)$. Consider the following coalition structure: $CS^1 = \{(C^*, V^*)\}$ (if $C = A$) or $\{(C^*, V^*), (A \setminus C^*, T \setminus V^*)\}$ (if C is a strict subset of A), we then have $V(CS^1) \geq v(C^*, V^*)$ (according to assumption 1).

Now, for any coalition structure $CS = \{(C_1, V_1), (C_2, V_2), \dots, (C_k, V_k)\}$ we have:

$$V(CS) = \sum_{i=1}^k v(C_i, V_i) = \sum_{i=1, C_i \neq \emptyset, V_i \neq \emptyset}^k v(C_i, V_i)$$

Now, as there are n agents and m tasks, there are at most only $\min(m, n)$ coalitions with a non-zero value in any coalition structures. Thus:

$$V(CS) \leq \min(m, n) \cdot v(C^*, V^*) \leq \min(m, n) \cdot V(CS^1)$$

Thus $V(CS^*) \leq \min(m, n) \cdot V(CS^1)$. As $CS^1 \in K$, after searching through all the coalition structures in K , a bound $b = \min(m, n)$ from the optimal can be established. \square

Now, it can be seen that the set K contains most of layer L_1 (except $\{(A, \emptyset)\}$) and a subset of layer L_2 (as L_2 contains all coalition structures $\{(C, V_1), (A \setminus C, V_2)\}$ while K contains only coalition structures $\{(C, V_1), (A \setminus C, V_2)\}$ where $V_1 \cup V_2 = T$).

After establishing the bound $b = \min(m + 1, n)$, if additional time remains, it would be desirable to lower the bound with further search. Thus, the next section will present an anytime algorithm that can do this if time permits.

4 The Anytime Algorithm

In this section we present an *anytime algorithm* that can be interrupted at any time, and it establishes a monotonically improving bound. This algorithm is an adaptation of the anytime coalition structure generation algorithm in CFG settings developed in [1].

Definition 2 Let $SL(n, k, c)$ be the set of all coalition structures that have exactly k coalitions and at least one coalition that contains at least c agents.

Definition 3 Let $SL(n, c)$ be the set of all coalition structures whose cardinality is between 3 and $n - 1$ that have at least one coalition that contains at least c agents. That is:

$$SL(n, c) = \bigcup_{k=3}^{n-1} SL(n, k, c)$$

With these definitions in place, we can now express our algorithm for solving the problem (see Figure 1). Basically, at first it searches all the coalition structures in the set K . Then after that, our algorithm searches $SL(n, \lceil n(q-1)/q \rceil)$ with q running from $\lfloor \frac{\min(m,n)}{2} \rfloor$ down to 2. Note that we start from $q = \lfloor \frac{\min(m,n)}{2} \rfloor$ because we have shown that after searching through the set K a bound $b = \min(m, n)$ is established and, later in this section, we will show that after searching $SL(n, \lceil n(q-1)/q \rceil)$, our algorithm can establish a bound $b = 2q - 1$. Thus, we start from the biggest q such that $2q - 1 < \min(m, n)$ or $q = \lfloor \frac{\min(m,n)}{2} \rfloor$.

The next step is to show that the solution generated by the algorithm is within a bound from the optimal and that the bound is reduced further after each round. Thus ours is an **anytime algorithm**: it can be interrupted at any time and the bound keeps improving with an increase in execution time.

The algorithm proceeds as follows:

- Step 1: Search through the set K
- From step 2 onwards, search, consecutively, through the sets $SL(n, \lceil n(q-1)/q \rceil)$ with q running from $\lfloor \frac{\min(m,n)}{2} \rfloor$ down to 2. That is, search $SL(n, \lceil n(\frac{\min(m,n)}{2} - 1) / (\frac{\min(m,n)}{2}) \rceil)$ in step 2, $SL(n, \lceil n(\frac{\min(m,n)}{2} - 2) / (\frac{\min(m,n)}{2} - 1) \rceil)$ in step 3 and so on. Moreover, from step 3 onwards, as $SL(n, \lceil nq/(q+1) \rceil) \subseteq SL(n, \lceil n(q-1)/q \rceil)$, we only have to search through the set $SL(n, \lceil n(q-1)/q \rceil) \setminus SL(n, \lceil nq/(q+1) \rceil)$ in order to search through the set $SL(n, \lceil n(q-1)/q \rceil)$.
- At each step return the coalition structure with the biggest social welfare so far.

Figure 1. The coalition structure generation algorithm

Theorem 4 Immediately after finishing searching $SL(n, \lceil n(q-1)/q \rceil)$, the solution generated by our algorithm is within a finite bound $b = 2q - 1$ from the optimal.

PROOF. Due to the lack of space we omit the proof. It is, however, similar to the one in [1]. \square

5 Single-Task Coalitions

Up to now, we have considered the general setting in which a coalition can carry out an arbitrary number of tasks. However, in some settings, there is a natural restriction such that each coalition can only undertake a single task at any one time. Now, with this additional structure in place, we can improve upon the general results that we have derived so far.

In this special case, we consider settings where for each subset $C \subseteq A$ and each task t there is a coalition value $v(C, t)$ for the coalition (C, t) . Thus, here the coalition value is a function $v : 2^A \times T \rightarrow R$. It can be seen that for each CFG coalition C there are m corresponding single-task coalitions (C, t) as there are m possible tasks. As there are 2^n CFG coalitions C , there are $m2^n$ single-task coalitions.

A coalition structure CS is an exhaustive partition of A into $m+1$ disjoint (possibly empty) coalitions, each of the first m coalitions will do a different task and the last coalition does nothing. That is, $CS = \{(C_1, t_1), (C_2, t_2), \dots, (C_m, t_m), C_{m+1}\}$, coalition C_i , $1 \leq i \leq m$, will do task t_i , such as the following conditions are satisfied:

- $C_i \cap C_j = \emptyset$
- $\bigcup_{i=1}^{m+1} C_i = A$

For example, for $A = \{a_1, a_2, a_3, a_4, a_5, a_6\}$ and $T = \{t_1, t_2, t_3\}$, the following is a coalition structure: $\{(\{a_1, a_2\}, t_1), (\{a_3\}, t_2), (\{a_4, a_5\}, t_3)\}$.

For the convenience of presentation, we will also write $CS = \{(C_1, t_1), (C_2, t_2), \dots, (C_m, t_m)\}$ or $CS = \{C_1, C_2, \dots, C_m\}$ in short.

Like the general case, the problem of coalition structure generation is then to find a coalition structure CS^* that maximises the social welfare (i.e. the sum of the values of all its coalitions).

By following a similar analysis as in the general case, we have the following corresponding results. First, we present the results regarding the size of the search space.

Proposition 4 For each CFG coalition structure (C_1, C_2, \dots, C_k) ($k \leq m+1$), there are $P(m+1, k)$ corresponding task-based coalition structures⁷

Theorem 5 The total number of coalition structures is $(m+1)^n$.

Definition 4 The size of a coalition structure is the number of non-empty coalitions that it contains.

Proposition 5 The number of coalition structures with size k ($1 \leq k \leq m+1$) can be computed by the following formula:

$$|L_k| = P(m+1, k)S(n, k)$$

We can see that the size of the search space in single-task coalitions case is much smaller than one in the general case. Thus, we can expect that the smallest number of coalition structures that need to be searched in order to establish a bound from the optimal will also be much smaller. This expectation is true, as will be shown below.

Theorem 6 The smallest number of coalition structures that need to be searched in order to establish a bound from the optimal is at least $m \cdot 2^{n-1}$.

Corollary 2 The problem of coalition structure generation for task-based coalition formation is NP-hard.

Theorem 7 The smallest number of coalition structures that need to be searched in order to establish a bound from the optimal is $m \cdot 2^{n-1}$.

In this case, the set of $m \cdot 2^{n-1}$ coalition structures that after searching through, a bound of the optimal can be established is:

$$K = K_1 \cup K_2 \cup \dots \cup K_m$$

with $K_i = \{\{C_1, C_2, \dots, C_m\}\}$ where for C is any subset of A :

- $C_j = \emptyset, \forall 1 \leq j < i$ or $j > i + 1$
- $C_i = C$
- $C_{i+1} = A \setminus C$ (for ease of presentation let $C_{m+1} \equiv C_1$)

Note that, for the above K_i , if a subset C of A is already considered, then we won't consider $A \setminus C$ as it will result in double counting. With this set K , a bound $b = \min(m, n)$ from the optimal can be guaranteed. As in the general case, after searching this set K , we can lower the bound if time permits by searching through the sets $SL(n, \lceil n(q-1)/q \rceil)$ with q running from $\lfloor \frac{\min(m,n)}{2} \rfloor$ down to 2.

6 Related Work

As introduced in section 1, to date, most work on coalition structure generation has focused on CFGs. In particular, Sandholm et al. [5] analysed the problem of coalition structure generation in CFG theoretically and proved that this problem is NP-hard and, moreover, even finding a sub-optimal solution requires searching an exponential number of solutions. They also developed an anytime algorithm that can establish a worst-case bound from the optimal. Dang and

⁷ $P(n, k)$, or ${}_nP_k$, is the standard mathematical notation to denote the number of different permutations of k objects, taken from a pool of n objects and is calculated using the following formula [7]: $P(n, k) = \frac{n!}{(n-k)!}$.

Jennings [1] later developed another anytime algorithm with worst-case bound guarantees that was significantly faster than Sandholm et al.'s algorithm when small bounds are desirable.

More specifically related to this work, Shehory and Kraus [6] consider a task-based setting where the coalitions can overlap. In their work, however, they reduce the complexity of the problem by limiting the size of the coalitions. They then develop a greedy algorithm that guarantees to produce a solution that is within a bound from the best solution possible given the limit on the number of agents. However, this best solution can be arbitrarily far from the actual optimal solution (without the limit on the size of the coalitions). Li and Sycara [2] addressed a similar task-based setting to our single-task based one. However they made some limiting assumptions (including the fact that the cost for a task only depends on the number of agents and the task cost per agent decreases as the number of agents increases). We place no such restrictions on our environment.

7 Conclusions and Future Work

In this paper, we examined the problem of coalition structure generation in task-based settings, which are an important extension over traditional CFGs. For this setting, we showed that the problem is NP-hard and, moreover, even a sub-optimal solution (which is within a finite bound from the optimal) requires searching an exponential number of coalition structures. We also developed an anytime algorithm that can establish a solution within a bound from the optimal with a minimal search and can reduce the bound further if time permits. We then considered the single-task coalitions case where each coalition can carry out at most one task and show that in this case, the minimum number of coalition structures that need to be searched through in order to establish a bound from the optimal is much smaller than the general case.

In future work, we intend to further reduce the complexity of the algorithm, especially if more assumptions can be made. For example, we may consider the case where the task-based coalition value is monotonic for each task, (that is, the larger number of agents in a coalition, the bigger its coalition value).

Programming Agents with Emotions

Mehdi Dastani and John-Jules Ch. Meyer¹

Abstract. This paper presents the syntax and semantics of a simplified version of a logic-based agent-oriented programming language to implement agents with emotions. Four types of emotions are distinguished: happiness, sadness, anger and fear. These emotions are defined relative to agent's goals and plans. The emotions result from the agent's deliberation process and influence the deliberation process. The semantics of each emotion type is incorporated in the transition semantics of the presented agent-oriented programming language.

1 Introduction

In the area of intelligent agent research many papers have been written on rational attitudes of agents pertaining to beliefs, desires and intentions (BDI) [8]. More recently one sees a growing interest in agents that display behaviour based on mental attitudes that go beyond rationality in the sense that also emotions are considered (e.g. [12]). There may be several reasons to endow artificial agents with emotional attitudes. For instance, one may be interested to imitate human behaviour in a more natural way [11]. This is in the first instance the perspective of a cognitive scientist, although, admittedly, also computer scientists involved in the construction of systems such as games or believable virtual characters may find this interesting. Our interest in emotional agents here is slightly different. We are interested in agents with emotions, since we believe that emotions are important heuristics that can be used to define effective and efficient decision-making process.

As Dennett [4] has pointed out, it may be sensible to describe the behaviour of complex intelligent systems as being generated by a consideration of their beliefs and desires (the so-called intentional stance). Bratman [1] has made a case for describing the behaviour of such systems in terms of their beliefs, desires and intentions. Here intentions play a role of stabilizing agents decisions, i.e., in deliberating about desires make choices and stick to these as long as it is 'rational'. Following this work it has been recognised that to design and create intelligent *artificial* agents this is a fruitful way of proceeding as well, leading to the so-called BDI architecture of intelligent agents [8]. Pursuing this line of developments we believe that it makes sense to go even further and incorporate also emotional attitudes in agent design and implementation. The role of emotions is to specify heuristics that make the decision process more efficient and effective and, moreover, result in more *believable* behavior [11].

If one takes the stance that endowing artificial agents with emotions is a worthwhile idea, the next question is how to construct or implement such agents. We believe that the agent architectures proposed in the literature are very complicated and hard to engineer, and this holds *a fortiori* for architectures that have been proposed for emotional agents, such as Sloman's CogAff architecture [10].

We start by looking at a logical description of agents with emotions as presented in [5]. Inspired by this logical specification, we aim at constructing agents with emotions through dedicated agent-oriented programming language, in which mental (BDI-like) notions have been incorporated in such a way that they have an unambiguous and rigorous semantics drawn from the meaning they have in the logical specification. In agent programming languages one programs the way the mental state of the agent evolves, and the idea goes back to Shoham [9], who proposed AGENT-0. *In particular, we devise a logic-based agent-oriented programming language, which is inspired by 3APL [3], and can be used to implement emotional agents, following the logical specification of [5] as closely as possible.*

The structure of this paper is as follows. In section 2, we briefly discuss four emotion types and explain their roles in agent programming. In section 3, the syntax of a simplified version a logic-based agent-oriented programming language is presented that allows the implementation of emotional agents. Section 4 presents the part of the semantics that is relevant for the involved emotion types. In section 5, the general structure of the deliberation process is presented. Finally, the paper will be concluded in section 6.

2 Emotions and Deliberation

Following [6, 7] we will incorporate four basic emotions: happiness, sadness, anger and fear. As in [5] we will concentrate on the functional aspects of these emotions with respect to the agent's *actions* ignoring all other aspects of emotions. We do this since we are (only) interested here in how emotions affect the agent's practical reasoning. Briefly, *happiness* results when in the pursuit of a goal subgoals have been achieved as a sign that the adopted plan for the goal is going well. In this case nothing special has to be done: plans and goals simply should persist. On the other hand, *sadness* occurs when subgoals are not being achieved. In this case we have to deliberate to either drop its goal or try to achieve it by an alternative plan. *Anger* is the result of being frustrated from not being able to perform the current plan, and causes the agent to try harder so that the the plan becomes achievable again. An agent of which a maintenance goal is being threatened becomes *fearful*, which causes it to see to it that the maintenance goal gets restored before proceeding with other activities.

From this description we see that the emotions that we will consider here are relativised with respect to certain parameters such as certain plans and goals. A consequence of this is that agent may at any time have many different emotions regarding different plans and goals. Thus in this paper we do not consider a kind of 'general' emotional state (e.g. happy) which is not further qualified. Another thing that should be clear is that some emotional types (such as happiness and sadness) come about from performing actions while other emotion types (such as anger and fear) come about from monitoring the

¹ Utrecht University, The Netherlands, Email: {mehdi,jj}@cs.uu.nl

deliberation process that decides the next action itself. The resulted emotions have an influence on this deliberation process. This is exactly what we are interested in here: how does these emotions arise and affect the agent's course of action.

3 Programming Language: Syntax

In this section, we propose a simplified version of a logic-based agent-oriented programming language that provides programming constructs for implementing agents with emotions. This programming language treats an agent's mental attitudes such as beliefs, goals, and plans, as data structures which can be manipulated by meta operations that constitute the so-called deliberation process. In particular, beliefs and goals are represented as formulas in data bases, plans consists of actions composed by operators such as sequence and iterations, and reasoning rules specify which goals can be achieved by which plans and how plans can be modified. The deliberation process, which constitutes the agent's reasoning engine, is a cyclic process that iterates the sense-reason-act operations. The deliberation process can be implemented by a deliberation language [2]. It should be clear that the deliberation language can be considered as a part of the agent-programming language.

In order to focus on different types of emotions and their computational semantics, we ignore many details that may be relevant or even necessary for a practical logic-based agent-oriented programming language. The practical extension of this logic-based programming language for agents without emotions is presented in [3].

Although the implemented agents will be endowed with emotions, the programming language does not provide any programming constructs to implement emotions. In fact, the syntax of the programming language is similar to the syntax of the language presented in [3]. However, the semantics of the language is extended with the emotional state. The idea is that the emotional state of an agent, which is determined by its deliberation process and the effects of the executed actions, influences the deliberation process itself. Thus, while the syntax of the programming language is similar to the one presented in [3], the semantics of this language is extended with an emotional state.

For this logic-based agent-oriented programming language, we assume a propositional language L , called the *base language*, and the propositional entailment relation \models . The beliefs and goals of an agent are propositional formulas from the base language L . In this paper, we distinguish two different goals types: achievement goals and maintenance goals. An achievement goal denotes a state that the agent wants to achieve and will be dropped as soon as the state is (believed to be) achieved. A maintenance goal denotes a state that the agent wants to maintain. In contrast to achievement goals, a maintenance goal can hold even if the state denoted by it is believed to hold.

The plans of an agent are considered as a sequence of basic actions and test actions. Basic actions are specified in terms of pre- and post-condition. They are assumed to be deterministic in the sense that they either fail (if the precondition does not hold) or have unique resulting states. The precondition of a basic action indicates the condition under which the action can be performed and the postcondition of a basic action indicates the expected effect of the action. The test actions check if propositions are believed, i.e., if propositions are derivable from the agent's belief base.

Definition 1 (plan) Let $Action$ with typical element α be the set of basic actions and $\phi \in L$. The set of plans $Plans$ with typical element

π is then defined as follows:

$$\pi ::= \alpha \mid \phi? \mid \pi_1; \pi_2$$

We use ϵ to denote the empty plan.

Planning rules are used for selecting an appropriate plan for a goal under a certain belief condition. A planning rule is of the form $\beta, \kappa \Rightarrow \pi$ and indicates that it is appropriate to decide plan π to achieve the goal κ , if the agent believes β . In order to check whether an agent has a certain belief or goal, we use propositional formulas from the base language L .

Definition 2 (plan selection rule) The set of plan selection rules \mathcal{R}_{PG} is a finite set defined as follows:

$$\mathcal{R}_{PG} = \{\beta, \kappa \Rightarrow \pi \mid \beta, \kappa \in L, \pi \in Plans\}$$

In the following, we use $belief(r)$, $goal(r)$, and $plan(r)$ to indicate, respectively, the belief condition β , the goal condition κ , and the plan π that occur in the planning rule $r = (\beta, \kappa \Rightarrow \pi)$.

Given these languages, an agent can be implemented by programming two sets of propositional formulas (representing the agent's beliefs and goals), a set of basic actions specified in terms of their pre- and postcondition, one set of planning rules, and an order on the set of planning rules to indicate the order according to which the planning rules should be applied.

Definition 3 (agent program) An agent program is a tuple $(\sigma, (\gamma_a, \gamma_m), A, PG, <)$ where $\sigma, \gamma_a, \gamma_m \subseteq L$, $A \subseteq Action$, $PG \subseteq \mathcal{R}_{PG}$, and $<$ is a strict order on PG .

For technical reasons, we demand that if two planning rules in PG have equivalent goal formulas in their heads, then they will be identical formulas. Moreover, we assume that an agent's plans are generated by applying planning rules and that an agent does not have initial plans. This simplification is due to the focus of this paper and can be relaxed for a practical agent-oriented programming language.

4 Programming Language: Semantics

The semantics of the logic-based agent-oriented programming language is defined by means of a transition system. A transition system for a programming language consists of a set of axioms and derivation rules for deriving transitions for this language. A transition is a transformation of one configuration into another and it corresponds to a single computation step. A configuration represents the state of an agent at each point during computation.

For the purpose of this paper, a configuration consists of a belief base σ representing the agent's beliefs, a goal base $\gamma = (\gamma_a, \gamma_m)$ representing the agent's (achievement and maintenance) goals, an action base A consisting of the specifications of basic actions, a plan base Π containing the plans, a set of planning rules PG , an ordering $<$ on the set of planning rules, and an emotion state consisting of emotions of the agent with respect to certain goals and/or plans.

Definition 4 (agent configuration) Let $\Sigma = \{\sigma \mid \sigma \subseteq L, \sigma \neq \perp\}$. An agent configuration is a tuple $(\sigma, (\gamma_a, \gamma_m), A, \Pi, PG, <, E)$ where $\sigma \in \Sigma$ is the belief base, $\gamma = (\gamma_a, \gamma_m)$ is the goal base, A is the action base, $\Pi \subseteq (L \times Plans)$ is the plan base, $PG \subseteq \mathcal{R}_{PG}$ is a set of planning rules, $<$ is a strict order on PG , and $E = (E_h, E_s, E_a, E_f)$ are emotion bases for happiness, sadness, anger, and fear, where $E_h \subseteq \{\text{happy}(\pi, \kappa, \kappa') \mid \pi \in Plans \& \kappa, \kappa' \in L\}$, $E_s \subseteq \{\text{sad}(\pi, \kappa) \mid \pi \in Plans \& \kappa \in L\}$, $E_a \subseteq \{\text{angry}(\pi) \mid \pi \in Plans\}$, and $E_f \subseteq \{\text{fearful}(\kappa) \mid \kappa \in L\}$.

Note that the elements of the plan base are defined as tuples consisting of a plan and a goal formula, which indicates the original intended state to be reached/maintained by the plan. Note also that the emotions of an agent are with respect to particular goals and plans such that, for example, an agent can be happy with respect to one of its goal/plan while it is sad with respect to another goal/plan. In the sequel, we often omit the set of basic actions, the set of planning rules PG and the ordering $<$ in the agent configuration for reasons of presentation, i.e., we use configurations of the form $\langle \sigma, \gamma, \Pi, E \rangle$ instead of $\langle \sigma, \gamma, A, \Pi, PG, <, E \rangle$. This is not problematic, since the set of basic actions, the set of planning rules, and the ordering defined on them does not change during executions of an agent.

Moreover, in order to check if an agent, which is represented by a configuration $\langle \sigma, (\gamma_a, \gamma_m), \Pi, E \rangle$, has certain beliefs and (achievement or maintenance) goals, we use \models_b and \models_g defined as follows:

$$\begin{aligned} \langle \sigma, (\gamma_a, \gamma_m), \Pi, E \rangle \models_b \phi &\Leftrightarrow \sigma \models \phi, \\ \langle \sigma, (\gamma_a, \gamma_m), \Pi, E \rangle \models_g \text{achieve}(\kappa) &\Leftrightarrow \gamma_a \models \kappa, \\ \langle \sigma, (\gamma_a, \gamma_m), \Pi, E \rangle \models_g \text{maintain}(\kappa) &\Leftrightarrow \gamma_m \models \kappa. \end{aligned}$$

In the following, we do not present the complete operational semantics of the proposed agent programming language, but provide only the transition rules that are related to the emotional states of the agents. Other transition rules for this agent programming language are trivial extensions of the operational semantics presented in [3].

For the transition rules, we assume a belief update operator $\tau : \Sigma \times Action \rightarrow \Sigma$ that determines the updates of the belief base by a basic action. Moreover, we assume $PreCond : Plans \rightarrow L$ and $PostCond : Action \rightarrow L$ to be functions that determine the precondition and the expected effect (postcondition) of a basic action, respectively. The precondition of a plan can be determined recursively in terms of the involved basic actions in a STRIPS like fashion. Moreover, we assume that the postcondition of an action is not necessarily derivable from the update of the belief base by the action, i.e., it is not generally the case that $\tau(\sigma, \alpha) \models PostCond(\alpha)$. This means that the expected effect of an action is not necessarily realized by the action execution (due to the unpredictability of the environment).

Before presenting the emotion related transitions, we need to present some preliminary concepts. We will do this in a rather informal way and refer to [5] for a rigorous treatment. First of all, we use dynamic logic expressions to specify the effects of actions: $[\alpha]\psi$ denotes that after all possible executions of action α it holds that ψ . $\langle\alpha\rangle\psi = \neg[\alpha]\neg\psi$ expresses there is an execution of α resulting in a state where ψ holds. Note that $\langle\alpha\rangle\top$ (α is executable) is equivalent with $PreCond(\alpha)$, and that $\langle\alpha\rangle\psi \rightarrow \langle\alpha\rangle\top$ is valid in dynamic logic. Furthermore, we have the validity $\langle\alpha; \pi\rangle\psi \leftrightarrow \langle\alpha\rangle(\langle\pi\rangle\psi)$.

As mentioned, a planning rule is meant to indicate which plan can be executed to realize a goal. A planning rule $r = (\kappa, \beta \Rightarrow \pi)$ is called correct, denoted by $correct(r)$, if the goal κ is achievable by the execution of the plan π , i.e., $correct(\kappa, \beta \Rightarrow \pi) \Leftrightarrow (\beta \rightarrow \langle\pi\rangle\kappa)$ where $\langle\pi\rangle\kappa$ states that (under condition β) after the performance of π , the state denoted by κ holds. We assume that the agent programmer is responsible for the correctness of the planning rules.

Moreover, given the agent configuration C , an agent *can* perform a plan π to achieve a goal κ if and only if π is executable (i.e., its precondition is derivable from the agent's belief base) and achieves κ after it is executed, i.e., $C \models Can(\pi, \kappa) \Leftrightarrow C \models_b \langle\pi\rangle\kappa$. (Note that $\langle\pi\rangle\kappa \rightarrow PreCond(\pi)!$ ²). The notion of 'Can' can be made more concrete in the present setting involving planning rules as follows:

² In [5] in the 'Can' operator also a notion of ability regarding plan π is incorporated, which may be viewed here as the agent's having access to all basic actions involved in the plan. For simplicity we omit this here.

An agent can (Can') perform a plan π to achieve a goal κ if and only if there exists a correct planning rule $r = (\kappa, \beta \Rightarrow \pi'; \pi)$, and the belief condition β is entailed by the agent's beliefs, i.e.,

$$\begin{aligned} C \models Can'(\pi, \kappa) \Leftrightarrow \exists r \in PG : & correct(r) \& \\ & goal(r) = \kappa \& \\ & belief(r) = \beta \& \\ & \exists \pi' \in Plans : plan(r) = \pi'; \pi \& \\ & C \models_b belief(r) \end{aligned}$$

Note that $Can'(\pi, \kappa) \Rightarrow Can(\pi, \kappa)$. Finally, as in [5] we employ a notion of possible intention to perform a plan π to achieve a goal κ stating that the agent 'Can' do π to achieve its goal κ . In the setting here it is operationalised as follows. An agent possibly intends to perform a plan π to achieve a goal κ if and only if the goal κ is a goal of the agent, and the agent can perform π to achieve κ , i.e., $C \models PossIntend(\pi, \kappa) \Leftrightarrow C \models Can'(\pi, \kappa) \& C \models_g achieve(\kappa)$.

Note that the intended plans are assumed to be generated by the applications of planning rules. Moreover, if the first part π' of an intended plan $\pi'; \pi$ gets executed, the agent remains intended to perform the rest of the plan (i.e., π) to achieve the original goal κ .

4.1 Happiness

According to [5], an agent that is happy observes that its subgoals are being achieved. In particular, an agent that has the intention to do π for achieving goal κ (denoted $I(\pi, \kappa)$ below), and is committed to it, and that believes that by performing the initial part α the subgoal κ' should be achieved, is *happy* (with respect to the remainder $\pi \setminus \alpha$ of the plan – to which it is still committed, the goal κ and subgoal κ') if after the performance of α it believes that indeed the subgoal κ' has been achieved. This is formulated as follows:

$$\begin{aligned} I(\pi, \kappa) \wedge Com(\pi) \wedge \alpha \preceq \pi \wedge B([\alpha]\kappa') \rightarrow \\ [\alpha]((B\kappa' \wedge Com(\pi \setminus \alpha)) \rightarrow \text{happy}(\pi \setminus \alpha, \kappa, \kappa')) \end{aligned}$$

Moreover, it is defined: $\text{happy}(\pi, \kappa, \kappa') \Leftrightarrow \text{happy}(\pi, \kappa)$ for all subgoals κ' that are deemed important/crucial by the agent. In this work, we assume that all subgoals are crucial to the agent.

We first observe that an agent becomes happy after the execution of actions. Therefore, the transition rule for action execution is an appropriate transition rule through which agents can become happy with respect to a plan and its corresponding goal and subgoal. In order to define the transition rule for action execution, we translate $I(\pi, \kappa)$ as possible intention $PossIntend(\alpha; \pi, \kappa)$, $Com(\pi)$ as the fact that the agent has the plan π in the plan base, and $B([\alpha]\kappa')$ as the fact that the postcondition of the basic action α is κ' . After the execution of the basic action α , if the updated belief base entails the postcondition of the basic action, then the agent becomes happy. Note that the agent becomes committed to the rest-plan π' of the plan $\pi = \alpha; \pi'$ since π' is added to the new plan base Π' . The transition rule for action execution can be defined as follows:

$$\frac{(\sigma, \gamma, \Pi, E) \models PossIntend(\alpha; \pi', \kappa) \& \\ (\alpha; \pi', \kappa) \in \Pi \& PostCond(\alpha) = \kappa' \& \tau(\sigma, \alpha) = \sigma'}{(\sigma, \gamma, \Pi, E) \rightarrow (\sigma', \gamma, \Pi', E')}$$

where

$$\Pi' = (\Pi \setminus \{(\alpha; \pi', \kappa)\}) \cup \{(\pi', \kappa)\}$$

$$E = (E_h, E_s, E_a, E_f)$$

$$\begin{aligned} E' = (E_h \cup \{\text{happy}(\pi, \kappa, \kappa')\}, E_s, E_a, E_f) \text{ if } \sigma' \models \kappa' \\ = E \text{ otherwise} \end{aligned}$$

According to [5], happiness causes a kind of persistence with respect to possible intention and commitments, i.e.,

$$I(\pi, \kappa) \wedge Com(\pi) \wedge \text{happy}(\pi, \kappa) \rightarrow [\text{deliberate}]I(\pi, \kappa) \wedge Com(\pi)$$

This means that intentions and commitments of an agent with respect to plans and goals persist through the deliberation *operations* (i.e., operations for selecting and applying reasoning rules) when the agent is happy with respect to those goals and plans. In order to ensure the persistence of intentions and commitments through the deliberation operations, we define in section 5 a deliberation *process* that does not drop any intention with respect to which the agent is happy. We assume that the deliberation operation, represented as *[deliberate]*, is a part of the deliberation process, represented as *[deliberate; executePlans]*. In fact, the deliberation process consists of deliberation operations plus the execution of plans (not a deliberation operation).

4.2 Sadness

A sad agent is disappointed about the way its plans are progressing, and will look for ways of revising its plans (or perhaps even adjust the goals to be achieved) and make them more realistic. In particular, an agent, who intends to perform a plan to achieve a goal and believes that the first action of its plan will have a certain effect, will become sad with respect to the rest of that plan after executing the first action if the agent believes that the expected effect is not achieved. This is formally specified as follows.

$$\begin{aligned} I(\pi, \kappa) \wedge Com(\pi) \wedge \alpha \preceq \pi \wedge \mathbf{B}([\alpha]\kappa') \rightarrow \\ [\alpha]((\mathbf{B}\neg\kappa' \wedge \mathbf{Com}(\pi \setminus \alpha)) \rightarrow \mathbf{sad}(\pi \setminus \alpha, \kappa)) \end{aligned}$$

Like happiness, we observe that an agent can become sad after executing a basic action, and that the transition rule for action execution is therefore an appropriate transition rule through which agents can become sad with respect to a plan and its corresponding goal. Under similar translation of logical concepts, the transition semantics for the sadness is as follows.

$$\frac{\langle \sigma, \gamma, \Pi, E \rangle \models PossIntend(\alpha; \pi', \kappa) \wedge (\alpha; \pi', \kappa) \in \Pi \wedge PostCond(\alpha) = \kappa' \wedge \tau(\sigma, \alpha) = \sigma'}{\langle \sigma, \gamma, \Pi, E \rangle \rightarrow \langle \sigma', \gamma, \Pi', E' \rangle}$$

where

$$\begin{aligned} \Pi' &= (\Pi \setminus \{(\alpha; \pi', \kappa)\}) \cup \{(\pi', \kappa)\} \\ E &= (E_h, E_s, E_a, E_f) \\ E' &= (E_h, E_s \cup \{\mathbf{sad}(\pi, \kappa)\}, E_a, E_f) \text{ if } \sigma' \not\models \kappa' \\ &= E \text{ otherwise} \end{aligned}$$

Sadness results in a revision of intention/plan or goal. In particular, an agent who is sad with respect to a plan that he intends to perform to achieve a goal, will become committed to either perform the plan if he can perform it, or otherwise generate an alternative plan and performs the new plan. This effect of sadness is specified as follows.

$$\begin{aligned} I(\pi, \kappa) \wedge Com(\pi) \wedge \mathbf{sad}(\pi, \kappa) \rightarrow \\ [deliberate]\neg I(\pi, \kappa) \vee \neg Com(\pi) \vee \\ Com(\text{if } Can(\pi, \kappa) \text{ then } \pi \text{ else replan}(\pi', \kappa); \pi') \end{aligned}$$

Observe that after *[deliberate]*, it holds:

$$I(\pi, \kappa) \wedge Com(\pi) \rightarrow \\ Com(\text{if } Can(\pi, \kappa) \text{ then } \pi \text{ else replan}(\pi', \kappa); \pi')$$

In order to operationalize this, we check after the deliberation operation if the agent still intends to perform (and is committed to) the plans with respect to which the agent is sad. If so, then we should ensure that the agent checks if he 'can' perform the plan before actually executing it; if he 'can not' perform it, then the agent should generate and execute an alternative plan. In order to simplify this, we check after the deliberation operation and after selecting a plan to execute, if the agent is sad with respect to the selected plan (obviously, the agent intend and is committed to the selected plan for execution) and if he still 'can not' perform it (if the plan 'can' be performed, then it will be executed). In such a case, an alternative plan will be generated

and executed. Given π as the selected plan to execute, the following deliberation step should be included in the deliberation process.

```
If  $\mathbf{sad}(\pi, \kappa) \in E_s \wedge C \not\models Can(\pi, \kappa)$  then
  {replan( $\pi'$ ,  $\kappa$ ); execute( $\pi'$ )}
else execute( $\pi$ )
```

We have assumed that the agent can generate an alternative plan by performing the deliberation operation *replan*(π' , κ), which provides an alternative plan π' to achieve the goal κ . If there is no alternative plan possible, this operation provides a plan which has already been generated. Details about this operation can be found in [2].

4.3 Anger

An agent gets angry if its plan is frustrated. This is specified as follows: $Com(\pi) \wedge \neg Can(\pi, \top) \rightarrow \mathbf{angry}(\pi)$

For the transition semantics, an active plan is considered to be frustrated if its precondition does not hold. This implies that the anger of an agent cannot be incorporated in the transition rule for action execution. We introduce an additional transition rule to update the angry state of the agent with respect to the plans that are not executable. This transition rule is specified as follows:

$$\frac{(\kappa, \pi) \in \Pi \wedge \langle \sigma, \gamma, \Pi, E \rangle \not\models Can(\pi, \top)}{\langle \sigma, \gamma, \Pi, E \rangle \rightarrow \langle \sigma, \gamma, \Pi, E' \rangle}$$

where

$$\begin{aligned} (\kappa, \pi) &\in \Pi \\ E &= (E_h, E_s, E_a, E_f) \\ E' &= (E_h, E_s, E_a \cup \{\mathbf{angry}(\pi)\}, E_f) \end{aligned}$$

Note that in our present setting we have that $Can(\pi, \top) \leftrightarrow PreCond(\pi)$. So, $Can(\pi, \top)$ is not derivable from an agent's configuration iff the precondition of the plan π does not hold. Note that we should ensure that this transition rule will be applied during each deliberation cycle.

An angry agent will see to it that he *will* be able to achieve its plans and goals. The effect of being angry is specified as follows:

$$\mathbf{angry}(\pi) \rightarrow [deliberate]Com(stit(PreCond(\pi)))$$

The specification of the effect of being angry indicates that the agent should try to realize the precondition of the plan with respect to which the agent is angry. This can be done by adopting the precondition of the plan as a goal. In order to realize this effect, the deliberation process will include the following deliberation step.

```
For all  $\mathbf{angry}(\pi) \in E_a$  do
  if  $C \not\models_g achieve(PreCond(\pi))$  then
    adopt\_goal(PreCond(\pi))
```

This deliberation step ensures that the agent will try to realize the conditions that enable the execution of plans with respect to which the agent is angry.

4.4 Fear

An agent becomes fearful if one of its maintenance goals is threatened. This is logically specified as:

$$\models \kappa \rightarrow \neg \kappa' \Rightarrow (goal_m(\kappa') \wedge G(\kappa)) \rightarrow \mathbf{fearful}(\kappa')$$

For the transition semantics, it means that an agent becomes fearful with respect to a goal if a transition takes place through which a goal is adopted that contradicts a maintenance goal. The transition semantics for the fearfulness is as follows.

$$\begin{aligned} \langle \sigma, (\gamma_a, \gamma_m), \Pi, E \rangle \rightarrow \langle \sigma', (\gamma'_a, \gamma'_m), \Pi', E' \rangle \wedge \\ \gamma'_a \models \kappa \wedge \gamma'_m \models \kappa' \wedge \models \kappa \rightarrow \neg \kappa' \\ \langle \sigma, (\gamma_a, \gamma_m), \Pi, E \rangle \rightarrow \langle \sigma', (\gamma'_a, \gamma'_m), \Pi', E'' \rangle \end{aligned}$$

where

$$\begin{aligned} E' &= (E'_h, E'_s, E'_a, E'_f) \\ E'' &= (E'_h, E'_s, E'_a, E'_f \cup \{\text{fearful}(\kappa')\}) \end{aligned}$$

This transition rule states that whenever there is a transition (action execution transition, rule application transition, etc.) possible through which the agent adopts a goal that threaten one of its maintenance goals, then the agent becomes fearful with respect to the maintenance goal.

The effect of the fearfulness is that the deliberation process should ensure that the feared maintenance goal holds before executing any plan. This is logically specified as follows.

$$\begin{aligned} \text{Goal}_m(\kappa') \wedge \text{Com}(\pi) \wedge \text{fearful}(\kappa') \rightarrow \\ [\text{deliberate}] \text{Com}(\text{if } \kappa' \text{ then } \pi \text{ else } \text{stit}(\kappa'); \pi) \end{aligned}$$

Normally, the deliberation *process* of an agent selects a plan and executes it. In order to ensure the effect of the fearfulness, the deliberation process will adopt the feared maintenance goals (such that the agent generate plans to realize them) before it proceeds with the execution of its selected plan. Below we make sure that the agent proceeds with executing its selected plan after it has adopted its feared goals. Suppose that the deliberation process has the following deliberation operation through which a plan is selected and executed.

$$\pi := \text{SelectPlanToExecute}(\Pi)$$

The effect of the fearfulness can be incorporated in the deliberation *process* by replacing this deliberation *operation* with the following sequence of deliberation operations.

$$\pi := \text{SelectPlanToExecute}(\Pi);$$

for all $\text{fearful}(\kappa') \in E_f$ such that $C \not\models_b \kappa'$ and
 $C \not\models_g \text{achieve}(\kappa')$ do

$$\{\pi := \text{adopt_goal}(\kappa'); \pi\};$$

Note that this for-loop generates a plan that consists of the selected plan preceded by the operations to adopt all feared maintenance goals. Note also that the effect of the fearfulness can be strengthened by adding the condition that the maintain goal should hold before proceeding with the executions of the selected plan. This can be done by replacing the body of the for-loop with the following statement:

$$\pi := \text{adopt_goal}(\kappa'); \pi'; \pi$$

5 Deliberation Process

For the purpose of this paper, we present the following general structure of the deliberation *process* for agents with emotional state.

```

While TRUE Do {
    Sensedata := perceive(environment);
    BeliefBase := update(BeliefBase, Sensedata);
    r := SelectPlanningRule(PG, <);
    ApplyPlanningRule(r);
    For all angry( $\pi_a$ )  $\in E_a$  do
        if  $C \not\models_g \text{achieve}(\text{PreCond}(\pi_a))$  then
            adopt_goal(PreCond( $\pi_a$ ));
     $\pi := \text{SelectPlanToExecute}(\Pi)$ ;
    If sad( $\pi, \kappa$ )  $\in E_s$  &  $C \not\models \text{Can}(\pi, \kappa)$  then
        {replan( $\pi', \kappa$ );  $\pi := \pi'$ }
    for all  $\text{fearful}(\kappa') \in E_f$  such that
         $C \not\models_b \kappa'$  and  $C \not\models_g \text{achieve}(\kappa')$  do
             $\{\pi := \text{adopt\_goal}(\kappa'); \pi\};$ 
            execute( $\pi$ );
    Apply transition rules for angry and fearful
}

```

The deliberation process is assumed to be an cyclic process consisting of perception, reason, and act cycles. During each cycle the

agent perceives its environment and updates its belief base accordingly, applies planning rules to generate plans for its goals, reasons about its emotions and realizes the effect of the emotions, selects and executes plans, and finally makes sure that the transition rules related to different types of emotions are applied. This deliberation cycle can be summarized as follows. Note that the transition rules for **angry** and **fearful** are applied during the last deliberation operation. The transition rules for **happy** and **sad** are applied by the statement **Execute** since these transition rules are the transitions for the execution of basic actions. Note also that the deliberation operations (i.e., the deliberation process except its execution part) does not drop any intention and commitment. Therefore, they ensure that all intentions and commitments, with respect to which the agent is happy, persist during the deliberation operation.

6 Conclusion

In this paper, we presented a logic-based agent-oriented programming language that allows the implementation of emotional agents. Four emotion types are discussed and their computational semantics incorporated in the transition system of the programming language. For each emotion type, we presented a transition rule that generates that specific emotions. Based on generated emotions, the deliberation process determines the effect of those emotion on the mental state of the agent. We aim to extend the set of emotion types in the future research. Moreover, we are working on an implementation of an interpreter for the presented programming language. The specified semantics of the emotion types can then be evaluated based on implemented agents. In particular we will test our concept of emotional agents in the realization of a companion robot for young children.

Goal Types in Agent Programming

Mehdi Dastani and M. Birna van Riemsdijk and John-Jules Ch. Meyer¹

Abstract. This paper presents three types of declarative goals: perform goals, achieve goals, and maintain goals. The integration of these goal types in a simple but extendable logic-based agent-oriented programming language is discussed and motivated. The computational semantics for each goal type is presented by means of a transition system. It is shown that the presented semantics of the goal types ensure some desirable and expected properties.

1 Introduction

An essential characteristic of autonomous intelligent agents is their pro-active behaviour [7]. These agents are assumed to have goals for which they (pro-actively) decide actions to perform. Different logics have been proposed to characterize goals, to represent and reason about them, and to specify their relations to other agent concepts such as beliefs and actions [2, 3, 5]. These logics allow the specification of various agent types, i.e., agents that have a certain attitude towards their goals.

Motivated by these logics, various agent-oriented programming languages have been proposed [1]. In order to allow the implementation of various goal related agent types (i.e., agents that can have different attitudes towards their goals) existing programming languages provide constructs to implement various types of goals. For example, JACK provides programming constructs to implement, among others, test, achieve, insist, and maintain goals, Jason has achieve and test goals, and Jadex has achieve, query, perform and maintain goals [1]. The way in which goals are treated by these programming languages differs. In Jadex, goals are represented in XML in terms of a label/name and a number of other parameters. In Jason and JACK, goals are particular types of events. Further, neither JACK nor Jadex provides the formal semantics of their goal types. A detailed comparison between the goal types of the various languages is beyond the scope of this paper.

In this paper, we focus on three types of goals: perform goals, achieve goals, and maintain goals. These goals are represented as logical formulas having formal semantics. Perform goals can be used to generate plans without demanding that the plans *must* reach the states denoted by the goals. The attitude of an agent toward a perform goal is thus to generate relevant plans after which the goal will be dropped. For example, consider “FC and CC” as a perform goal of an agent where FC stands for having-fuel-in-car and CC for having-clean-car. The goal “FC and CC” can be used to generate, e.g., a plan to refuel at the gas station gs1 and a plan to clean the car in the car wash cw1. After generating the plans, the agent drops the goal entirely regardless of the plans’ effects. However, if the agent has only means to generate the plan to refuel, then it will only generate the refuel plan after which the entire goal is dropped. Dropping goals after generating relevant plans is a practical idea that has been im-

plemented in most agent-oriented programming languages, although sometimes under different names. In JACK and Jason this type of goal is known as achieve goal. As in Jadex, we associate a *redo* flag with a perform goal. If this flag is false, then the agent will behave as described above. Otherwise, if the flag is true, the agent will not drop its perform goal but apply relevant planning rules repeatedly and indefinitely. For example, a vacuum cleaner that has to clean a number of rooms repeatedly without the ability to check if a room is clean can be modelled as having a perform goal with a true redo flag.

The idea of an achieve goal is to reach the state denoted by it. Similar to perform goals, an agent with an achieve goal will apply relevant planning rules to generate and execute plans. If the achieve goal is not reached after the execution of these plans, it applies the planning rules again, hopefully generating different plans, since the circumstances might have changed. Once the achieve goal is reached, it will stop generating and executing plans for this goal. For example, consider an agent that has FC as an achieve goal and that can generate two plans, i.e., to refuel at gas stations gs1 and gs2. The agent can generate and execute the plan to refuel at gs1. If the plan is successful, the achieve goal will be dropped. Otherwise, it will generate and execute the second plan to refuel at gs2. If both plans do not achieve the goal, then it will apply the rules again. As suggested in [6] and implemented in Jadex, we assign a failure condition to each achieve goal to indicate when the agent should stop trying to achieve the goal and thus drop the goal. For example, no-fuel-at-gs1-and-gs2 can be the failure condition of the achieve goal FC. A similar type of goal is introduced in Jadex and in JACK under the name *insist* goal.

Finally, the idea of maintain goal is to ensure that a state holds and continues to hold. Plans should be generated and executed if the state denoted by the maintain goal is *threatened* not to hold, rather than waiting and taking action once the state does not hold. The condition under which the maintain goal is threatened not to hold will be called the maintain condition. The agent starts to generate and execute plans when the maintain condition becomes true. For example, consider an agent with FC as a maintain goal. This means that the agent wants to maintain having a fueled car. The maintain condition is the illuminated lamp warning of a shortage of fuel. The agent should generate and execute a refuel plan if the lamp is illuminated. If the maintain condition continues to hold after the execution of the plan, because for example the tank station had no fuel, the agent may try to generate and execute another plan, e.g., to go to another tank station to refuel. If all plans are generated and the maintain condition still holds, then there are two options. The agent can either stop generating and executing plans since it has tried all plans, or it can continue to apply the planning rules once again, hopefully generating new plans this time. In order to allow both options, we add a *retry* flag, like in Jadex [1], to the maintain goals. If the flag is true, the agent will try to re-apply planning rules, otherwise it does not.

2 Syntax

In order to implement different types of goals, we propose a simple but extendable logic-based agent-oriented programming language. We assume a propositional language L and the propositional entailment relation \models . A perform goal consists of a propositional formula and a *redo* flag that indicates whether the goal should be performed repeatedly. An achieve goal consists of two propositional formulas. The first formula denotes the state to be achieved and the second formula represents a failure condition. Finally, a maintain goal consists of two propositional formulas and a *retry* flag. The first formula denotes the state to be maintained and the second formula represents the maintain (trigger) condition. The retry flag indicates whether to repeat performing plans as long as the maintain trigger condition holds.

Definition 1 (*belief and goal languages*) The belief language L_σ , the perform goal language L_{γ_p} , the achieve goal language L_{γ_a} , and the maintain goal language L_{γ_m} are defined as follows:

- $L_\sigma = L$
- $L_{\gamma_p} = \{(\phi, f) \mid \phi \in L \& f \in \{\top, \perp\}\}$
- $L_{\gamma_a} = \{(\phi, fc) \mid \phi, fc \in L\}$
- $L_{\gamma_m} = \{(\phi, mc, f) \mid \phi, mc \in L \& f \in \{\top, \perp\}\}$

A plan is considered as a sequence of basic actions which update the beliefs of an agent when executed. The plan language can be extended with other actions such as test and communication, which can be composed by if-then-else and while constructs [4, 1].

Definition 2 (*plan*) Let *BasicAction* with typical element a be the set of basic actions. The set of plans *Plan* with typical element π is defined as: $\pi ::= a \mid \pi_1; \pi_2$. We use ϵ to denote the empty plan.

Planning rules are used for selecting an appropriate plan for a goal under a certain belief condition. A planning rule is of the form $\beta, \kappa \Rightarrow \pi$ and indicates to select plan π for the goal κ , if the agent believes β . In order to be able to check whether an agent has a certain belief or goal, we use propositional formulas from L to represent belief and goal query expressions.

Definition 3 (*plan selection rule*) The set of plan selection rules \mathcal{R}_{PG} is defined as: $\mathcal{R}_{PG} = \{\beta, \kappa \Rightarrow \pi \mid \beta, \kappa \in L, \pi \in \text{Plan}\}$.

In the following, we use $\mathbf{G}(r)$ and $\mathbf{B}(r)$ to indicate the goal condition κ and the belief condition β , respectively, that occur in the head of the planning rule $r = (\beta, \kappa \Rightarrow \pi)$.

Given these languages, an agent can be implemented by programming four sets of propositional formulas (representing the agent's beliefs, perform goals, achieve goals, and maintain goals), one set of planning rules, and an ordering on the set of planning rules to indicate the order in which the planning rules should be applied.

Definition 4 (*agent program*) An agent program is a tuple $(\sigma, \gamma_p, \gamma_a, \gamma_m, PG, <)$ where $\sigma \subseteq L_\sigma$, $\gamma_p \subseteq L_{\gamma_p}$, $\gamma_a \subseteq L_{\gamma_a}$, $\gamma_m \subseteq L_{\gamma_m}$, $PG \subseteq \mathcal{R}_{PG}$, and $<$ is a strict order on PG .

3 Semantics

The semantics of the programming language is defined by means of a transition system. A transition system for a programming language consists of a set of axioms and derivation rules for deriving transitions for this language. A transition is a transformation of one configuration into another and it corresponds to a single computation step. A configuration represents the state of an agent at each point during computation.

For the purpose of this paper, a configuration consists of a belief base σ representing the agent's beliefs, a goal base γ representing the agent's goals, a plan base Π containing the generated plans, a set of planning rules PG , and a set T to administrate the set of planning rules that have already been tried for application. These rules will not be applied anymore because either they have been applied already or the goals that occur in their heads are achieved. In the rest of this paper, we will call these rules *tried rules*.

Definition 5 (*agent configuration*) Let $\Sigma = \{\sigma \mid \sigma \subseteq L_\sigma, \sigma \neq \perp\}$, $\gamma_p \subseteq \{(\phi, f) \in L_{\gamma_p} \mid \phi \not\models \perp\}$, $\gamma_a \subseteq \{(\phi, fc) \in L_{\gamma_a} \mid \phi \not\models \perp\}$, and $\gamma_m \subseteq \{(\phi, mc, f) \in L_{\gamma_m} \mid \phi \not\models \perp\}$. An agent configuration is a tuple $(\sigma, \gamma, \Pi, PG, <, T)$ where $\sigma \in \Sigma$ is the belief base, $\gamma = (\gamma_p, \gamma_a, \gamma_m)$ is the goal base, $\Pi \subseteq (L \times L \times \text{Plan})$ is the plan base, $PG \subseteq \mathcal{R}_{PG}$ is a set of planning rules, $<$ is a strict order on PG , and $T \subseteq \{(\phi, R) \mid \phi \in L, R \subseteq \{r \mid r \in PG \& \phi \models \mathbf{G}(r)\}\}$ administrates the sets of tried planning rules.

The goal base γ in this definition is a 3-tuple consisting of three goal bases $\gamma_p, \gamma_a, \gamma_m$. These goal bases represent the agent's perform goals, achieve goals, and maintain goals, respectively. Moreover, the elements of the plan base are defined as 3-tuples consisting of a plan and two goal formulas that indicate the reasons for generating the plan. More specifically, a plan can be generated by applying a planning rule $\beta, \kappa \Rightarrow \pi$, if κ is a subgoal of an agent's goal ϕ , i.e., if $\phi \models \kappa$. The two formulas associated with a plan in a 3-tuple are the agent's goal ϕ and its subgoal κ based on which a planning rule is applied and the plan is generated. This means that we have $\forall (\phi, \kappa, \pi) \in \Pi : \phi \models \kappa$. Finally, the set T is added to the agent configuration in order to administrate the planning rules R that have been tried to be applied for each goal ϕ of the agent. This information will be used to avoid applying the same planning rules repeatedly.

The initial configuration of an agent can be built based on the agent program (definition 4) that specifies the initial beliefs, goals, planning rules, and the ordering on the rules. As noted, an agent does not have initial plans for simplicity reasons. This implies that the plan base is empty in the initial configuration. Also, because none of the planning rules have been tried to be applied before an agent starts to execute, the set of applied planning rules for each goal in the initial configuration is empty.

Definition 6 (*initial configuration*) Let $(\sigma, \gamma_p, \gamma_a, \gamma_m, PG, <)$ be an agent program. The initial configuration of the agent is $(\sigma, (\gamma_p, \gamma_a, \gamma_m), \Pi, PG, <, T)$, where $\Pi = \emptyset$, and $T = \{(\phi, \emptyset) \mid (\phi, f) \in \gamma_p \text{ or } (\phi, fc) \in \gamma_a \text{ or } (\phi, mc, f) \in \gamma_m\}$.

In the sequel, we omit the set of planning rules PG and the ordering $<$ in the agent configuration for reasons of presentation. Moreover, in the following we use \models_b which is defined as follows: $(\langle \sigma, \gamma, T \rangle \models_b \phi) \Leftrightarrow (\sigma \models \phi)$.

When executing an agent, planning rules will be selected and applied based on its goals, beliefs, and the ordering on the planning rules. The application of planning rules generates plans which can be selected and performed. Before introducing the transition rules to specify possible agent execution steps, we need to define what it means to perform a plan. For simplicity reasons, we assume here that the performance of a plan affects only the belief base. The effect of plans on the belief base is captured through an update operator τ , which takes the belief base and a basic action and generates the updated belief base. This update operator can be as simple as adding/deleting atoms to/from the belief base.

Definition 7 (*plan performance*) Let *BasicAction* be the set of basic actions, $\tau : \text{BasicAction} \times \Sigma \rightarrow \Sigma$ be a partial function implement-

ing a belief update operator, and $a; \pi$ be a plan consisting of action a followed by the plan π . The performance of a plan with respect to a belief base is defined by the function $Perform : \Sigma \times \text{Plan} \rightarrow \Sigma$ that updates the belief base consecutively by the sequence of actions involved in the plan, i.e., $Perform(\sigma, a) = \tau(\sigma, a)$ and $Perform(\sigma, a; \pi) = Perform(Perform(\sigma, a), \pi)$.

Note that $Perform$ is a partial function since the belief update operator is a partial function: we assume that the function $Perform$ evaluates to *undefined* if it is applied to an undefined input element. Given the function $Perform$, the following two transition rules (called EP_1 and EP_2) define plan execution.

$$\frac{(\phi, \kappa, \pi) \in \Pi \& \pi \neq \epsilon \& Perform(\sigma, \pi) = \sigma'}{\langle \sigma, \gamma, \Pi, T \rangle \rightarrow \langle \sigma', \gamma, (\Pi \setminus \{(\phi, \kappa, \pi)\}) \cup \{(\phi, \kappa, \epsilon)\}, T \rangle}$$

$$\frac{(\phi, \kappa, \pi) \in \Pi \& \pi \neq \epsilon \& Perform(\sigma, \pi) = \text{undefined}}{\langle \sigma, \gamma, \Pi, T \rangle \rightarrow \langle \sigma, \gamma, \Pi \setminus \{(\phi, \kappa, \pi)\}, T \rangle}$$

The first transition rule (EP_1) captures the case where the plan π is successfully performed. The resulting configuration contains the empty plan and the belief base is updated appropriately. The second transition rule (EP_2) captures the case that the performance of the plan has failed. Note that in this case, the failed plan (ϕ, ψ, π) will be removed from the plan base.

In order to define the transitions for different types of goals, we first define the notion of *relevant* and *applicable* planning rules w.r.t. an agent's goal, and an auxiliary function called *next*. Intuitively, a planning rule is relevant for an agent's goal if it can contribute to the agent's goal, i.e., if the goal that occurs in the head of the planning rule is a subgoal of the agent's goal. A planning rule is applicable to an agent's goal if it is not applied yet, if it is relevant for that goal, and if the belief condition of the rule is entailed by the agent's configuration. Finally, the next function selects the *first applicable planning rule* for an agent's goal if there exists one, evaluates to *nil* if all relevant planning rules have been tried to be applied, and evaluates to *undefined* otherwise.

Definition 8 (*relevant, applicable, next planning rules*) Let $C = \langle \sigma, \gamma, \Pi, \text{PG}, <, T \rangle$ be an agent configuration and $\langle \phi, R \rangle \in T$. For the given configuration C and goal ϕ , the set of relevant and applicable planning rules, and the next function are defined as follows:

- $rel(\phi, C) = \{r \in \text{PG} \mid \phi \models \mathbf{G}(r)\}$
 - $app(\phi, C) = \{r \in rel(\phi, C) \mid r \notin R, \sigma \models \mathbf{B}(r)\}$
 - $next(\phi, C)$
- = r if $r \in app(\phi, C) \& \forall r' \in app(\phi, C) : r \neq r' \rightarrow r > r'$
= nil if $rel(\phi, C) = R$
= $undefined$ otherwise

In the following transition rules, we omit the reference to configuration C and assume that $rel(\pi)$, $app(\phi)$, and $next(\phi)$ are used in the context of the left-hand side configuration of the transition.

Proposition 1 Let $\langle \sigma, \gamma, \Pi, \text{PG}, <, T \rangle$ be an agent configuration where $\langle \phi, R \rangle \in T$. Then, $next(\phi) = \text{undefined}$ iff $rel(\phi) \neq \emptyset \wedge \forall r \in rel(\phi) : (\sigma \not\models \mathbf{B}(r) \wedge r \notin R)$.

In order to compare the behaviours of an agent for different goal types, we need to define an agent's execution. An execution of an agent is the sequence of configurations that can be generated by applying transition rules. Agent executions can be generated by a cyclic procedure where in each cycle each transition rule gets the opportunity to be applied, i.e., in each cycle each transition rule is selected once and, if possible, applied. Such a cyclic procedure is in fact a

round robin scheduling technique for selecting and applying transition rules. We call such a procedure for selecting and applying transition rules a *round robin procedure*.

Definition 9 (*agent execution*) An execution of an agent is a finite or infinite sequence $\langle C_1, C_2, \dots \rangle$, where $C_i \rightarrow C_{i+1}$ is a transition derived from the transition system for $i \in N$. A fair agent execution is an execution that is generated by a round robin procedure.

3.1 Perform Goals

The idea of perform goals is to allow the generation of plans by applying planning rules. A planning rule can be applied if the goal in its head is logically entailed by one of the agent's goals. We use thus logical formulas to allow reasoning about the goals to decide which planning rule to apply. The following transition rule (called P_1) selects and applies the first (w.r.t. the ordering $<$ on the rules) applicable planning rule. This transition rule can be applied if there are no plans generated for the subgoal that occurs in the head of the planning rule and if the subgoal is not achieved yet. The latter condition is for efficiency.

$$\frac{(\phi_p, f) \in \gamma_p \& next(\phi_p) = (\beta, \kappa \Rightarrow \pi) \& \exists \pi' \in \text{Plan} : (\phi_p, \kappa, \pi') \in \Pi \& \sigma \not\models \kappa}{\langle \sigma, \gamma, \Pi, T \rangle \rightarrow \langle \sigma, \gamma, \Pi \cup \{(\phi_p, \kappa, \pi)\}, T' \rangle}$$

where $T' = (T \setminus \{\langle \phi_p, R \rangle\}) \cup \{\langle \phi_p, R \cup \{\beta, \kappa \Rightarrow \pi\}\rangle\}$.

Below is the second transition rule for a perform goal (called P_2) to administrate planning rules as being tried if the subgoal that occurs in their heads has already been achieved. As noted this is for efficiency reasons.

$$\frac{(\phi_p, f) \in \gamma_p \& r \in \text{PG} \& \sigma \models \mathbf{G}(r)}{\langle \sigma, \gamma, \Pi, T \rangle \rightarrow \langle \sigma, \gamma, \Pi, T' \rangle}$$

where $T' = (T \setminus \{\langle \phi_p, R \rangle\}) \cup \{\langle \phi_p, R \cup \{r\}\rangle\}$.

The third transition rule for a perform goal (called P_3) removes all empty plans from the plan base. This transition rule makes it possible to apply transition rule P_1 once again to generate an alternative plan for the perform goal.

$$\frac{(\phi_p, f) \in \gamma_p \& (\phi_p, \psi, \epsilon) \in \Pi}{\langle \sigma, \gamma, \Pi, T \rangle \rightarrow \langle \sigma, \gamma, \Pi \setminus \{(\phi_p, \psi, \epsilon)\}, T \rangle}$$

The perform goal is enriched with a *redo* flag which can be true or false. If all relevant planning rules for a perform goal have been applied (i.e., if the next function evaluates to nil) and the *redo* flag is false, then the perform goal will be removed from the goal base and the set of tried planning rules for this perform goal is emptied (reset). However, when the *redo* flag is true, the perform goal remains in the goal base while the set of planning rules will be emptied. This ensures that the plans associated with the perform goal will be generated and performed again. These two cases are captured by the below two transition rules (called P_4 and P_5).

$$\frac{(\phi_p, \perp) \in \gamma_p \& next(\phi_p) = \text{nil} \& \exists \phi \in L \exists \pi \in \text{Plan} : (\phi_p, \phi, \pi) \in \Pi}{\langle \sigma, (\gamma_p, \gamma_a, \gamma_m), \Pi, T \rangle \rightarrow \langle \sigma, (\gamma'_p, \gamma_a, \gamma_m), \Pi, T \setminus \{\langle \phi_p, R \rangle\} \rangle}$$

where $\gamma'_p = \gamma_p \setminus \{(\phi_p, \perp)\}$.

$$\frac{(\phi_p, \top) \in \gamma_p \& next(\phi_p) = \text{nil} \& \exists \phi \in L \exists \pi \in \text{Plan} : (\phi_p, \phi, \pi) \in \Pi}{\langle \sigma, \gamma, \Pi, T \rangle \rightarrow \langle \sigma, \gamma, \Pi, (T \setminus \{\langle \phi_p, R \rangle\}) \cup \{\langle \phi_p, \emptyset \rangle\} \rangle}$$

The above transition rules determine how an agent processes its perform goals. The following proposition shows that an agent with

a perform goal to which a false redo flag is assigned, can drop the goal if the relevant planning rules have tautologies as belief conditions. It shows that such an agent will drop the goal if its behaviour is generated by a fair execution procedure.

Proposition 2 Let $C = \langle \sigma, (\gamma_p, \gamma_a, \gamma_m), \Pi, T \rangle$ be an initial agent configuration, where $(\phi_p, \perp) \in \gamma_p$ and $\forall r \in \text{PG} : \mathbf{B}(r) = \top$. There exists a finite execution that removes (ϕ_p, \perp) from the goal base. All fair executions eventually remove (ϕ_p, \perp) from the goal base.

3.2 Achieve Goals

For an achieve goal plans should be generated to reach the state denoted by it. If the generated and performed plans do not achieve the desired state, then the achieve goal remains in the goal base. The first transition rule below (called A_1) is designed to apply planning rules in order to achieve the subgoals of the achieve goals. A planning rule can be applied if the goal in the head of the rule is not achieved yet, if there is no plan for the same subgoal in the plan base, and if the failure condition does not hold. The application of a planning rule will add the plan of the planning rule to the plan base and administrate it as a tried rule.

$$\frac{(\phi_a, fc) \in \gamma_a \& \text{next}(\phi_a) = (\beta, \kappa \Rightarrow \pi) \& \exists \pi' \in \text{Plan} : (\phi_a, \kappa, \pi') \notin \Pi \& \sigma \not\models \kappa \& \sigma \not\models fc}{\langle \sigma, \gamma, \Pi, T \rangle \rightarrow \langle \sigma, \gamma, \Pi \cup \{(\phi_a, \kappa, \pi)\}, T' \rangle}$$

where $T' = (T \setminus \{\langle \phi_a, R \rangle\}) \cup \{\langle \phi_a, R \cup \{(\beta, \kappa \Rightarrow \pi)\}\rangle\}$.

If the head of a planning rule is already achieved, then the rule will be considered as tried and will be administrated accordingly. This is realized by the next transition rule (called A_2).

$$\frac{(\phi_a, fc) \in \gamma_a \& r \in \text{PG} \& \sigma \models \mathbf{G}(r)}{\langle \sigma, \gamma, \Pi, T \rangle \rightarrow \langle \sigma, \gamma, \Pi, T' \rangle}$$

where $T' = (T \setminus \{\langle \phi_a, R \rangle\}) \cup \{\langle \phi_a, R \cup \{(\beta, \kappa \Rightarrow \pi)\}\rangle\}$.

The next transition rule (A_3) removes all empty plans, which are generated for the achieve goals, from the plan base. Note that this transition rule is similar to P_3 . We did not generalize this rule to be applicable to all goal types since the empty plans for the maintain goals should be removed differently (see next section).

$$\frac{(\phi_a, fc) \in \gamma_a \& (\phi_a, \psi, \epsilon) \in \Pi}{\langle \sigma, \gamma, \Pi, T \rangle \rightarrow \langle \sigma, \gamma, \Pi \setminus \{(\phi_a, \psi, \epsilon)\}, T \rangle}$$

An achieve goal can be dropped under two circumstances: either when the failure condition, which is assigned to it, becomes true, or when the state it denotes is reached. The transition rule A_4 below captures these two cases of dropping the achieve goal. In both cases, besides the removal of the achieve goal, the plans associated with it will be removed and the set of tried planning rules will be set to empty.

$$\frac{(\phi_a, fc) \in \gamma_a \& (\sigma \models \phi_a \text{ or } \sigma \models fc)}{\langle \sigma, (\gamma_p, \gamma_a, \gamma_m), \Pi, T \rangle \rightarrow \langle \sigma, (\gamma_p, \gamma'_a, \gamma_m), \Pi', T \setminus \{\langle \phi_a, R \rangle\} \rangle}$$

where $\gamma'_a = \gamma_a \setminus \{(\phi_a, fc)\}$ and $\Pi' = \Pi \setminus \{(\phi_a, \kappa, \pi) \mid \kappa \in L, \pi \in \text{Plan}\}$.

When all planning rules that could achieve a subgoal of an achieve goal have been applied, all generated plans have been performed, but the state denoted by the achieve goal is not reached, then the set of tried rules will be set to empty in order to enable a new round of rule applications and plan performance. This is realized by the following transition rule A_5 .

$$\frac{(\phi_a, fc) \in \gamma_a \& \text{next}(\phi_a) = \text{nil} \& \sigma \not\models \phi_a \& \sigma \not\models fc \& \exists \kappa \in L \exists \pi \in \text{Plan} : (\phi_a, \kappa, \pi) \in \Pi}{\langle \sigma, \gamma, \Pi, T \rangle \rightarrow \langle \sigma, \gamma, \Pi, (T \setminus \{\langle \phi_a, R \rangle\}) \cup \{\langle \phi_a, \emptyset \rangle\} \rangle}$$

Given the transition rules A_1, \dots, A_5 for the achieve goals, we can now show that an achieve goal will not be removed from the goal base unless the state denoted by it is reached.

Proposition 3 Let $\langle C_1, C_2, \dots \rangle$ be an agent execution, where $C_i = \langle \sigma^i, (\gamma_p^i, \gamma_a^i, \gamma_m^i), \Pi^i, T^i \rangle$ and $(\phi, \perp) \in \gamma_a^1$. Then,
 $\forall k \in N : (\sigma^1 \not\models \phi \wedge \dots \wedge \sigma^k \not\models \phi) \rightarrow (\phi, \perp) \in \gamma_a^k$

The achievement of an achieve goal depends on many factors among which whether the planning rules are designed correctly and whether the plans of different rules interfere with each other. In order to define whether a planning rule is designed correctly, we need to specify the consequence of performing a plan in an agent configuration. The following function XP maps an agent configuration C to another agent configuration C' such that C' can be reached from configuration C by performing successfully the plan π (from the plan base of C), i.e., $C \rightarrow C'$ is a transition derived by applying the transition rule EP_1 .

Definition 10 (XP function) Let \mathcal{C} be the set of agent configurations. The eXecute Plan function $XP : \mathcal{C} \times (L \times L \times \text{Plan}) \rightarrow \mathcal{C}$ is defined as follows: $XP(C, (\phi, \kappa, \pi)) = C'$ iff $C \rightarrow C'$ is derivable by applying transition rule EP_1 through which (ϕ, κ, π) from the plan base of C is executed, i.e., where $C = \langle \sigma, \gamma, \Pi, T \rangle$, $C' = \langle \sigma', \gamma, \Pi', T \rangle$, $(\phi, \kappa, \pi) \in \Pi$, $\Pi' = (\Pi \setminus \{(\phi, \kappa, \pi)\}) \cup \{(\phi, \kappa, \epsilon)\}$, and $\text{Perform}(\sigma, \pi) = \sigma'$.

A correct planning rule is a rule for which the performance of its plan in an agent configuration achieves the goal occurring in its head.

Definition 11 (correct planning rules) Let XP be the eXecute Plan function. A planning rule $\beta, \kappa \Rightarrow \pi$ is correct iff for all configurations C and $\phi, \psi \in L$ it holds that: $XP(C, (\phi, \psi, \pi)) \models_b \kappa$

The applications of planning rules generate a set of plans that can be performed in an arbitrary order. If plans are not designed carefully, then their order of performance can have undesirable effects. In order to guarantee that a set of plans reach certain states independent of their order of performance, we employ a notion of non-interfering plans.

Definition 12 (non-interfering plans) Let $C = \langle \sigma, \gamma, \Pi, T \rangle$ be an agent configuration, $p_1 = (\phi_1, \psi_1, \pi_1)$, $p_2 = (\phi_2, \psi_2, \pi_2)$, and $p_1, p_2 \in \Pi$. The plans π_1 and π_2 are non-interfering iff
 $XP(XP(C, p_1), p_2) = XP(XP(C, p_2), p_1)$

If all planning rules are correct and they can always be applied (the belief condition of the rules are tautologies), then all fair executions reach eventually the state denoted by an achieve goal that is equivalent with the goals occurring in the head of the planning rules.

Proposition 4 Let $C_1 = \langle \sigma, (\gamma_p, \gamma_a, \gamma_m), \Pi, T \rangle$ be an initial configuration, $(\phi, fc) \in \gamma_a$, all planning rules in PG be correct, the plans in these rules be non-interfering, and there exists $\{(\top, \kappa_1 \Rightarrow \pi_1), \dots, (\top, \kappa_n \Rightarrow \pi_n)\} \subseteq \text{PG}$ such that $\{\kappa_1, \dots, \kappa_n\} \models \phi$ and $\phi \models \kappa_i$ for $1 \leq i \leq n$. Then, there exists a configuration C_n in every fair agent execution $\langle C_1, C_2, \dots \rangle$ such that $C_n \models_b \phi$.

The transition rules for the perform and achieve goals show close similarities. In order to examine and compare an agent's behaviours with respect to different goal types, we define goal-equivalent agent executions. The idea is that the consecutive agent configurations in these agent executions are identical in all components except their goal bases.

Definition 13 (*goal-equivalent executions*) Let $e_1 = \langle C_1, C_2, \dots \rangle$ and $e_2 = \langle C'_1, C'_2, \dots \rangle$ be agent executions, where for $i \in N$, $C_i = \langle \sigma_i, \gamma_i, \Pi_i, T_i \rangle$ and $C'_i = \langle \sigma'_i, \gamma'_i, \Pi'_i, T'_i \rangle$ are agent configurations. The executions e_1 and e_2 are goal-equivalent iff $\sigma_i = \sigma'_i$, $\Pi_i = \Pi'_i$, and $T_i = T'_i$ for $i \in N$.

Note that the goal-equivalent relation is an equivalence relation. We can now show that under certain conditions the achieve goal of an agent can be replaced with a perform goal. In particular, an agent with an achieve goal such that the state denoted by it cannot be reached and its failure condition never becomes true (e.g., the goal to have fuel in the car FC while there is no fuel anywhere, with the failure condition no-fuel-in-world assuming that the agent cannot come to conclude this belief), can be replaced by a perform goal with a true redo flag (e.g., the goal FC with a flag \top while there is no fuel anywhere).

Proposition 5 Let $C_1 = \langle \sigma, (\gamma_p, \gamma_a, \gamma_m), \Pi, T \rangle$ be an agent configuration. If there exists no execution $\langle C_1, C_2, \dots \rangle$ with $C_i \models_b \phi$ for some $i \in N$, then for every execution starting from $\langle \sigma, (\gamma_p, \gamma_a \cup \{(\phi, \perp)\}, \gamma_m), \Pi, T \rangle$ there exists a goal-equivalent execution starting at $\langle \sigma, (\gamma_p \cup \{(\phi, \top)\}, \gamma_a, \gamma_m), \Pi, T \rangle$.

3.3 Maintain Goals

The state denoted by a maintain goal should hold at any moment during the agent execution. In order to maintain the denoted state, plans should be generated and performed. The question is when exactly plans should be generated and performed. A maintain goal is enriched with a triggering condition which, if it becomes true, indicates that plans should be generated and performed. This triggering condition can be considered as an alarm to act in order to ensure the maintenance of the state denoted by the maintain goal. It should be noted that there might be no logical relation between the maintain goals and their triggering conditions. This relation depends usually on the application domain. However, we assume that in all agent configurations, if the triggering condition does not hold, then the maintain goal holds: $\forall \sigma \in \Sigma, \forall \phi_m, mc \in L : (\sigma \not\models mc) \rightarrow (\sigma \models \phi_m)$. We associate a *retry* flag to maintain goals. If this flag is set to false, all planning rules have been applied, the generated plans have been performed, and the maintain triggering condition still holds, then no new rounds of actions should be taken. This flag can thus be used to avoid new attempts to maintain a goal.

The first transition rule M_1 is designed to allow the application of planning rules when the maintain triggering condition becomes true. The applied rule should be such that there is no plan already in the plan base for the subgoal that occurs in the head of the selected rule.

$$\frac{(\phi_m, mc, f) \in \gamma_m \text{ & } next(\phi_m) = (\beta, \kappa \Rightarrow \pi) \text{ & } \exists \pi' \in \text{Plan} : (\phi_m, \kappa, \pi') \in \Pi \text{ & } \sigma \models mc}{\langle \sigma, \gamma, \Pi, T \rangle \rightarrow \langle \sigma, \gamma, \Pi \cup \{(\phi_m, \kappa, \pi)\}, T' \rangle}$$

where $T' = (T \setminus \{\langle \phi_m, R \rangle\}) \cup \{\langle \phi_m, R \cup \{(\beta, \kappa \Rightarrow \pi)\}\rangle\}$.

In order to maintain a goal, applicable planning rules should be applied independently of whether the goal in their heads, which are subgoals of the maintain goals, are achieved. But this means that all planning rules that have the same subgoal in their heads will be applied if they are applicable. This can, however, make the executions inefficient. For example, suppose that the maintain goal of an agent is to have fuel in the car FC and that the agent has several planning rules that indicate several plans to refuel. It is undesirable to allow the agent to apply all planning rules to generate all possible ways to refuel. Therefore, we administrate all planning rules with the same

goal in their heads as tried rules when one plan for this subgoal is successfully performed. This idea is captured by the transition rule M_2 .

$$\frac{(\phi_m, mc, f) \in \gamma_m \text{ & } \{(\phi_m, \kappa, \epsilon)\} \in \Pi}{\langle \sigma, \gamma, \Pi, T \rangle \rightarrow \langle \sigma, \gamma, \Pi \setminus \{(\phi_m, \kappa, \epsilon)\}, T' \rangle}$$

where $T' = (T \setminus \{\langle \phi_m, R \rangle\}) \cup \{\langle \phi_m, R \cup \{r \in \text{PG} \mid \mathbf{G}(r) = \kappa\}\rangle\}$.

If there are no plans to perform, no rules to apply, and either the goal is maintained (maintain condition does not hold) or the retry flag is true, the administration of applied rules is reset. The reset makes it possible to re-apply rules and re-perform plans if needed. Note that if the maintain condition holds (actions should be taken to maintain the goal) and the retry flag is false, then the goal is not maintainable and the agent cannot do anything to maintain the goal.

$$\frac{(\phi_m, mc, f) \in \gamma_m \text{ & } next(\phi_m) = nil \text{ & } (f = \top \text{ or } \sigma \not\models mc) \text{ & } \exists \kappa \in L \exists \pi \in \text{Plan} : (\phi_m, \kappa, \pi) \in \Pi}{\langle \sigma, \gamma, \Pi, T \rangle \rightarrow \langle \sigma, \gamma, \Pi, (T \setminus \{\langle \phi_m, R \rangle\}) \cup \{\langle \phi_m, \emptyset \rangle\} \rangle}$$

Given these transition rules for the maintain goal, the perform goal (ϕ, \perp) and the maintain goal (ϕ, \top, \perp) are identical.

Proposition 6 Let σ be a belief base, for all $r \in \text{PG} : \sigma \not\models \mathbf{G}(r)$, all planning rules are correct, and plans are non-interfering. Then, for every execution starting from $C_1 = \langle \sigma, (\gamma_p, \gamma_a, \gamma_m \cup \{(\phi, \top, \perp)\}), \Pi, T \rangle$ there exists a goal-equivalent execution starting from $C'_1 = \langle \sigma, (\gamma_p \cup \{(\phi, \perp)\}, \gamma_a, \gamma_m), \Pi, T \rangle$.

4 Conclusion

In this paper, we have introduced three types of declarative goals for which we argued that they should be integrated in logic-based agent-oriented programming languages. We presented a simple agent-oriented programming language that allows the implementation of these goal types. The formal semantics of the programming language, and thus of the goal types, is given and it is shown that this semantics has desirable properties (because of the space limit we could not present the proofs). The presented programming language is simplified for the purpose of this paper. The language can be extended by using a (computational) subset of a first-order predicate language instead of using a propositional language. In this way, declarative goals become more expressive. Also, the plan language can be extended to allow more complex plans. We have started implementing an interpreter for an extended version of the presented programming language which we hope will be available soon. For this implementation, we have decided to generate a specific fair execution of agents by means of a deliberation cycle. In future work, we will investigate possible deliberation cycles and use temporal logics to prove properties of different deliberation cycles and to compare them.

Alternating-Offers Bargaining under One-Sided Uncertainty on Deadlines

Francesco Di Giunta and Nicola Gatti¹

Abstract. Alternating-offers is the most prominent negotiation protocol for automatic bilateral bargaining. Nevertheless, in most settings it is still not known how two fully rational agents should behave in the protocol. In this paper we study the finite-horizon alternating-offers protocol under one-sided uncertain deadlines. We make a novel use of backward induction in studying bargaining with uncertainty; we employ a “natural” system of beliefs and find, when it exists, the pertinent pure strategy sequential equilibrium. We further show, as an intrinsic limitation of the protocol, that for some parameter values there is no pure strategy sequential equilibrium, whatever system of beliefs is employed.

1 Introduction

Automated negotiation is a prominent research area of distributed artificial intelligence which studies the processes whereby rational software agents try to solve disputes and reach mutually beneficial agreements [7]. It is well known that the automation of the negotiating agents leads to more effective negotiations since agents are more efficient than humans in finding optimal agreements [14].

Among the negotiation settings for commercial transactions, a very common one is *bargaining*: a buyer and a seller try to agree on the choice of the value of some variables, named *issues*, that define the transaction they are carrying out (e.g. the price and quantity of a traded good). The formalized study of bargaining is commonly carried out with game-theoretical tools [9] in which one distinguishes the negotiation *protocol* and the negotiation *strategies*: the protocol sets the negotiation rules, specifying which actions are allowed and when [10]; the strategy defines an agent’s possible specific behavior in the negotiation. Given a protocol, rational agents should employ strategies that maximize their payoffs, and the classic game-theoretic approach prescribes that agents employ equilibrium strategies, where the notion of equilibrium is Nash equilibrium or extensions [5].

The best known protocol for bilateral bargaining, the *alternating-offers* protocol, pioneered by Ståhl [16], has reached an outstanding place in literature thanks to Rubinstein [11], and comes in many variations. Basically, an agent starts by offering values for the issues under dispute to her opponent, who can accept or make a counteroffer or exit the negotiation. If a counteroffer is made, the process is repeated until one of the agents accepts or exits the negotiation. There can be one or more bargained issues, leading respectively to *one-issue* and *multi-issue* bargaining. The issues are usually continuous, i.e. they are real-valued variables. The agents have reservation values, temporal utility discount factors, and negotiation deadlines. If the agents have finite negotiation deadlines, the protocol is a *finite-horizon* one; otherwise, it is *infinite-horizon*.

Although much economics and computer science literature deals with the alternating-offers protocol (see e.g. [7]), several major problems are still open, the main ones concerning *multi-issue* and *incomplete information* bargaining. Easy and general solutions are currently available when the bargaining is on one issue and every pertinent information is common knowledge between the two agents, but both assumptions are very restrictive. The problem of efficient multi-issue bargaining has been addressed in [2]. The problem of incomplete knowledge is harder. Rubinstein [12] has provided the first results about uncertainty over two possible time discount factors of one of the two agents. Several other authors have followed his research line, providing results on very narrow lacks of information completeness. We refer to [1] for a survey.

Given the difficulties in finding classic solutions to alternating-offers problems with incomplete information, several authors have proposed non-standard approaches. The best known proposal is Fátima, Wooldridge, and Jennings’s framework in [4]. Their approach is based on the *negotiation decision functions* paradigm [3], where the agents are supposed to constraint themselves to employ one of some predefined bidding tactics in their bargaining.

The aim of our paper is to analyze and solve the finite-horizon alternating-offers protocol under incomplete information on the bargaining deadline of one of the two agents (*one-sided* incomplete information). We adopt a classical approach, where the agents are not *a priori* assumed self-restricted to any class of strategies, in the belief that this approach is more coherent with the multiagent system paradigm (see, e.g., the discussion in [15]). Furthermore, in accordance with virtually all the literature on the topic, we employ pure strategies rather than mixed ones.

Our original contributions are: (1) the solution of the single-issue finite-horizon alternating-offers bargaining under one-sided uncertainty on deadlines, for a wide range of bargaining parameters; (2) the proof of non-existence of a general solution in pure strategies.

The paper is structured as follows: in the next section we review the finite-horizon alternating-offers protocol with complete information and its well known solution, in order to introduce basic concepts and state notation; in Section 3 we analyze the protocol under one-sided uncertain deadlines; in Section 4 we show that the general problem has no solution in pure strategies; Section 5 summarizes our conclusions.

2 Complete information alternating-offers

The protocol we study is a discrete time finite-horizon alternating-offers bargaining protocol on one continuous issue (say, a price).²

¹ Politecnico di Milano, Italy, email: {digiunta, ngatti}@elet.polimi.it

² The multi-issue problem [2] is orthogonal to the incomplete information problem. So, for the sake of simplicity, we consider one-issue bargaining.

Formally, the buyer b and the seller s can act at times $t \in \mathbb{N}$. The *player function* $\iota : \mathbb{N} \rightarrow \{b, s\}$ returns the agent that acts at time t and is such that $\iota(t) \neq \iota(t+1)$. Possible actions $\sigma_{\iota(t)}^t$ of agent $\iota(t)$ at time $t > 0$ are:

- (1) *offer*(\bar{x}), where $\bar{x} \in \mathbb{R}$,
- (2) *exit*,
- (3) *accept*.

At $t = 0$ the only allowed actions are (1) and (2). If $\sigma_{\iota(t)}^t = \text{accept}$ the bargaining stops and the *outcome* is (\bar{x}, t) , where \bar{x} is the tuple such that $\sigma_{\iota(t-1)}^{t-1} = \text{offer}(\bar{x})$. If $\sigma_{\iota(t)}^t = \text{exit}$ the bargaining stops and the outcome is *NoAgreement*. Otherwise the bargaining continues to the next time point.

Each agent i has an utility function $U_i : (\mathbb{R} \times \mathbb{N}) \cup \{\text{NoAgreement}\} \rightarrow \mathbb{R}$, that represents her gain on the possible bargaining outcomes. Each utility function U_i depends on three parameters of agent i :

- the *reservation price* $RP_i \in \mathbb{R}^+$,
- the *temporal discount factor* $\delta_i \in (0, 1]$,
- the *deadline* $T_i \in \mathbb{N}$, $T_i > 0$.

Exactly, if the outcome of the bargaining is an agreement (x, t) , then the utility functions U_b and U_s are respectively:

$$U_b(x, t) = \begin{cases} (RP_b - x)\delta_b^t & \text{if } t \leq T_b \\ -1 & \text{otherwise} \end{cases}, \quad U_s(x, t) = \begin{cases} (x - RP_s)\delta_s^t & \text{if } t \leq T_s \\ -1 & \text{otherwise} \end{cases}.$$

If the outcome is *NoAgreement*, then $U_b(\text{NoAgreement}) = U_s(\text{NoAgreement}) = 0$.³

Some standard hypothesis are assumed. *Feasibility*: $RP_b \geq RP_s$. *Rationality*: it is common knowledge that each agent will act to maximize her utility. *Benevolence*: it is common knowledge that if an agent has to choose between two outcomes which are indifferent for her but not for her opponent, she will choose the one that is better for her opponent.

The bargaining strategies that the agents should select also depend on the knowledge that the agents have of the protocol and of each other's utility function. In *complete information* bargaining it is assumed that the protocol and the utility functions (including the values of RP_i , δ_i and T_i) are common knowledge between the two agents.

The appropriate notion of solution for a complete information extensive form game like the one we are dealing with is *subgame perfect equilibrium* [6]. Subgame perfect equilibrium strategies can be easily found by *backward induction*, as we discuss in the following.

No agent is willing to bargain after her deadline, when any agreement would have negative utility. Therefore, at time $\bar{T} = \min\{T_b, T_s\}$ the acting agent – let's say s – would accept any offer with non-negative utility. Therefore, at time $\bar{T} - 1$ her opponent b could safely offer RP_s (which would be accepted) or could accept any possible previous offer x which is not worse than offering RP_s (i.e., $U_b(x, \bar{T} - 1) \geq U_b(RP_s, \bar{T})$). Therefore, at time $\bar{T} - 2$ agent s could safely offer the maximum x such that $U_b(x, \bar{T} - 1) \geq U_b(RP_s, \bar{T})$, i.e. x such that $U_b(x, \bar{T} - 1) = U_b(RP_s, \bar{T})$, or accept any possible previous offer which is not worse than offering x . This reasoning can be inductively carried on until the beginning of the game, finding an offer that agent $\iota(0)$ would do and her opponent would accept.

At each time point t , from \bar{T} back, it is therefore possible to know which offer would be made by agent $\iota(t)$ if she would make an offer:

³ Notice that employment of $U_i = -1$ after agent i 's deadline allows a rational behaviour of the agent after her deadline: an agent prefers to exit the negotiation than to reach any agreement.

we denote this series of offers by $x^*(t)$. In order to provide a recursive formula for $x^*(t)$, we introduce the notion of backward propagation: given value x and agent i , we call *backward propagation* of value x for agent i the value y such that $U_i(y, t-1) = U_i(x, t)$; we will employ the arrow notation $x \leftarrow_i$ for backward propagations.⁴ The calculation of $x^*(t)$ can now be stated like this:

$$x^*(t-1) = \begin{cases} RP_{\iota(t)} & \text{if } t = \bar{T} \\ (x^*(t))_{\iota(t)} & \text{if } t < \bar{T} \end{cases},$$

and is computationally linear with \bar{T} . A backward induction and the relevant $x^*(t)$ values can be plotted on the space (x, t) as in Figure 1.

The backward induction reasoning so far sketched proves the following result [9]:

Proposition 2.1 *Finite-horizon alternating-offers over single-issue bargaining with complete information has one and only one subgame perfect equilibrium. The equilibrium strategies for $t < \bar{T}$ are*

$$\sigma_{\iota(t)}^t = \begin{cases} \text{accept} & \text{if } \begin{cases} t \geq 0 \\ \sigma_{\iota(t-1)}^{t-1} = \text{offer}(x) \text{ with } U_{\iota(t)}(x, t) \geq U_{\iota(t)}(x^*(t), t+1) \end{cases} \\ \text{offer}(x^*(t)) & \text{otherwise} \end{cases}$$

and when $t = \bar{T}$

$$\sigma_{\iota(\bar{T})}^{\bar{T}} = \begin{cases} \text{accept} & \text{if } \sigma_{\iota(\bar{T}-1)}^{\bar{T}-1} = \text{offer}(x) \text{ with } U_{\iota(\bar{T})}(x, \bar{T}) \geq 0 \\ \text{exit} & \text{otherwise} \end{cases}.$$

The agreement is therefore achieved at time $t = 1$ on the price $x^*(0)$.

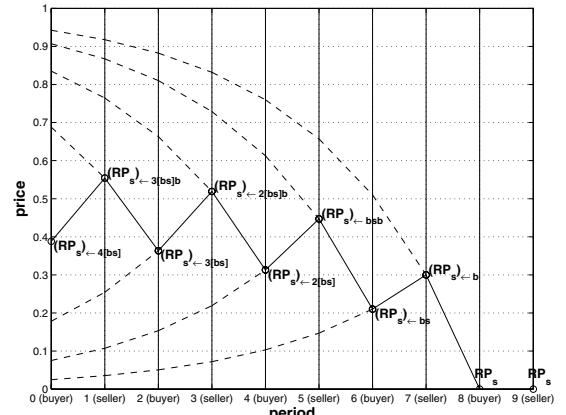

Figure 1. Backward induction with $RP_b = 1$, $RP_s = 0$, $\delta_b = 0.7$, $\delta_s = 0.7$, $T_b = 9$, $T_s = 10$, $\iota(0) = b$

3 Alternating-Offers with Uncertain Deadlines

Let us consider one-issue alternating-offers bargaining when one of the two agents does not exactly know her opponent's deadline. We will assume that the uncertain deadline is the buyer's.

As is customary in game theory in order to avoid underdetermined problems, we assume that b 's possible deadlines are distributed according to a probability distribution on \mathbb{R}^+ which is common knowledge between the agents. We further assume that the support of b 's deadline distribution is bounded; and since the agents

⁴ If a value x is backward propagated n times along the level curves of agent i , we write $x \leftarrow_{i[n]}$. If a value is backward propagated along the level curves of more than one agent, we list them left to right in the subscript; for instance, $x \leftarrow_{i3[j]}$ is value x backward propagated along the level curves of agent i and subsequently three times along the curves of agent j .

can act only at times $t \in \mathbb{N}$, we can assume, without loss of generality, that b 's deadline has a finite distribution on \mathbb{N} . We denote by $\mathcal{T}_b = \{T_{b_1}, \dots, T_{b_m}\}$ the set of possible deadlines of b , by $\mathcal{P}_b^0 = \{\alpha_{b_1}^0, \dots, \alpha_{b_m}^0\}$ the pertinent probability distribution, and by BT_b^0 the couple $BT_b^0 = \langle \mathcal{T}_b, \mathcal{P}_b^0 \rangle$. Agent b 's real deadline is known only to b itself: it is her *private information*.

In games with uncertainty, rational agents try to maximize their expected utilities relying on their beliefs about the opponent's private information and such beliefs are updated during the game, depending on which actions have been actually undertaken. The set of beliefs held by each agent over the other's private information after every possible sequence of actions in the game is called a *system of beliefs* and is usually denoted by μ . These beliefs are probabilistic and their values at time $t = 0$ is a given problem data. How beliefs evolve during the game, instead, is part of the solution which should be found for the game. A solution to an incomplete information bargaining is therefore a suitable couple $a = \langle \mu, \sigma \rangle$ called *assessment*.

An assessment $a = \langle \mu, \sigma \rangle$ must be such that the strategies in σ are mutual best responses given the probabilistic beliefs in μ (*rationality*); and the beliefs in μ must reasonably depend on the actions prescribed by σ (*consistency*). Different notions of solution differ on how they specify these two requirements.

We will employ the most common notion of solution for incomplete information bargaining, namely the the *sequential equilibrium* of Kreps and Wilson [8]. For a sequential equilibrium $a^* = \langle \mu^*, \sigma^* \rangle$, with $\sigma^* = \langle \sigma_b^*, \sigma_s^* \rangle$, the rationality requirement is specified as *sequential rationality*. Informally, after every possible sequence of actions S , on or off the equilibrium path, the strategy σ_s^* must maximize s 's expected utility given s 's beliefs prescribed by μ for S , and given that b will there on act according to σ_b^* ; and *vice versa*. The notion of consistency is defined as follows: assessment a is *consistent in the sense of Kreps and Wilson* (or simply *consistent*) if there exists a sequence a_n of assessments, each with completely mixed strategies and such that the beliefs are updated according to Bayes rule, that converges to a .

The method we will employ to find sequential equilibria is: (1) *a priori* fix a reasonable system of beliefs $\bar{\mu}$; (2) use backward induction to find, if they exist, the strategies σ of sequentially rational assessments a with beliefs $\bar{\mu}$; (3) *a posteriori* prove the consistency of the assessment.

We will use a system of beliefs $\bar{\mu}$ which is easy and natural: after any sequence of actions, agent s just excludes those deadlines T_{b_h} , among the initially possible ones, that have already expired and normalizes the probabilities of the future ones. Thus, in particular, the beliefs about the deadlines after a sequence of actions S depend only on the length of S . For it will be useful later, we introduce the *deadline function* $d(t)$, whose value is the probability, given at time t according to $\bar{\mu}$, that time t itself is a deadline for agent b .

Given the system of beliefs $\bar{\mu}$, we can find the sequentially rational strategies by backward induction. But the use of backward induction in this context is more involved than in the complete information bargaining and requires some explanations.

With complete information the backward induction can start at the earlier of the two deadlines; but with our incomplete information framework, the earlier deadline is not *a priori* known. Nevertheless, the backward induction can start at $\bar{T} = \min\{\max_h\{T_{b_h}\}, T_s\}$, because it is *a priori* known that after time \bar{T} agent b will exit the negotiation; if the bargaining process would reach time \bar{T} , then agent $\iota(\bar{T})$ would accept any nonnegative utility offer; therefore, at time $\bar{T} - 1$ agent $\iota(\bar{T} - 1)$, if she would make an offer, would offer $\iota(\bar{T})$'s reservation price.

It is therefore possible, like in the complete information setting of Section 2, to backward infer the offers $x^*(t)$ that the agents would do if they would choose to make an offer. But there are some complications in the construction of the optimal offers $x^*(t)$.

In the complete information case the values $x^*(t)$ are (i) the optimal offers, (ii) the values to be backward propagated, and (iii) the backward propagated values. In incomplete information bargaining, instead, this three series of values are distinct in general. Let us see these topics in more detail.

First, in complete information bargaining the optimal offer $x^*(t)$ is simply the backward propagation of $x^*(t + 1)$; with incomplete information this is not generally true: the backward propagated value is only the best among the surely accepted offers. But if at a time t , such that $\iota(t) = s$, there is a high probability that time $t + 1$ is a deadline of b , then agent s could prefer to offer RP_b rather than offer the best among the surely accepted offers, although offer RP_b could be rejected (if $t + 1$ is not b 's real deadline).

Second, as optimal offers of agent $s = \iota(t + 1)$ could be rejected, the value that should be backward propagated from time $t + 1$ to time t , in order to obtain the best one among the offers of b at time t that would be surely accepted by s , is not $x^*(t + 1)$ in general. The right value to be backward propagated is the value that we call *equivalent value* and is defined as follows: given an offer x of s , the equivalent value of x , denoted by $e(t)$, is the value such that $EU_s(e(t), 0) = EU_s(x)$.⁵ If offered value $(e^*(t + 1))_{\leftarrow s}$ at time t , agent s would accept it instead of offering $x^*(t + 1)$; if offered a worse value, she would refuse it and counteroffer $x^*(t + 1)$.

Summarily, backward propagation should be applied in general to equivalent values e^* rather than to best offers x^* , and best offers x^* of agent s are not always the backward propagated values. Formulas to find equivalent values and best offers are easy to find. If $\iota(t) = b$ then $e^*(t) = x^*(t)$ and $x^*(t) = (e^*(t + 1))_{\leftarrow s}$. Conversely, if $\iota(t) = s$ then $e^*(t) = RP_s + \delta^{t-1} \cdot EU_s(x^*(t))$ and $x^*(t) = \arg \max_{x=RP_b, (e^*(t+1))_{\leftarrow b}} \{EU_s(x)\}$ where:

$$\begin{aligned} EU_s(RP_b) &= (1 - d(t)) \cdot \left(d(t + 1) \cdot U_s(RP_b, t + 1) + (1 - d(t + 1)) \cdot \right. \\ &\quad \left. U_s(x^*(t + 1), t + 2) \right) \\ EU_s((e^*(t + 1))_{\leftarrow b}) &= (1 - d(t)) \cdot U_b((e^*(t + 1))_{\leftarrow b}, t + 1) \end{aligned}$$

Given $x^*(\cdot)$, the optimal strategy σ_i^* for agent i at time t is: if t is i 's deadline and at $t - 1$ she received an offer that gives her negative utility, then exit; if t is i 's deadline and at $t - 1$ she received an offer that gives her nonnegative utility, then accept; if t is not i 's deadline and at time $t - 1$ she received an offer not worse for her than $(x^*(t))_{\leftarrow i}$, then accept; otherwise offer $x^*(t)$.

The above backward construction provides the sequentially rational strategies with the system of beliefs $\bar{\mu}$ we have chosen, when they exist. But actually, they could not exist with some parameter setting. This can happen because one agent (precisely, the buyer) might deviate from strategy σ^* to offer something unacceptable for the opponent in order to be refused and to later be in a much stronger position and gain more. An example is given in Fig. 2. Here the backward induction construction imposes that at time 6 an offering buyer should make offer $e_{\leftarrow s}^7$; but it is easily seen that it is more convenient for her to offer something unacceptable (e.g., RP_s), then receive counteroffer RP_b , and finally re-counteroffer RP_s at time 8 (that would be surely accepted).

This anomaly arises because different types of buyers might have different optimal offers, thus revealing their private information and thus not allowing the seller to adopt the simple system of beliefs $\bar{\mu}$.

⁵ Clearly, the equivalent value of a surely accepted offer of s is the offer itself.

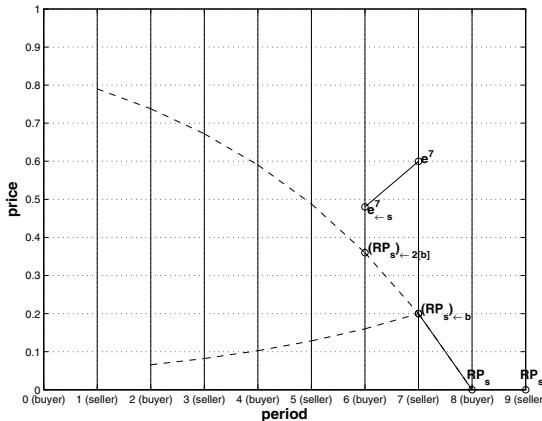

Figure 2. Non-existence of equilibrium with $RP_b = 1$, $RP_s = 0$, $\delta_b = 0.8$, $\delta_s = 0.8$, $\langle T_b = \{5, 8, 9\}, P_b^0 = \{0.5, 0.3, 0.2\}\rangle$, $T_s = 10$, $\iota(0) = b: x_{\leftarrow 2[b]} < e_{\leftarrow s}^7$

This happens when an “early deadline buyer” would offer the backward propagation of the seller’s equivalent value at the next time point, while a “late deadline buyer” would let time pass by to reach the part of the bargaining process where backward induction prescribes her utility to be higher. Precisely, this happens when t is a possible deadline of b , the optimal strategy of s at time $t - 1$ is to offer RP_b , and $U_b(x^*(t - 2), t - 2) < U_b(x^*(t), t)$. In other words it is not sequentially rational for b to offer $x^*(t - 2)$, but it is more convenient to deviate from the $x^*(t - 2)$ to offer $x^*(t)$ at t . This is the condition for the sequential rationality of strategies σ_i^* .

In Fig. 3 we depict an example of bargaining under one-sided uncertain deadlines that satisfies the above condition, so that the devised strategies are sequentially rational.

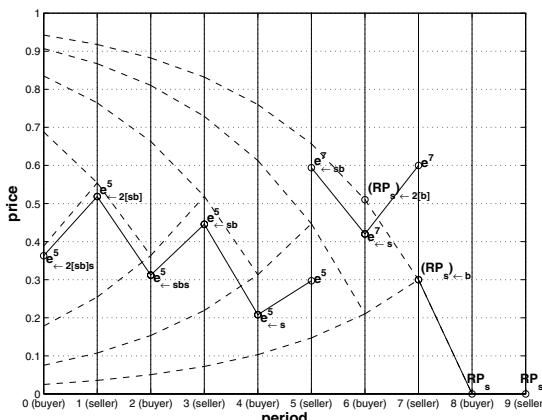

Figure 3. Backward induction with $RP_b = 1$, $RP_s = 0$, $\delta_b = 0.7$, $\delta_s = 0.7$, $\langle T_b = \{5, 8, 9\}, P_b^0 = \{0.5, 0.3, 0.2\}\rangle$, $T_s = 10$, $\iota(0) = b$: the existence is given by $e_{\leftarrow s}^7 < x_{\leftarrow 2[b]}$

We can now state the following:

Theorem 3.1 If for all t such that $\iota(t) = b$ holds $U_b(x^*(t - 2), t - 2) \geq U_b(x^*(t), t)$, then the assessment $a = \langle \bar{\mu}, \sigma^* \rangle$ above described

is a sequential equilibrium.

Proof sketch. The sequential rationality is easily seen from the above discussion. Consistency can be proved by the assessment sequence $a_n = \langle \mu_n, \sigma_n \rangle$ where:

- σ_n is the totally mixed strategy profile such that before the real deadline of an agent there is probability $1 - \frac{1}{n}$ of performing the action prescribed by σ and the remaining probability $\frac{1}{n}$ is uniformly distributed among the other allowed actions; while at the deadline or after it there is probability $1 - \frac{1}{n^2}$ of performing the action prescribed by σ and the remaining probability $\frac{1}{n^2}$ is uniformly distributed among the other allowed actions.
- μ_n is the system of beliefs obtained applying Bayes rule starting from the same *a priori* probability distribution P_b^0 as in $\bar{\mu}$.

Each assessment a_n is “Bayes consistent” by construction. The convergence of σ_n to σ^* is trivial. As to μ_n , given any arbitrary legal sequence S of actions (such that the bargaining does not end at the end of S and such that s is the agent acting after S), call $P_n^S = \langle \alpha_{n,b_1}^S, \alpha_{n,b_2}^S, \dots, \alpha_{n,b_m}^S \rangle$ the probabilities that agent s assigns to b ’s deadlines after sequence S according to μ_n . Sequence S might contain actions that could be interpreted as being in accordance to the strategies σ^* (i.e. actions that are the actions prescribed by strategies σ^* for some deadline T_{b_i}); be τ the time of the latest such action in S (if there are no such actions, set $\tau = -1$ by convention). Be $t = |S|$. Some calculation shows that, if $t \leq \bar{T}$, then

$$\alpha_{n,b_i}^S = \begin{cases} 0 & \text{if } T_{b_i} \leq \tau \\ \frac{\frac{1}{n^{t-T_{b_i}}} \cdot \alpha_{b_i}^0}{\sum_{T_{b_h} \geq t} \alpha_{b_h}^0 + \sum_{\tau < T_{b_h} \leq t} \frac{1}{n^{t-T_{b_h}}} \cdot \alpha_{b_h}^0} & \text{if } \tau < T_{b_i} \leq t \\ \frac{\alpha_{b_i}^0}{\sum_{T_{b_h} > t} \alpha_{b_h}^0 + \sum_{\tau < T_{b_h} < t} \frac{1}{n^{t-T_{b_h}}} \cdot \alpha_{b_h}^0} & \text{if } t < T_{b_i} \end{cases}$$

Therefore

$$\lim_{n \rightarrow +\infty} \alpha_{n,b_i}^S = \begin{cases} 0 & \text{if } T_{b_i} \leq t \\ \frac{\alpha_{b_i}^0}{\sum_{T_{b_h} \geq t} \alpha_{b_h}^0} & \text{if } t < T_{b_i} \end{cases}$$

Therefore P_n^S converges to the beliefs prescribed by $\bar{\mu}$ in S . Thus μ_n converges to $\bar{\mu}$. \square

4 Unsolvable Bargaining

The non-existence problem is an intrinsic limitation of the protocol. In fact, alternating-offers protocol under uncertain deadlines does not always admit pure strategy sequential equilibria. The sequential equilibrium theory assures the existence of at least one sequential equilibrium in behavioural strategies [8], but the use of behavioural strategy equilibria is not considered fully satisfying [13].

In this section we produce an example of bargaining that does not admit any pure strategy sequential equilibrium. The example does not even admit a *weak sequential equilibrium* [5] (a weaker notion of sequential equilibrium). Basically, an assessment is a weak sequential equilibrium if it is sequentially rational and *weakly consistent* (i.e., consistent on the equilibrium path).

Our example is depicted in Fig. 4. The b ’s deadline can be either at time 2 (buyer b_{early}) or at time 10 (buyer b_{late}). Shown in the figure is the backward induction construction that would have been produced by our method, but this does not lead to a solution, because if agent b ’s real deadline would be 10, she would not offer $e_{\leftarrow s}^1$ at

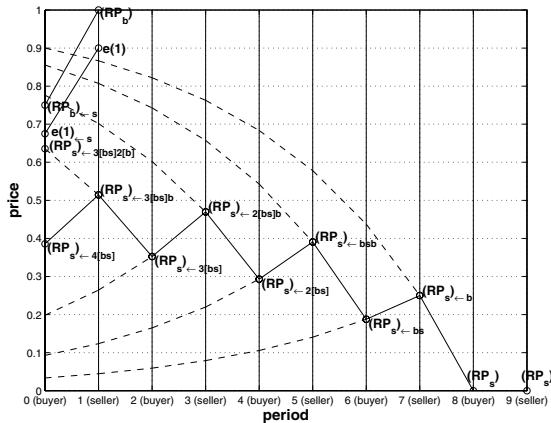

Figure 4. Non-existence of equilibrium with $RP_b = 1$, $RP_s = 0$, $\delta_b = 0.75$, $\delta_s = 0.75$, $\langle T_b = \{2, 10\}, P_b^0 = \{0.9, 0.1\} \rangle$, $T_s = 9$, $\iota(0) = b$

time $t = 0$ but would find more convenient to offer something unacceptable for s in order to offer $x_{\leftarrow 3[bs]}$ at time $t = 2$. In what follows we prove by contradiction that no pure strategy assessment works.

Theorem 4.1 *Alternating-offers bargaining with uncertain deadlines does not always admit a (weak) sequential equilibrium in pure strategies.*

Proof. Consider the bargaining of Fig. 4. By contradiction, be $a^* = \langle \sigma^*, \mu^* \rangle$ a pure strategy weak sequential equilibrium. At any time $t > 2$ the only possible system of beliefs for agent s at the equilibrium prescribes that the deadline of b is 10; therefore, for $t \geq 2$ the equilibrium strategies must be those prescribed by the backward induction construction. At time $t = 1$, instead, the beliefs of s at the equilibrium depend on which are the equilibrium actions of agent b at time $t = 0$. Two cases are possible (i) $\sigma_{b_{early}}^*(0) = \sigma_{b_{late}}^*(0)$ or (ii) $\sigma_{b_{early}}^*(0) \neq \sigma_{b_{late}}^*(0)$. We treat the two cases separately.

(i) If $\sigma_{b_{early}}^*(0) = \sigma_{b_{late}}^*(0)$, then by Bayes rule the beliefs of s at $t = 1$ on the equilibrium path are the initial ones (i.e., $P_b = \{0.9, 0.1\}$). Therefore, if at $t = 0$ agent b acts at the equilibrium, then at $t = 1$ the optimal strategy of agent s is to accept any offer greater than or equal to $e_{\leftarrow s}^1$ and otherwise offer RP_b . Thus, at time $t = 0$ the optimal strategy for b_{early} is to offer $e_{\leftarrow s}^1$; instead, at $t = 0$ the optimal strategy for b_{late} is to offer anything lesser than $e_{\leftarrow s}^1$ in order to be rejected and then, at $t = 2$ offer $x_{\leftarrow 3[bs]}$ that will be accepted. So $\sigma_{b_{early}}^*(0) \neq \sigma_{b_{late}}^*(0)$.

(ii) If $\sigma_{b_{early}}^*(0) \neq \sigma_{b_{late}}^*(0)$ then by Bayes rule the beliefs of s at $t = 1$ on the equilibrium path are: if action $\sigma_{b_{early}}^*(0)$ is observed, then $P_b = \{1, 0\}$; if action $\sigma_{b_{late}}^*(0)$ is observed, then $P_b = \{0, 1\}$. Therefore, if at $t = 0$ agent b acts at the equilibrium, then at $t = 1$ the optimal strategy of agent s is:

- if $\sigma_{b_{early}}^*(0)$ is observed, then accept any offer greater than or equal to $(RP_b)_{\leftarrow s}$ and otherwise offer RP_b ;
- if $\sigma_{b_{late}}^*(0)$ is observed, then accept any offer greater than or equal to $x_{\leftarrow 4[bs]}$ and otherwise offer $x_{\leftarrow 3[bs]b}$.

Thus, at time $t = 0$ the optimal strategy for both b_{early} and b_{late} is to offer $x_{\leftarrow 4[bs]}$; so $\sigma_{b_{early}}^*(0) = \sigma_{b_{late}}^*(0)$.

In conclusion it is neither $\sigma_{b_{early}}^*(0) = \sigma_{b_{late}}^*(0)$ nor $\sigma_{b_{early}}^*(0) \neq \sigma_{b_{late}}^*(0)$. Hence the pure strategy assessment $a^* = \langle \sigma^*, \mu^* \rangle$ is not a weak sequential equilibrium. \square

5 Conclusions

In this work we studied the effect of one-sided uncertain deadlines in the alternating-offers bargaining protocol with agents whose strategies are not self-constrained to any particular set of tactics. Although our study considers only one-sided uncertainty, the obtained results are particularly significant: (1) the equilibrium strategies can be found, when they exist, employing a simple backward procedure; (2) alternating-offers protocol does not always admit equilibrium in pure strategies.

The first result states that, for a wide range of bargaining parameters, the determination of equilibrium strategies of fully rational agents with one-sided uncertain deadlines can be simply tackled and the equilibrium prescribes that agreement is reached almost always at time 1.

The second result is more critical. The possible non-existence of a pure strategy equilibrium limits the possible employment of alternating-offers in real settings. Therefore the protocol should be modified (for example with the strategic delay option), or employing behavioural strategies.

In future work we plan to analyze alternating-offers with strategic delay, as well as carry on the study of incomplete information alternating-offers with two-sided uncertainty over deadlines, discount factors, and reservation prices.

A logic-based framework to compute Pareto agreements in one-shot bilateral negotiation

Azzurra Ragone and **Tommaso Di Noia** and **Eugenio Di Sciascio¹** and **Francesco M. Donini²**

Abstract. We propose a logic-based approach to automated one-shot multi-issue bilateral negotiation. We use logic in two ways: (1) a logic theory to represent relations among issues – *e.g.*, logical implication – in contrast with approaches that describe issues as uncorrelated with each other; (2) utilities over formulas to represent agents having preferences over different bundles of issues. In this case, the utility assigned to a bundle is not necessarily the sum of utilities assigned to single elements in the bundle itself. We illustrate the theoretical framework and the one-shot negotiation protocol, which makes use of a facilitator to compute some particular Pareto-efficient outcomes. We prove the computational adequacy of our method by studying the complexity of the problem of finding Pareto-efficient solutions in a propositional logic setting.

1 Introduction

Many recent research efforts have been focused on automated negotiation among agents in various contexts, including e-marketplaces, resource allocation settings, online auctions, supply chain management and, generally speaking, e-business processes. Basically, two different approaches to automated negotiation exist: *centralised* and *distributed* ones. In the first ones, agents elicit their preferences and then a facilitator, or some central entity, selects the most suitable deal based on them. In the latter ones, agents negotiate through various negotiation steps reaching the final deal by means of intermediate deals, without any external help [3]. Although the main target of an agent is reaching a satisfying agreement, knowing if it is Pareto-efficient³ is a matter that cannot be left out. Furthermore it is fundamental to assess *how hard* it is to find a Pareto-efficient agreement, and if such an agreement actually exists. Recently, there has been a growing interest toward multi-issue negotiation, also motivated by the idea that richer and expressive descriptions of demand and supply can boost e-marketplaces (*see e.g.*, [21] for a reasonable set of motivations) but –to the best of our knowledge– also in recent literature, issues are still described as uncorrelated terms, without considering any underlying semantics, which could instead be exploited –among other reasons– to perform a pre-selection of candidate deals. Moreover, agents can have different preferences over different bundles of issues, and utility assigned to each bundle is not merely the sum of utilities assigned to a single resource in that bundle. When multiple issues are involved

in the negotiation process, it is usually the case that the issues are not completely independent; sometimes an issue implies another one (for instance, *SatelliteAlarm* implies *AlarmSystem* in an automotive domain), sometimes their relation is more complex (as in bundles of optionals). We propose to fill this lack of expressiveness by relating with each other the issues involved in the process via a logical theory. In particular, here we present a framework for automated multi-issue bilateral negotiation where logic is exploited both to represent existing relations between issues and in utilities over formulas. The rest of the paper is structured as follows: next section presents a brief summary of the huge literature on bilateral negotiation. Section 3 presents the reference scenario and assumptions we make. In Section 4 the Multi-issue Bilateral Negotiation problem (MBN) is formally defined based on a logic framework. We define utility functions over a set of logic formulas representing preferences on bundles of interrelated issues. In Section 5, we prove the computational adequacy of our method by studying the complexity of the problem of finding Pareto-efficient solutions in a propositional logic setting. The bargaining process is detailed in Section 6 and an illustrative example is given in Section 7. Conclusion and future work close the paper.

2 Related Work

Automated bilateral negotiation among agents is a challenging research topic, widely investigated, both in artificial intelligence (AI) and in microeconomics research communities. Several definitions have been proposed in the literature. Rubinstein [19] defined the *Bargaining Problem* as the situation in which "two individuals have before them several possible contractual agreements. Both have interests in reaching agreement but their interests are not entirely identical. What 'will be' the agreed contract, assuming that both parties behave rationally?" Also Nash [13] defined: "a TWO-PERSON bargaining situation involves two individuals who have the opportunity to collaborate for mutual benefit in more than one way." The negotiation is *distributive*, also called Win-Lose negotiation [18], when a single item is involved and bargainers have opposite interests: if one gets more the other part gets less. If several items are negotiated simultaneously the negotiation is called *integrative* (Win-Win negotiation), each issue has a different utility (or score) for each player and differently from the distributive case, the players are not strict competitors: they can cooperate and if one gets more, the other player does not necessarily get less. Finally it is possible to have *many issues* to be negotiated among *many parties*; this is a more complex setting, because of the interplay among shifting coalitions: parties can join and act against other parties involved [17]. In game theory, the bargaining problem has been modeled either as *cooperative* or

² University of Tuscia, Italy, email: donini@unitus.it

³ An agreement is Pareto-efficient if there is no other agreement that will make at least one participant better off without making at least one other participant worse off. If a negotiation outcome is not Pareto-efficient, then there is another outcome that will make at least one participant happier while keeping everyone else at least as happy [7].

non-cooperative games [6]. The first approach, given a set of axioms and a coalition, determines how to split the surplus among the participants; so the aim is finding a solution given a set of possible outcomes. Instead, in non-cooperative games there are a well-defined set of rules and strategies; in such a game it is possible to define an *equilibrium* strategy, which ensures the rational outcomes of a game: no player could benefit by unilaterally deviating from her strategy, given the other players follow their own strategies [9]. On the other hand, AI-oriented research has been more focused on automated negotiation among agents and on designing high-level protocols for agent interaction [10]. Agents can play different roles: act on behalf of buyer or seller, but also play the role of a mediator or facilitator. Agents are considered individually rational: they will never accept a deal which involves a loss, *i.e.*, a disadvantageous deal [5]. Different approaches exist to automate negotiation. Many of these consider self-interested agents negotiate over a set of resources in order to obtain an optimal allocation of such resources [5, 4, 3]. Endriss et al. [5] propose an optimal resource allocation in two different negotiation scenarios: one, with money transfer, results in an allocation with maximal social welfare; the second is a money-free framework which results in a Pareto outcome. In [3] agents negotiate over small bundles of resources and a mechanism of resource allocation is investigated, which maximizes the social welfare by means of a sequence of deals involving at most k items each. Both papers [5, 3] extend the framework proposed in [20] concerning negotiation for (re)allocating tasks among agents. We share with [22] the definition of agreement as a model for a set of formulas from both agents. However, in [22] only multiple-rounds protocols are studied, and the approach taken leaves the burden to reach an agreement to the agents themselves, although they can follow a protocol. Results do not take preferences into account, so that it is not possible to guarantee the reached agreement is Pareto-efficient. Our approach, instead, aims at giving an *automated* support to negotiating agents to reach, in one shot, Pareto agreements. In [16] an initial propositional logic framework was presented. Here we extend and generalize the approach, study the computational complexity of the problem showing how to compute a solution of the problem through combinatorial optimization techniques, and prove the computational adequacy of our method.

3 Scenario and assumptions

We illustrate our logic-based negotiation framework in accordance with [8], which defines: the *Space of possible deals*, that is the set of potential agreements; the *Negotiation Protocol*, the set of rules that an agent follows in order to reach an agreement; the *Negotiation Strategy* that an agent adopts given the set of rules specified in the negotiation protocol. In our framework the *Space of possible deals* is computed with the aid of a logic language. The *Negotiation Protocol* we adopt here is a *one-shot* protocol. We refer to *Single-shot* bargaining [17], also called *ultimatum game*, where one player proposes a deal and the other player may only accept or refuse it [2]. Therefore we focus our initial investigation on a one-shot protocol, although several other negotiation protocols exist, like *e.g.*, *alternate-offers* protocol [19] or *monotonic concession* protocol [8]. In some negotiations the parties cannot reach an agreement without some external help, that is without the intervention of a third-party. The third-party can be defined as a *facilitator*, *mediator* or *arbitrator*, depending on her influence and power in the negotiation, that is depending on her role: the more the role is evaluative, more appropriate is to define the third-party intervention as arbitration rather than facilitation or

mediation. We adopt in this paper the centralized approach, so we hypothesize the presence of an electronic facilitator, who may automatically explore the negotiation space and discover Pareto-efficient agreements to be proposed to both parties. The presence of a facilitator and the one-shot protocol is an incentive for the two parties to reveal the true preferences, because they can trust in the facilitator and they have a single possibility to reach the agreement with that counterpart. Usually bargainers may not want to disclose their preferences or utility function to the other party, but they can be ready to reveal these information to a trusted – automated – facilitator helping negotiating parties to achieve efficient and equitable outcomes [18, p.311]. Therefore we propose a one-shot protocol with the intervention of a *facilitator* with a proactive behavior: it suggests to each participant the solution which is Pareto-efficient. For what concerns *strategy*, the players can choose to accept or refuse the solution proposed by facilitator; they refuse if they think possible to reach a better agreement looking for another partner, or another shot, or for a different set of bidding rules. Here we do not consider the influence of the *outside options* in the negotiation strategy [12]. Obviously, in e-marketplaces, both buyer and seller know that the opponent is probably not the only partner available for negotiating with, and that there might be more than one single e-marketplace.

4 Logic-based Multi Issue Bilateral Negotiation

We use propositional formulas to model the buyer's demand and the seller's supply. Relations among issues are represented by a set \mathcal{T} – for Theory – of propositional formulas. We point out that each of the following definitions can be reformulated and still keep its validity within First Order Logic as long as only closed formulas are used.

Given a set $\mathcal{A} \doteq \{A_1, \dots, A_n\}$ of propositional atoms (Attributes), we denote with $\mathcal{L}_{\mathcal{A}}$ the set of propositional formulas (denoted by greek letters β, σ, \dots) built from \mathcal{A} using $\wedge, \vee, \neg, \Rightarrow$. A *propositional theory* is a finite subset of $\mathcal{L}_{\mathcal{A}}$, which we denote by $\mathcal{T} \subset \mathcal{L}_{\mathcal{A}}$. An interpretation m assigns values *true*, *false* to elements of \mathcal{A} , and we extend m to $\mathcal{L}_{\mathcal{A}}$ according to truth tables for connectives. We denote with $m \models \beta$ the fact that m assigns *true* to $\beta \in \mathcal{L}_{\mathcal{A}}$. A *model* of \mathcal{T} is an interpretation m assigning *true* to all formulas of \mathcal{T} , written $m \models \mathcal{T}$. A theory is *satisfiable* if it has a model. \mathcal{T} logically implies a formula φ , denoted by $\mathcal{T} \models \varphi$ iff φ is true in all models of \mathcal{T} . We denote with $\mathcal{M}_{\mathcal{T}} = \{m_1, \dots, m_n\}$, the set of all models for \mathcal{T} , and omit the subscript when no confusion arises.

Usually, in a bilateral negotiation the issues within both the buyer's request and the seller's offer can be split into *strict requirements* and *preferences*. The former are constraints the buyer and the seller want to be necessarily satisfied to accept the final agreement – this is what we call *demand/supply* – while the latter are issues they may accept to negotiate on – this is what we call *preferences*.

Anticipating our illustrative example, let us consider an automotive domain and suppose the buyer is asking for a sedan with leather seats, preferably red with car CD reader. She strictly wants a sedan with leather seats and expresses her preferences (she is willing to negotiate on) on the color red and the car CD reader in order to reach an agreement with the seller.

Definition 1 (Demand, Supply, Agreement) Let \mathcal{A} be a set of propositional atoms, and $\mathcal{T} \subset \mathcal{L}_{\mathcal{A}}$.

- a buyer's demand is a propositional formula β (for Buyer) in $\mathcal{L}_{\mathcal{A}}$ such that $\mathcal{T} \cup \{\beta\}$ is satisfiable.

- a seller's supply is a propositional formula σ (for Seller) in $\mathcal{L}_\mathcal{A}$ such that $\mathcal{T} \cup \{\sigma\}$ is satisfiable.
- m is a possible deal between β and σ iff $m \models \mathcal{T} \cup \{\sigma, \beta\}$, that is, m is a model for \mathcal{T} , σ , and β . We also call m an agreement.

Intuitively, σ and β stand for the minimal requirements that each partner accepts for the negotiation. On the other hand, if seller and buyer have settled strict attributes that are in conflict with each other, that is $\mathcal{M}_{\mathcal{T} \cup \{\sigma, \beta\}} = \emptyset$, the negotiation ends immediately because, *sic stantibus rebus*, it is impossible to reach an agreement. If the participants are willing to avoid the *conflict deal* [8], and continue the negotiation, it will be necessary they revise their strict requirements.

In the negotiation process both the buyer and the seller set some preferences on attributes, or combination of attributes, they want to negotiate on. The utility function is usually defined based on these attributes. We start defining buyer's and seller's preferences and the associated utilities. Obviously, in a negotiation process there are two utility functions: u_β for the buyer, and u_σ for the seller.

Definition 2 (Preferences) Let \mathcal{A} be a set of propositional atoms, and $\mathcal{T} \subset \mathcal{L}_\mathcal{A}$.

- the buyer's negotiation preferences $\mathcal{B} \doteq \{\beta_1, \dots, \beta_k\}$ are a set of propositional formulas in $\mathcal{L}_\mathcal{A}$, each of them representing the subject of a buyer's preference, and a utility function $u_\beta : \mathcal{B} \rightarrow \mathbb{R}^+$ assigning a utility to each formula, such that $\sum_i u_\beta(\beta_i) = 1$.
- analogously, the seller's negotiation preferences $\mathcal{S} \doteq \{\sigma_1, \dots, \sigma_h\}$ are a set of propositional formulas in $\mathcal{L}_\mathcal{A}$, and a utility function $u_\sigma : \mathcal{S} \rightarrow \mathbb{R}^+$ such that $\sum_j u_\sigma(\sigma_j) = 1$.

Buyer's/seller's preferences are used to evaluate how good is a possible agreement and to select the best one. As usual, both agents' utilities are normalized to 1 to eliminate outliers, and make them comparable. Since we assumed that utilities are additive, the *global utility* is just a sum of the utilities of preferences satisfied in the agreement. To lower the number of symbols, we use u_β and u_σ also to denote the functions computing the global utility of agents over an agreement.

Definition 3 (Global Utilities) Let \mathcal{B} and \mathcal{S} be respectively the buyer's and seller's preferences, and \mathcal{M} be their agreements set. The global utility of an agreement $m \in \mathcal{M}$ for a buyer and a seller, respectively, are defined as:

$$u_\beta(m) \doteq \sum_i u_\beta(\beta_i) \mid m \models \beta_i \}, \quad u_\sigma(m) \doteq \sum_j u_\sigma(\sigma_j) \mid m \models \sigma_j \}$$

where $\sum \{\dots\}$ stands for the sum of all elements in the set.

Based on the previous definitions it is possible now to define a Multi-issue Bilateral Negotiation problem. The only other elements we still need to introduce are the *disagreement thresholds*, also called disagreement payoffs, or reservation values, t_β, t_σ , that are the minimum utility that each agent requires to pursue a deal. They may incorporate an agent's attitude toward concluding the transaction, but also overhead costs involved in the transaction itself, e.g., fixed taxes.

Definition 4 (MBN) Given a demand β and a set of buyer's preferences \mathcal{B} with utility function u_β , a supply σ and a set of seller's preferences \mathcal{S} with utility function u_σ , a propositional theory \mathcal{T} and two disagreement thresholds t_β, t_σ , a **Multi-issue Bilateral Negotiation problem (MBN)** is finding a model m (agreement) such that $m \models \mathcal{T} \cup \{\sigma, \beta\}$ and both $u_\beta(m) \geq t_\beta$ and $u_\sigma(m) \geq t_\sigma$.

Observe that not every agreement m is a solution of an MBN, if either $u_\sigma(m) < t_\sigma$ or $u_\beta(m) < t_\beta$. Such an agreement represents

a deal which, although satisfying strict requirements, it is not worth the transaction effort.

Obviously among all possible agreements that we can compute given a theory \mathcal{T} , we are interested in agreements that are Pareto-efficient, so we define:

Definition 5 (Pareto) A Pareto agreement for an MBN is an agreement m , such that for no agreement m' both $u_\beta(m') \geq u_\beta(m)$ and $u_\sigma(m') \geq u_\sigma(m)$, with at least one strict inequality.

We can also define the search of particular agreements for an MBN, maximizing the welfare $u_\beta + u_\sigma$, or maximizing the product $u_\beta \cdot u_\sigma$

Definition 6 Given an MBN, we define the following problems:

- MAX-SUM-MBN is the problem of finding an agreement m for which $u_\sigma(m) + u_\beta(m)$ is maximal
- MAX-PROD-MBN is the problem of finding an agreement m for which $u_\sigma(m) \cdot u_\beta(m)$ is maximal

Clearly, every solution for MAX-SUM-MBN and MAX-PROD-MBN is also a Pareto agreement, but not vice versa.

5 Computational issues

In this section we start by proving membership in NPO [1] of MAX-SUM-MBN and MAX-PROD-MBN. Then, we outline how to compute solutions for MAX-SUM-MBN and MAX-PROD-MBN through general combinatorial optimization techniques. Finally, we prove NPO-hardness of both problems, that is, tailored algorithms yielding solutions approximated within a polynomial bound from the optimum are unlikely to exist.

Theorem 1 Given an instance of MBN, deciding whether it has a solution can be checked in nondeterministic polynomial-time, even if a lower bound $k > 0$ is given on either the sum or the product of u_σ, u_β .

Proof. Simply guess an interpretation m , and check in polynomial time that it is a model of $\mathcal{T} \cup \{\sigma, \beta\}$ and that $u_\sigma(m) \geq t_\sigma, u_\beta(m) \geq t_\beta$. If a lower bound k is given, also checking that either $u_\sigma(m) + u_\beta(m) \geq k$ or $u_\sigma(m) \cdot u_\beta(m) \geq k$ can be done in polynomial time. \square

Hence both MAX-SUM-MBN and MAX-PROD-MBN belong to NPO. We now outline how an actual solution to both problems can be found by Integer Linear Programming (ILP).

Regarding MAX-SUM-MBN, proceed as follows. First of all, let $\{B_1, \dots, B_k, S_1, \dots, S_h\}$ be $k+h$ new propositional atoms, and let $\mathcal{T}' = \mathcal{T} \cup \{B_i \equiv \beta_i \mid i = 1, \dots, k\} \cup \{S_j \equiv \sigma_j \mid j = 1, \dots, h\}$ – that is, every preference in $\mathcal{B} \cup \mathcal{S}$ is equivalent to a new atom in \mathcal{T}' . Then, by using standard transformations in clausal form [11] obtain a set of clauses \mathcal{T}'' which is satisfiable iff $\mathcal{T}' \cup \{\sigma, \beta\}$ does. Then, use a well-known encoding of clauses into linear disequations (e.g., [14, p.314]) so that every solution of the disequations identifies a model of \mathcal{T}'' . Let $\{b_1, \dots, b_k\}$ the (0,1)-variables one-one with $\{B_1, \dots, B_k\}$ and similarly $\{s_1, \dots, s_h\}$. Then, maximize the linear function

$$\sum_{i=1}^k b_i u_\beta(\beta_i) + \sum_{j=1}^h s_j u_\sigma(\sigma_j)$$

Regarding MAX-PROD-MBN, let $\{B_{ij} \mid i = 1, \dots, k, j = 1, \dots, h\}$ be a set of $k \cdot h$ new propositional atoms. Let $\mathcal{T}' = \mathcal{T} \cup \{B_{ij} \equiv$

$\beta_i \wedge \sigma_j \mid i = 1 \dots, k \ j = 1, \dots, h\}$ – that is, this time every pair of conjoined preferences is equivalent to a new atom. Then, transform \mathcal{T}' into a set of clauses \mathcal{T}'' , code clauses as disequations and maximize

$$\sum_{i=1}^k \sum_{j=1}^h b_{ij} u_\beta(\beta_i) u_\sigma(\sigma_j)$$

Hence, also MAX-PROD-MBN can be solved by ILP as a problem whose size is at most quadratic in the size of the original MAX-PROD-MBN.

When an optimization problem is NP-complete, one can ask whether there exists an algorithm approximating the optimum. For instance, it is known that the following problem MAX-WEIGHTED-SAT is not approximable [1] within any polynomial.

Definition 7 MAX-WEIGHTED-SAT is the following NPO-complete problem: given set of atoms \mathcal{A} , a propositional formula $\varphi \in \mathcal{L}_\mathcal{A}$ and a weight function $w : \mathcal{A} \rightarrow \mathbb{N}$, find a truth assignment satisfying φ such that the sum of the weights of true variables is maximum.

If MAX-SUM-MBN or MAX-PROD-MBN admitted some approximation algorithm, using general ILP for solving them might be an overshoot. However, the theorem below proves that this is not the case, by giving an L-reduction [1] of MAX-WEIGHTED-SAT to both problems.

Theorem 2 MAX-SUM-MBN and MAX-PROD-MBN are NPO-complete problems, even if \mathcal{T} is in 3CNF and both \mathcal{B} and \mathcal{S} are sets of positive literals.

Proof. Let $W = \langle \varphi, w \rangle$ be an instance of MAX-WEIGHTED-SAT, with φ in 3CNF. Define an instance M_+ of MAX-SUM-MBN as follows. Let $\mathcal{T} = \varphi$, $\mathcal{B} = \{A_1, \dots, A_k\}$ with any $k = 1, \dots, n - 1$, and let $\mathcal{S} = \{A_{k+1}, \dots, A_n\}$. Moreover, let $u_\beta(A_i) = w(A_i)$ for $i = 1, \dots, k$ and $u_\sigma(A_j) = w(A_j)$ for $j = k + 1, \dots, n$. Finally, let $t_\beta = t_\sigma = 0$. Clearly, every solution for W is also a solution for M_+ , and for every model m , the value of the objective function $u_\beta(m) + u_\sigma(m)$ is the same as the one for W . Hence, the above is an L-reduction with $\alpha = \beta = 1$.

Similarly, define an instance M_\times of MAX-PROD-MBN as follows. Let $\mathcal{T} = \varphi$, $\mathcal{B} = \mathcal{A}$, $\mathcal{S} = \{A_0\}$ where A_0 is a new atom not in \mathcal{A} . Moreover, let $u_\beta(A_i) = w(A_i)$ for $i = 1, \dots, n$ and $u_\sigma(A_0) = 1$. Finally, let $t_\beta = t_\sigma = 0$. Also in this case, every solution for W satisfies also M_\times , and for every model m the objective function $u_\beta(m) \cdot u_\sigma(m)$ of M_\times has the same value as W 's one. Hence, also the above reduction is an L-reduction with $\alpha = \beta = 1$. \square

The proof of the above theorem highlights the fact that a source of complexity for MAX-SUM-MBN and MAX-PROD-MBN comes from the inherent conflicts between the preferences of a single agent.

6 The bargaining process

We now present the bargaining process, which covers the following phases:

Preliminary Phase. The buyer defines β and \mathcal{B} , as well as the threshold t_β , and the seller defines σ , \mathcal{S} and t_σ . In this paper we are not interested in how to compute these values; we assume they are determined in advance by means of either direct assignment methods (Ordering, Simple Assessing or Ratio Comparison) or pairwise comparison methods (like AHP and Geometric Mean) [15]. Both agents inform the facilitator about these specifications and the theory \mathcal{T} they refer to.

Initial phase. The facilitator computes $\mathcal{M}_{\mathcal{T} \cup \{\sigma, \beta\}}$. If $\mathcal{M}_{\mathcal{T} \cup \{\sigma, \beta\}} = \emptyset$ the facilitator requests the buyer and the seller to refine –respectively– their β and σ and recomputes $\mathcal{M}_{\mathcal{T} \cup \{\sigma, \beta\}}$. Once/If buyer and seller solve any conflicts about reservation requirements, the negotiation can start.

Negotiation-Core phase. The facilitator proposes one of the two agreements mutually beneficial for both the buyer and the seller: an agreement which maximizes the social welfare and one which maximizes the product of utilities. If either one of the participants rejects it, then the facilitator proposes the second one. Since both of the agreements are Pareto-efficient, the order they are proposed to the participants is not relevant. From this point on, it is a *take-it-or-leave-it* offer, because the participants can either accept or reject it [7]. Notice that since both the proposed deals are Pareto-efficient, although the participants can move from the proposed deals, they might end in a less (no-Pareto) efficient agreement. Once the facilitator computes the space of all possible deals $\mathcal{M}_{\mathcal{T} \cup \{\sigma, \beta\}}$, it evaluates the utility of each model $m \in \mathcal{M}_{\mathcal{T} \cup \{\sigma, \beta\}}$, both for the buyer – $u_\beta(m)$ – and for the supplier – $u_\sigma(m)$.

Among all possible models, it chooses \bar{m} maximizing the product $u_\beta(m) * u_\sigma(m)$ and \underline{m} maximizing the sum. The facilitator proposes such solutions to the opponents. If one of the opponents, or both of them, refuse the deals proposed by the facilitator, they reach a *conflict deal* and then they will likely look for other partners in the e-marketplace.

7 An illustrative example

In the following we illustrate our logic based approach to automate negotiation process with the aid of a simple example, which refers to an e-marketplace related to the automotive domain. Buyer and seller express their demand/supply and preferences. According to the previous definitions, a simple instance of an MBN can be formalized as follows:

$$\begin{aligned} \beta &= \text{StationWagon} \wedge \text{AirConditioning} \wedge \text{DriverAirbag} \wedge \text{SatelliteAlarm} \\ \beta_1 &= \neg \text{ExternalColorRed} \wedge \text{ExternalColorBlack} \wedge \text{InteriorColorBlack} \\ \beta_2 &= \text{Gasoline} \vee \text{Diesel} \\ u_\beta(\beta_1) &= 0.6 \\ u_\beta(\beta_2) &= 0.4 \\ t_\beta &= 0.3 \\ \\ \sigma &= \text{StationWagon} \wedge \text{Diesel} \\ \sigma_1 &= (\text{ExternalColorBlack} \vee \text{ExternalColorBlue}) \wedge (\text{InteriorColorGrey} \vee \text{InteriorColorBlack}) \\ \sigma_2 &= \text{DriverAirbag} \wedge \neg \text{PassengerAirbag} \\ \sigma_3 &= \text{AlarmSystem} \wedge \neg \text{SatelliteAlarm} \\ u_\sigma(\sigma_1) &= 0.2 \\ u_\sigma(\sigma_2) &= 0.3 \\ u_\sigma(\sigma_3) &= 0.5 \\ t_\sigma &= 0.2 \end{aligned}$$

In this example the thresholds are set considering some transaction costs like *e.g.*, operating costs for the seller and cost of taxes for the buyer.

$$\mathcal{T} = \left\{ \begin{array}{l} \text{ExternalColorBlue} \Rightarrow \neg \text{ExternalColorBlack} \\ \text{ExternalColorBlue} \Rightarrow \neg \text{ExternalColorRed} \\ \text{ExternalColorBlack} \Rightarrow \neg \text{ExternalColorRed} \\ \text{InteriorColorBlack} \Rightarrow \neg \text{InteriorColorGrey} \\ \text{Gasoline} \Rightarrow \neg \text{Diesel} \\ \text{SatelliteAlarm} \Rightarrow \text{AlarmSystem} \\ \text{PassengerAirbag} \Rightarrow \text{FrontAirbag} \\ \text{DriverAirbag} \Rightarrow \text{FrontAirbag} \end{array} \right.$$

Table 1. $\mathcal{M}_{\mathcal{T} \cup \{\sigma, \beta\}}$ and the utility associated to each model. In bold style the values chosen by the facilitator maximizing the sum and the product.

Table 1 shows all the models in the set $\mathcal{M}_{\mathcal{T} \cup \{\sigma, \beta\}}$. As it is shown in Table 1, after computing $u_\beta(m)$ and $u_\sigma(m)$ (rows 18 and 23) the sum and the product of the two utilities are calculated. The facilitator proposes to the participants (buyer and seller) the deal that maximizes the product and the sum of utilities (in this case the same). In the final agreement we have the following propositional atoms set true:

$m = \overline{m} = \text{StationWagon, AirConditioning, DriverAirbag, SatelliteAlarm, Diesel, AlarmSystem, FrontAirbag, ExternalColorBlack, InteriorColorBlack}$

where bold style atoms highlight strict attributes, while the others are preferences. The utilities related to \overline{m} are:

$$\begin{aligned} u_\beta(\overline{m}) &= u_\beta(\beta_1) + u_\beta(\beta_2) = 0.6 + 0.4 = 1 \\ u_\sigma(\overline{m}) &= u_\sigma(\sigma_1) + u_\sigma(\sigma_2) = 0.2 + 0.3 = 0.5 \end{aligned}$$

while product and sum are:

$$\begin{aligned} u_\beta(\overline{m}) * u_\sigma(\overline{m}) &= 1 * 0.5 = 0.5 \\ u_\beta(\overline{m}) + u_\sigma(\overline{m}) &= 1 + 0.5 = 1.5 \end{aligned}$$

8 Conclusion and Future Work

In this paper we proposed a logic based approach to automate multi issue bilateral negotiation (MBN), defining a protocol which leads to a Pareto-efficient deal. The relations among issues are represented through a logic theory \mathcal{T} and preferences are elicited by assigning utility to formulas, and then considering bundles of interrelated issues. Computational issues were also investigated: we proved that MAX-SUM-MBN and MAX-PROD-MBN are NPO-complete problems. In the near future, we plan to extend the approach using Description Logics, to cope with greater expressiveness in demand/supply descriptions. We are also investigating other negotiation protocols –also different from one-shot ones– still suitable for e-commerce applications. A prototype is also being implemented to validate the approach through large scale experiments.

Towards ACL semantics based on commitments and penalties

Leila Amgoud and Florence Dupin de Saint-Cyr¹

Abstract.

The importance of defining a standard framework for agent communication languages (ACL) with a simple, clear, and a verifiable semantics has been widely recognized.

This paper proposes a *logic-based* semantics which is *social* in nature. The basic idea is to associate with each speech act a meaning in terms of the *commitment* induced by that speech act, and the *penalty* to be paid in case that commitment is violated. A *violation criterion* based on the existence of arguments is then defined per speech act. Moreover, we show that the proposed semantics satisfies some key properties that ensure the approach is well-founded. The logical setting makes the semantics verifiable.

1 Introduction

When building multi-agent systems, we take for granted the fact that agents which make up the system will need to engage in the different types of dialogues identified by Walton and Krabbe in [11], using a communication language (ACL). The definition of an ACL from the syntactic point of view (the different *speech acts*² that agents can perform during a dialogue) poses no problems. The situation is different when semantics is taken into account. Given that agents in a multi-agent system may be independently designed by different programmers, a clear understanding of semantics is essential. Indeed, any speech act should have a *unique interpretation*. Moreover, it should be *verifiable*, i.e. it should be possible to check whether a system conforms to a particular ACL or not [13]. Although a number of agent communication languages have been developed, obtaining a suitable formal semantics for ACLs which satisfies the above objective remains one of the greatest challenges of multi-agent theory.

Our aim is to define a semantics which prevents the shortcomings of existing approaches while keeping their benefits. The basic idea behind our semantics is that each speech act has a goal. For instance, behind a question, one expects an answer. Hence, during a dialogue, as soon as a speech act is uttered, a kind of *commitment* for achieving its goal is created. In the case of a question, by uttering such a speech act, a commitment for answering is created (here for the hearer). Note that this does not mean at all that the hearer should necessarily answer.

The new semantics is grounded on a computational logic framework, thus allowing automatic verification of compliance by means of proof procedures. More precisely, the semantics associates with each speech act a meaning in terms of the *commitment* induced by it, and a *penalty* to be paid in case that commitment is violated. A *vi-*

lation criterion based on the existence of arguments is then defined per speech act.

From a *syntactic* point of view, utterances are stored in *commitment stores* as in [7]. Each agent is supposed to be equipped with a commitment store visible to all agents.

Note that the aim of this paper is not to propose a dialogue protocol whose role is to ensure coherent dialogues, etc. However, the protocol of a dialogue system that uses our semantics should at least enforce agents to minimize their violation costs. The definition of such protocol is beyond the scope of this paper.

This paper is organized as follows: section 2 introduces the logical language used throughout the paper. Section 3 defines the new semantics. Some logical properties are presented in section 4, and an example is given in section 5. Section 6 compares our semantics with existing approaches.

2 The logical language

Throughout the paper, we consider a *propositional language* \mathcal{L} . \vdash denotes classical inference and \equiv logical equivalence. A knowledge base Σ is a set of formulas of \mathcal{L} . *Arguments* can be built from any knowledge base Σ :

Definition 1 (Argument) An argument is a pair (S, c) where c is a formula of \mathcal{L} and $S \subseteq \Sigma$ such that:

1. S is consistent,
2. $S \vdash c$,
3. S is minimal for set inclusion among the sets satisfying 1) and 2).

S is the support of the argument and c its conclusion. $\text{Arg}(\Sigma)$ is the set of all the arguments that can be built from Σ .

Given that a knowledge base Σ may be inconsistent, arguments may be conflicting too. In what follows we will use the “undercut” relation which is the most suitable in our case.

Definition 2 (Undercut) Let $A_1 = (H_1, c_1)$, $A_2 = (H_2, c_2) \in \text{Arg}(\Sigma)$. A_1 undercuts A_2 if $\exists h'_2 \in H_2$ such that $c_1 \equiv \neg h'_2$.

Let $\mathcal{A} = \{ag_1, \dots, ag_n\}$ be the set of *agents* involved in the system. Each agent is assumed to have a *role* allowing it to have the control over a subset of formulas in \mathcal{L} (Role: $\mathcal{A} \mapsto 2^{\mathcal{L}}$). Roles are supposed to be visible to all agents. Thus they are not private.

A communication language is based on a set of *speech acts*. Let \mathcal{S} denote that set. From \mathcal{S} and \mathcal{L} , different moves can be built.

Definition 3 (Move) If $a \in \mathcal{S}$ and either $x \in \mathcal{L}$ with $x \not\vdash \perp$, or $x \in \text{Arg}(\mathcal{L})$ then $a:x$ is a move.

¹ IRIT - CNRS 118, route de Narbonne 31062 Toulouse Cedex 9, France
 amgoud, bannay@irit.fr

² The speech acts are also called *illocutionary acts* or *performatives*.

For a given move $a : x$, the function **Act** returns the speech act ($\text{Act}(a : x) = a$), and the function **Content** returns the content of the move ($\text{Content}(a : x) = x$). Let \mathcal{M} denote the set of all the possible moves that can be built from S and \mathcal{L} .

For example, the move **Question**: x (with x meaning that the sky is blue) is uttered to ask whether the sky is blue or not.

3 Semantics

The basic idea behind our semantics is to associate with each speech act a meaning in terms of the *commitment* induced by that speech act, and a *penalty* to be paid in case that commitment is violated. For each speech act, we define a *criterion* precising when the corresponding commitment is violated. These criteria are all based on the existence of arguments. The various moves uttered during a dialogue are stored in *commitment stores* which are visible to all agents.

3.1 Speech acts

We consider the following set of basic speech acts that are used in the literature for modeling the different types of dialogues identified by Walton and Krabbe in [11]:

$$\mathcal{S} = \{\text{Assert}, \text{Argue}, \text{Declare}, \text{Question}, \text{Request}, \text{Challenge}, \text{Promise}\}.$$

- **Assert** and **Argue** allow an agent to inform another agent about the state of the world. These acts are *assertive* according to the classification of Searle [9]. **Assert**: x and **Argue**: x differ in the syntactic form of x . In the case of **Assert**: x , x is a proposition ($x \in \mathcal{L}$) like “the weather is beautiful” or “it is my intention to hang a mirror”. However, in **Argue**: x , x is an argument ($x \in \text{Arg}(\mathcal{L})$).

- **Declare**: x , with $x \in \mathcal{L}$, is a move that brings about a state of affairs that makes its content x true. It is a *declarative* act like “the auction is open” or “John and Mary are husband and wife”.

- **Question**, **Request** and **Challenge** are *directive* acts that incite the agent who receives them to give an answer. The moves **Question**: x , **Request**: x and **Challenge**: x are all about the same kind of information, x is a *proposition* in the three cases ($x \in \mathcal{L}$). In **Question**: x , the agent asks for the truth value of x . In **Request**: x , the agent asks another agent to alter the value of x to true. **Request**: x has then a more imperative character than **Question**: x which does not ask the other agent to act on the world but only to give some information. A **Request** is used when an agent cannot, or prefers not to, achieve one of its goals alone. For instance, if ag_2 utters **Request**: $ag_2.\text{is_paid}$ then it means that ag_2 asks to be paid. By doing a **Challenge**: x move an agent asks for a reason/argument in favor of the conclusion x .

- A **Promise** move commits the agent to some future course of action. It is a *commissive* act according to Searle [9]. The expression **Promise**: x means that the agent is committed to make x true in the future, with $x \in \mathcal{L}$. For example, if ag_1 utters **Promise**: $ag_2.\text{is_paid}$, it means that ag_1 commits itself to ensure that ag_2 is paid in the future.

- In addition to the above speech acts, we will consider another act called **Retract** which does not belong to the different categories of speech acts defined by Searle. It can be seen as a meta-level act allowing agents to withdraw commitments already made. Allowing such a move makes it possible for agents to have a kind of non-monotonic behavior (i.e., to change their points of view, to revise their beliefs, etc.) without being sanctioned. Syntactically,

Retract: m is a move with $m \in \mathcal{M}$ being itself a possible move.

3.2 Commitments

In the scientific literature, one can find proposals where the semantics of an ACL is defined in terms of commitments. Examples of these are given by Colombetti [2] and Singh [10]. Colombetti and Singh argued that agents are social entities, involved in social interactions, so they are committed to what they say. In recent inter-agent communication approaches, the notions of dialogue games and (social) commitments are central. One rather influential dialogue game is DC, proposed by Hamblin [5]. DC associates with each player a *commitment store*, which holds its commitments during the dialogue. Commitments here are pieces of information given by players during the dialogue. Then, there are rules which define how commitment stores are updated. Take for instance assertion, it puts a propositional statement in the speaker’s commitment store. What this basically means is that, when challenged, the speaker will have to justify his claim. But this does not presuppose that the challenge will come at the next turn in the dialogue.

We adopt this representation of commitments. Note that in this paper we are not interested in modeling the reasoning of the agent, we only consider what is said by each agent. The idea is to provide a semantics without worrying about agents mental states. Each agent is supposed to be equipped with a commitment store, accessible to all agents, that will contain the utterances it makes during the dialogue. A commitment store keeps tracks of two kinds of speech acts:

- Speech acts made by the agent itself such as assertions, promises and declarations.
- Speech acts received from other agents, such as requests, challenges and questions. For instance if an agent ag_i makes a request r to another agent ag_j , the request (r) is stored in the commitment store of ag_j . Hence, ag_j is said *committed* to answer to it.

Definition 4 (Commitment store) A commitment store CS_i associated with an agent ag_i is a pair $CS_i = \langle A_i, O_i \rangle$ with:

$$\begin{aligned} A_i &\subseteq \{m \in \mathcal{M} \mid \text{Act}(m) \in \{\text{Assert}, \text{Argue}, \text{Declare}, \text{Promise}\}\}. \\ O_i &\subseteq \{m \in \mathcal{M} \mid \text{Act}(m) \in \{\text{Question}, \text{Request}, \text{Challenge}\}\}. \end{aligned}$$

A dialogue evolves from one step to another as soon as a move is uttered. In what follows, CS_i^s denotes the commitment store of agent i at step s . A commitment store is supposed to be *empty* at the beginning of a dialogue (i.e., at step 0). Hence, for all agent ag_i , $CS_i^0 = \emptyset$. Given a set X of moves, X^i denotes the moves of X that are uttered from step 0 to step i . Let us now introduce two functions **PROP** and **PROP_P** that return sets of formulas as follows:

Definition 5 Let $X \subseteq \mathcal{M}$.

- **PROP**(X) is defined recursively by:

$$\text{PROP}(X^0) = \emptyset$$

$$\text{PROP}(X^s) = \begin{cases} \text{PROP}(X^{s-1}) \cup \{x\} & \text{if } m = \text{Assert}:x \\ \text{PROP}(X^{s-1}) \cup S & \text{if } m = \text{Argue}:(S, c) \\ \text{PROP}(X^{s-1}) \diamond x & \text{if } m = \text{Declare}:x \\ \text{PROP}(X^{s-1}) & \text{else} \end{cases}$$

where m is the move uttered at step s in X^s and \diamond is an update operator described below.

- **PROP_P**(X) = { $x \in \mathcal{L}$ such that $\exists \text{Promise}:x \in X$ }.

The above definition computes the set of formulas that represent the state of the world (according to what has been uttered during the dialogue). Note that Questions, Challenges and Requests are not considered in the definition because they don't describe the state of the world. Formulas that appear in assertions and arguments are directly considered. However, things are different with the formulas related to a move **Declare**. Indeed, by definition, after **Declare**: x the world evolves in such a way that x becomes true. Consequently, one has to update the whole set of propositions previously uttered. For that purpose, an update operator [12], denoted by \diamond , is needed. Several update operators have been introduced in the literature. The choice of the precise one to be used in our semantics is beyond the scope of this paper.

3.3 The notion of penalty

As said before, from each move a commitment is induced. It is natural to associate with each commitment a penalty that sanctions the agent when this commitment is violated. For the sake of simplicity, the penalty is supposed to depend on the speech act and not on the content of the move. Hence, each speech act in \mathcal{S} is supposed to have a *cost* which is an integer: $\text{Cost} : \mathcal{S} \rightarrow \mathbb{N}$. Different speech acts may have different values. This captures the idea that some speech acts are more important than others. For instance, violating a promise may be more costly than not answering a question. With each commitment store is associated a penalty as follows:

Definition 6 (Penalty) Let $CS_i = \langle A_i, O_i \rangle$ be a commitment store, and $X \subseteq A_i \cup O_i$. The penalty associated with X w.r.t. CS_i is

$$c(X) = \sum_{m \in X} \text{Penalty}(m)$$

where $\text{Penalty}(m) = \text{Cost}(\text{Act}(m))$ if the commitment m is violated in A_i and $\text{Penalty}(m) = 0$ otherwise.

Since a commitment store is empty at the beginning of a dialogue, its initial penalty is equal to 0. Moreover, at any step, the penalty of a given commitment store can be computed in a very simple way as shown in the next section.

3.4 Violation criteria

As shown before, a penalty is to be paid if a commitment is violated. This section presents in details when commitments induced from each speech act of \mathcal{S} are violated. Subsequently, we suppose that the agent ag_i utters the move to the agent ag_j .

1. Assert: x

During a dialogue, an agent can assert that a given propositional formula is true. Then, this agent is not allowed to contradict itself during all the dialogue otherwise it will have to pay a penalty (except if it retracts that proposition). Indeed, a move **assert**: x is *violated* if the A_i part of the commitment store of the agent ag_i makes it possible to find an argument with a conclusion $\neg x$. Formally:

Definition 7 A move **Assert**: x is violated iff

$$\exists(S, \neg x) \in \text{Arg}(\text{PROP}(A_i)).$$

In order to avoid any form of wishful thinking, in the above definition, the promises are not taken into account when checking the violation of an assert move, even if they are stored in the A_i part

of the commitment store.

2. Argue: x

During a dialogue, an agent can provide an argument x in favor of some conclusion. Then, this agent is not allowed to contradict itself in the sense that it cannot produce an undercut against x .

Definition 8 A move **Argue**: x is violated iff

$$\exists(S', y) \in \text{Arg}(\text{PROP}(A_i)) \text{ such that } (S', y) \text{ undercuts}^3 x.$$

As for assert moves and for the same reason, promises are not taken into account when looking for counter arguments.

3. Declare: x

During a dialogue, an agent can modify the state of a certain proposition x by declaring it true. The move **Declare**: x commits the honesty of the agent which carries it out in the sense that the agent should be empowered to modify the value of x . This capacity is defined by the role of the agent. For instance, it is not allowed for a simple citizen to marry people. Moreover, an agent can really modify this value only if there is no argument against performing that action. Formally:

Definition 9 A move **Declare**: x is violated iff

$$x \notin \text{Role}(ag_i) \text{ or } \exists(S, \neg y) \in \text{Arg}(\text{Prop}(A_i)) \\ \text{with } y \in \text{Precond}(x)$$

where $\text{Precond} : \mathcal{L} \rightarrow 2^{\mathcal{L}}$ is a function that gives for any formula φ the pre-conditions for setting φ to true and that verifies: $\text{Precond}(\perp) = \{\perp\}$ and $\text{Precond}(\top) = \emptyset$

The definition of **Precond** may come from law, it is supposed to be furnished (its definition is beyond the scope of this paper). For example, in order to open an auction, one should check whether the buyers are present. If a formula can never be set to true then the function **Precond** returns $\{\perp\}$. When, there is no pre-condition for setting the formula to true, the function returns \emptyset .

4. Question: x

During a dialogue, an agent may receive questions from other agents to which it should answer either positively or negatively. The absence of any argument in favor of x or $\neg x$ in the part A_j of the commitment store of the agent that receives the move means that the agent has not given any answer.

Definition 10 A move **Question**: x is violated iff

- $\nexists(S, x) \in \text{Arg}(\text{PROP}(A_j))$ and
- $\nexists(S, \neg x) \in \text{Arg}(\text{PROP}(A_j))$.

Again, promises are not considered when building arguments. Note that we check the existence of an argument in favor of x or $\neg x$ instead of just the existence of a proposition equivalent to x or to $\neg x$ in A_j . The reason is that the question can be answered implicitly via other assertions of the agent. In this setting, it is not possible to answer "I don't know" to a question. But, this could be easily handled by introducing the speech act **Desinform**.

5. Request: x

An agent should give a positive or a negative answer to any request it receives from other agents.

³ See Definition 2 in Section 2.

Definition 11 A move $\text{Request}:x$ is violated iff

- $\nexists (S, x) \in \text{Arg}(\text{PROP}(A_j) \cup \text{PROP}_P(A_j))$ and
- $\nexists (S', \neg x) \in \text{Arg}(\text{PROP}(A_j) \cup \text{PROP}_P(A_j))$.

Note that to check whether a request is violated or not, we look for an argument in favor of x in both $\text{PROP}(A_j)$ and $\text{PROP}_P(A_j)$. The reason is that a request can get an answer in two ways: either because of a promise ensuring that in the future the requested proposition will be set to true or to false, or because it is already stated (either by declarations or assertions) to true or false.

6. Challenge: x

Agents should provide arguments for any challenged proposition.

Definition 12 A move $\text{Challenge}:x$ is violated iff

$$\nexists (S, x) \in \text{Arg}(\text{PROP}(A_j)) \text{ with } S \not\equiv x.$$

Let us take the example of agent which asserts x , after which the other agent makes a challenge on x . It is clear that the argument $(\{x\}, x)$ can be built from $\text{Arg}(\text{PROP}(A_j))$, however this is not an answer to the challenge. Thus in order to avoid such problem, the above definition requires that the argument presented after a challenge should be different from x .

7. Promise: x

During a dialogue, an agent can make promises to other agents. This agent should pay a penalty in case it does not respect this promise. This can be checked on the part A_i of its commitment store. Indeed, if an argument in favor of proposition x can be built then the promise is honored otherwise it is considered violated.

Definition 13 A move $\text{Promise}:x$ is violated iff

$$\nexists (S, x) \in \text{Arg}(\text{PROP}(A_i)).$$

8. Retract: m

Agents may decide to retract some previously uttered moves. The advantage of this move is to allow them to revise their beliefs without being sanctioned. The Retract move is different from the others since it is never violated, thus $\text{Penalty}(\text{Retract}:m) = 0$. Moreover, after such a move the commitment store is updated as follows:

Definition 14 Let CS_i^s be the commitment store of an agent ag_i at step s . A move $\text{Retract}(m)$ at step $s + 1$ has the following effect:

$$CS_i^{s+1} = CS_i^s \setminus \{m\}$$

Note that retracting a move that has not been uttered has no effect.

4 Logical properties

The aim of this section is to show that the proposed semantics satisfies some key and desirable properties. The first property ensures that the semantics sanctions only bad behaviors of agents, and that any bad behavior is sanctioned.

Proposition 1

- If $c(CS_i) > 0$, then $\exists m \in CS_i$ s.t m is violated.
- If $\exists m \in CS_i$ s.t m is violated, then $c(CS_i) > 0$.

Another important result is the fact that if the total penalty of part A_i is null then all the stated information is consistent.

Proposition 2 (Consistency) If $\sum_{m \in A_i} \text{Penalty}(m) = 0$, then $\text{PROP}(A_i)$ is consistent.

In [6], it has been shown that a propositional formula may be useful for explaining another formula in a given context. This property is called *novelty*. In what follows, we give its definition in terms of arguments.

Definition 15 (Novelty) Let φ, ϕ be two propositional formulas, and Σ a set of formulas.

- φ is new for ϕ w.r.t. Σ iff:
 - $\exists \langle S, \phi \rangle \in \text{Arg}(\Sigma \cup \varphi)$ and $\langle S, \phi \rangle \notin \text{Arg}(\Sigma)$, or
 - $\exists \langle S, \neg\phi \rangle \in \text{Arg}(\Sigma \cup \varphi)$ and $\langle S, \neg\phi \rangle \notin \text{Arg}(\Sigma)$
- φ is said to be independent from ϕ w.r.t. Σ otherwise.

We can show that if two formulas are independent w.r.t. the formulas of a commitment store, then the penalty of two moves conveying these formulas is decomposable. Formally:

Proposition 3 (Independence) Let $CS_i = \langle A_i, O_i \rangle$ be a commitment store, and let $m, m' \in \mathcal{M}$. If $\text{Content}(m)$ is independent from $\text{Content}(m')$ w.r.t. $\text{PROP}(A_i) \cup \text{PROP}_P(A_i)$, then

$$c(\{m, m'\}) = c(\{m\}) + c(\{m'\})$$

5 Example

Let us study the following dialogue between two agents ag_1 and ag_2 :

$ag_2 \rightarrow ag_1$: Do you think that Newspapers can publish (pub) the information X .

A_1	O_1
\emptyset	Question: pub

$c(CS_1) = \text{Cost}(\text{Question})$

$ag_1 \rightarrow ag_2$: No.

A_1	O_1
Assert: $\neg pub$	Question: pub

$c(CS_1) = 0$

$ag_2 \rightarrow ag_1$: why?

A_1	O_1
Assert: $\neg pub$	Question: pub
Argue: $(\{pri, \neg agr, pri \wedge \neg agr \rightarrow \neg pub\}, \neg pub)$	Challenge: $\neg pub$

$c(CS_1) = \text{Cost}(\text{Challenge})$

$ag_1 \rightarrow ag_2$: Because X concerns the private life of A (pri) and A does not agree to publish it (agr).

A_1	O_1
Assert: $\neg pub$	Question: pub
Argue: $(\{pri, \neg agr, pri \wedge \neg agr \rightarrow \neg pub\}, \neg pub)$	Challenge: $\neg pub$
$c(CS_1) = 0$	

$ag_2 \rightarrow ag_1$: But A is a minister (min) and information about ministers are public.

A_2	O_2
Argue: $(\{min, min \rightarrow \neg pri\}, \neg pri)$	\emptyset

$c(CS_2) = 0$

$ag_1 \rightarrow ag_2$: Yes, you are right.

A_1	O_1
Assert: $\neg pub$	Question: pub
Argue: $(\{pri, \neg agr, pri \wedge \neg agr \rightarrow \neg pub\}, \neg pub)$	Challenge: $\neg pub$

$c(CS_1) = 2 \times \text{Cost}(\text{Argue})$

In the above example, the agent ag_1 answers the question and the challenge it received, thus there is no penalty to pay for those moves. However, this agent has presented an argument $a = \langle \{pri, \neg agr\}, \neg pub \rangle$, and accepted its undercutter $b = \langle \{min, min \rightarrow \neg pri\}, \neg pri \rangle$. Consequently, the set $\text{PROP}(A_i)$ is inconsistent, and this makes it possible to even construct an undercutter $c = \langle \{pri, min \rightarrow \neg pri\}, \neg min \rangle$ for the argument b . The agent has then to pay twice the cost of an Argue move. Note, however that from $\text{PROP}(A_i)$ it is not possible to construct an argument whose conclusion is $\neg pub$. This means that the agent is still coherent w.r.t. its assertion ($\neg pub$). Thus, there is no cost to pay for the assert move.

6 Related work

The first standard agent communication languages are KQML [3] and FIPA-ACL [4]. Both languages have been given a mentalistic semantics. The semantics is based on a notion of speech act close to the concept of illocutionary act as developed in speech act theory [9]. Such semantics assumes, more or less explicitly, some underlying hypothesis in particular, that agents are sincere and cooperative. While this may be well fitted for some special cases of interactions, it is obvious that negotiation dialogues are not cooperative. Another more important limitation of this approach is the fact that it is not verifiable since it is based on agents mental states. Our semantics does not refer at all to the mental states of the agents. Moreover, it treats another speech act, namely **Argue**, which allows agents to exchange arguments.

In the second approach, called *social* and developed in [2, 10], primacy is given to interactions among agents. The semantics is based on social *commitments* brought about by performing a speech act. For example, by affirming a data, an agent commits on the truth of that data. After a promise, the agent is committed carrying it out. There are several weaknesses of this approach and we summarize them in the three following points: 1) The definition of commitments complicates the agent architecture in the sense that it needs an ad hoc apparatus. Commitments are introduced especially for modeling communication. Thus agents should reason not only on their beliefs, etc, but also on commitments. In our approach, we didn't introduce any new language to treat commitments. 2) The level at which communication is treated is very abstract, and there is a considerable gap to fill in order to bring the model down to the level of implementation. However, the semantics presented in this paper can be implemented easily. 3) The concept of commitment is ambiguous and its semantics is not clear. According to the speech act, the semantics of the commitment differs. For example, by affirming a data, an agent commits on the truth of that data. The meaning of the commitment here is not clear. It may be that the agent can justify the data or can defend it against any attack, or that the agent is sincere. In our approach, the semantics of a commitment is very intuitive, unique and simple. Penalties are computed in a very simple way and at any time during a dialogue.

The last approach developed by Pitt and Mamdani in [8] and Alberti et al. in [1] is based on the notion of protocol. A protocol defines what sequences of moves are conventionally expected in a dialogue. The meaning of a speech act equates to the set of possible following answers. However, protocols are often technically finite state machines. This turns out to be too rigid in several circumstances. Current research aims at defining flexible protocols, which rely more on the *state of the dialogue*, and less on dialogue history. This state of dialogue is captured by the notion of commitment.

7 Conclusion and perspectives

This paper has introduced a new simple and verifiable ACL semantics. The interpretation of each speech act equates to the penalty to be paid in case the commitment induced by that speech act is violated. In this semantics, a violation criterion is given for each considered speech act. Note that in order to add a new speech act, one needs simply to define a new violation criterion associated with it. This semantics is based on propositional logic, and the violation criteria amount to compute arguments.

An extension of this work to first order logic is under study. Another interesting extension would be to handle explicitly time in order to be able to deal with deadlines for instance.

The notion of penalty may play a key role in defining agent's *reputation* and *trust* degrees. It is clear that an agent that pays a lot of penalties during dialogues may lose its credibility, and will no longer be trusted. Examining more deeply penalties can help to figure out agents profiles: cooperative agent, consistent agent, thoughtful agent (i.e., agent which respects its promises)...

Another possible refinement consists of introducing granularity in the definition of the function **Cost**. The basic idea is to take into account the content of moves when defining their costs. This captures the idea that, for instance, some asserted propositions are more important than others. For example, affirming that the weather is beautiful can be less important than affirming that the president is dead. Our semantics satisfies interesting properties that show its well-foundedness. It also offers other advantages regarding dialogue protocols. For instance, one does not need to specify the different moves allowed after each move in the protocol itself. Agents only need to minimize the penalty to pay at the end of the dialogue. This give birth to very flexible protocols.

Computational Opinions

Felix Fischer¹ and Matthias Nickles²

Abstract. Existing approaches to knowledge representation and reasoning in the context of open systems either deal with “objective” knowledge or with beliefs. In contrast, there has been almost no research on the formal modelling of *opinions*, i.e., communicatively asserted ostensible beliefs. This is highly surprising, since opinions are in fact the only publicly visible kind of knowledge in open systems, and can neither be reduced to objective knowledge nor to beliefs. In this paper, we propose a formal framework for the representation of dynamic, context-dependent and revisable *opinions* and *ostensible intentions* as a sound basis for the external description of agents as obtained from observable communication processes. Potential applications include a natural semantics of communicative acts exchanged between truly autonomous agents, and a fine-grained, statement-level concept of trust.

1 INTRODUCTION

In the area of artificial intelligence, open systems with heterogeneous, more or less inscrutable actors, are becoming an increasingly important area of application for multi-agency. Prominent examples include the Semantic Web or Peer-to-Peer systems. Nevertheless, agents (including human users) are still mainly characterised in terms of their mental attitudes. The problem with this approach is that agents’ internal states are, by definition, concealed from the point of view of external observers, including other agents. And even if the mental states of all participants were accessible, it would be an extremely difficult task to describe the dynamic behaviour of a system as a function of all of its individuals, particularly if the number of actors is large (as it is usually the case in Web and Peer-to-Peer applications). Hence, although the description of an agent in terms of his beliefs, intentions and desires is a very natural and powerful tool, it reaches its limits rather quickly in complex open environments.

One way to cope with this situation, in order to ensure the controllability of individual agents as well as the achievement of supra-individual system goals, is to impose normative restrictions on agent behaviour, or to model the entire system in terms of static organisational structures. While such top-down approaches certainly have their merits, and systems without predefined policies and protocols are hardly imaginable, they may seriously limit the desirable properties of autonomous systems, like their robustness and flexibility. For example, the use of an agent communication language with a predefined mentalistic semantics [see, e.g., 4] may reduce the level of agent autonomy by prescribing to some degree what the communication parties have to “think” during communication. This is not to dismiss social structures and norms, of course. Public communication models like an ACL semantics cannot avoid normativity if they are to ensure that meaningful communication can take place. We

think, however, that normativity should be kept to a minimum, and the focus should be on adaptive models and on the measurement of the degree to which agents adhere to given models at run-time. After all, agent technology is basically a bottom-up approach, allowing for the emergence of behaviour and solutions, and should not be turned upside down.

Another approach, somewhat complementary to the ones just described, is to constrain the modelling of black-box agents from an external point of view by limiting the *validity* of cognitive models or commitments, thus inducing some sort of bounded observer rationality. A particular way of doing this is by using information about the trustability and reputation of the respective agent. The approach introduced in [13] and refined in this paper is largely compatible and in line with such means, but takes a different perspective. Instead of adding restrictions to statements about internal agent properties and commitments, we introduce the *communication attitudes* (CAs) *opinion* (also called *ostensible belief*) and *ostensible intention* as communication-level counterparts to belief and intention, and thus “lift” mental attitudes to the social level. As for the intended effect, this is similar to approaches using *social commitments* [18]. However, the latter have not yet been fully formalised, and there currently exists no consensus about the precise meaning of “being committed”. In contrast, CAs will be given an intuitive but precise formal semantics which resembles the modalities of agent belief and intention in many ways, and can be used as a direct replacement for belief and intention in most imaginable scenarios (e.g., in the semantics of KQML/KIF or FIPA ACL). CAs are nevertheless cleanly separated from mental attitudes, and can thus be used together with these without any interference. For example, an agent might reason simultaneously about the (alleged) “real” beliefs of another agent and the opinions held communicatively by this agent.

To the best of our knowledge, the formal, systematic treatment of opinions in the above sense, i.e., by distinguishing between rational mental attitudes on the one hand and (boundedly) rational yet “superficial” stances an agent exposes in discourse on the other, is new in the field of AI. This is highly surprising since opinions are in fact the only publicly visible kind of knowledge in open systems, and can neither be reduced to objective knowledge nor to beliefs. Unlike objective knowledge, opinions need not be grounded, shared or consistent. What distinguishes an agents CA of opinion from his mental attitude of belief is that the former is triggered and revised by social conditions, more precisely communicative acts and underlying social structures like legal, organisational and economic laws. While opinions might as well reflect the true beliefs of benevolent, trustworthy agents (an assumption that is made by most traditional approaches to agent communication semantics), this should be considered a special case for autonomous, self-interested agents in open systems. Also, the utterance of an opinion should not mean that one truthfully intends to make someone adopt this opinion as a belief (which would be unrealistic), but rather as an opinion. Opinions emerge from (more or less hidden) agent intentions and social processes, they are tailored to the intended communicative effect and

¹ Computer Science Department, University of Munich, 80538 Munich, Germany, email: fischer@tcs.ifi.lmu.de

to the opinions and ostensible intentions of the audience. Thus, traditional concepts like epistemic logic, knowledge acquisition, belief ascription and revision, etc., do not necessarily apply to opinions (for example, an opinion could be bought in exchange for money). Yet another approach, which many people use at least implicitly, would be to “abuse” mental attitudes and combine them with additional assumptions like the trustability of agents to model agent interaction. Related but somewhat more appropriate is the ascription of *weak intentions*, which are not necessarily pursued until the intended effect has been achieved or is deemed impossible [2]. This seems workable, since even ostensible intentions and opinions have to built upon some undeniable mental intentions (totally unconscious communication exempted), possibly with a duration of self-commitment that is shorter than claimed. However, it would again lead to problems with cognition and sociality getting mixed up, and force a socially reasoning communication observer to find an immediate, possibly complicated mapping of alleged attitudes to weak intentions. We think that such an amalgamation of mental and pseudo-communication attitudes, while still common, is dangerous and inappropriate. It is likely to impede the simultaneous reasoning about mental and social issues, and it is misleading with respect to the very nature of communication processes and assertions, which form a system of their own that is in a certain sense decoupled from the underlying mental cognition processes [12]. While we will also introduce a notion of trust tailored to the use with opinions, our approach resides on a different conceptual level than related areas like belief revision and information integration. While the latter are mainly concerned with the determination of correct, consistent and useful information, our primary goal is to represent communicatory properties of and differences between heterogeneous assertions, which precedes a potential assessment in terms of reliability.

2 A COMMUNICATION ATTITUDE LOGIC

In this section, we introduce a probabilistic and dynamic *Communication Attitude Logic CAL* as an extension of [7, 2, 1] with additional modalities for opinions and ostensible intentions. Our main goal here is to “lift” the usual modal logic and protocol languages for modelling agent beliefs and intentions and their revision [see, e.g., 8] to the communication (i.e., social) level, in order to deal with mentally opaque agents in open systems. Within the scope of this work, we have chosen a probabilistic variant of dynamic logic as a basis for this, but other formalisms like the *event calculus* [10] could certainly be used instead. Even more importantly, the underlying notions of opinion and ostensible intention do not depend in any way on a dynamic or probabilistic interpretation. As we have pointed out in the previous section, an important property of CAs is their dependency on social conditions, demarcating them, *inter alia*, from mental attitudes. Since an exhaustive description of all the possible ways by which CAs are steered by social conditions of various kinds is beyond the scope of this paper, we confine ourselves to the presentation of simple trigger events.

2.1 Syntax

Definition 1 The language \mathcal{L} of well-formed CAL formulas φ, ψ and processes α, β is given by

$$\begin{aligned} \varphi, \psi ::= & P(V_1, V_2, \dots) \mid \top \mid \perp \mid \neg\varphi \mid \varphi \wedge \psi \mid \varphi \vee \psi \mid \varphi \rightarrow \psi \\ & \mid \varphi \leftrightarrow \psi \mid \diamond \varphi \mid \square \varphi \mid \langle \alpha \rangle p \mid \text{done}(\alpha) \mid \text{happens}(\alpha) \\ & \mid \text{Op}(A_1, A_2, \varphi) \mid \text{OInt}(a_1, A_2, \varphi) \mid \text{Bel}_d(a_1, \varphi) \mid \text{Int}(a_1, \varphi) \end{aligned}$$

$$\alpha, \beta ::= \text{act} \mid a_i.\text{act} \mid \text{any} \mid \alpha; \beta \mid \alpha \cup \beta \mid \alpha^* \mid \varphi?$$

where

- $a_i \in A$ and $A_i \subseteq A$ denote an agent or a set of agents, the source or addressee of an opinion;
- P is a predicate symbol, V_i are variables;
- $\text{act}, a_i.\text{act}$ is an elementary action, possibly indexed with the acting agent a_i ;
- any is an arbitrary action;
- $\alpha; \beta$ denotes sequential process combination;
- $\alpha \cup \beta$ denotes non-deterministic choice between α and β ;
- α^* denotes zero or more iterations of α ;
- $\varphi?$ is a test action (i.e., the process proceeds if φ holds true);
- $\langle \alpha \rangle p$ denotes that α is processed and p holds afterwards;
- $\text{Op}(A_1, A_2, \varphi)$ denotes that agents A_1 hold opinion (ostensible belief) φ facing agents A_2 .
- $\text{OInt}(a_1, A_2, \varphi)$ denotes that agent a_1 , facing agents A_2 , exhibits the ostensible intention to make φ become true (either by himself or indirectly via agents A_2);
- $\text{Bel}_d(A_1, \varphi)$ denotes that every agent $a_1 \in A_1$ (sincerely) believes φ with degree d ; and
- $\text{Int}(a_1, \varphi)$ denotes that a_1 (sincerely) intends φ .

$P(V_1, V_2, \dots), \neg, \wedge, \top, \perp, \rightarrow$ and \leftrightarrow shall have the usual meaning. The meaning of $\text{done}(\alpha)$, $\text{happens}(\alpha)$, $\diamond \varphi$, and $\square \varphi$ is that α has just happened, or is currently taking place, and that φ will hold eventually or always, respectively. The set A may include both agent and non-agent opinion resources (like a Web document). For the sake of readability, we will henceforth refer to all of these resources as *agents*. We further use the following abbreviations:

$$\begin{aligned} \text{Op}(a_1, A_2, \varphi) &\equiv_{\text{def}} \text{Op}(\{a_1\}, A_2, \varphi) \\ \text{Op}(A_1, a_2, \varphi) &\equiv_{\text{def}} \text{Op}(A_1, \{a_2\}) \\ \text{OInt}(a_1, a_2, \varphi) &\equiv_{\text{def}} \text{OInt}(a_1, \{a_2\}, \varphi) \\ \text{Bel}_d(a_1, \varphi) &\equiv_{\text{def}} \text{Bel}_d(\{a_1\}, \varphi) \end{aligned}$$

As an example, consider the sequence of negotiation dialogues given in Table 1. An agent a_2 is offering some item o for sale, and agents a_1 and a_3 are both interested in buying this item. Agents a_1 and a_2 shall be mentally opaque from our point of view, but we shall know the beliefs of agent a_3 (e.g., we could ourselves be a_3). First of all, agent a_3 tells agent a_2 that he would be willing to pay \$100 for o (Step 1a). At the same time, he tells a_2 that a_1 is notoriously unreliable, while privately believing the opposite to be the case (Step 1b). Then, a_1 enters the scene, and a_3 tells a_2 (with a_1 observing) that a_1 is a reliable customer (Step 1c). In a separate dialogue, agent a_1 tells a_2 that he wants to buy item o for \$150 (Step 2a). Agent a_2 refuses this offer, insincerely telling a_1 that agent a_3 would be willing to pay \$200 for o (Step 2b). a_1 then asks a_3 whether he is actually willing to pay \$200, as claimed by a_2 (Step 3). This is when he becomes aware that a_2 (seemingly) tried to cheat him, and tries to extort a lower selling price by telling a_2 that he would otherwise reveal the attempted cheat to a_1 (Step 4). This threat is again insincere, as in fact a_3 does not plan to expose a_2 should he refuse the new offer.

The relevant internal states of a_1 and a_2 being invisible, this scenario cannot be modelled in terms of mental attitudes (e.g., within the BDI framework). This not only applies to the obvious cases of Steps 1b and 4, where $\text{Bel}(a_3, \text{reliable}(a_1))$ and $\text{Op}(a_3, a_2, \neg \text{reliable}(a_1))$, or $\text{OInt}(a_3, a_2, \text{buyFor}50)$ and $\neg \text{Int}(a_3, \text{buyFor}50)$, hold simultaneously. It is tempting to write $\text{Int}(a_2, \text{Bel}(a_1, \text{Int}(a_3, \text{buyFor}200)))$ to model the state after Step 2b,

$\langle a_3.request(buyFor100, a_2) \rangle OInt(a_3, a_2, buyFor100)$	(1a)
$Bel(a_3, reliable(a_1)) \wedge \langle a_3.inform(\neg reliable(a_1), a_2) \rangle$	(1b)
$Op(a_3, a_2, \neg reliable(a_1))$	
$\langle a_3.inform(reliable(a_1), \{a_2, a_1\}) \rangle Op(a_3, \{a_2, a_1\}, reliable(a_1))$	(1c)
$\langle a_1.request(buyFor150, a_2) \rangle OInt(a_1, a_2, buyFor150)$	(2a)
$\langle a_2.inform(OInt(a_3, a_2, buyFor200), a_1) \rangle$	(2b)
$Op(a_2, a_1, OInt(a_3, a_2, buyFor200), a_1))$	
$\langle a_1.request(confirm(OInt(a_3, a_2, buyFor200)), a_3) \rangle$	(3)
$Bel(a_3, Op(a_2, a_1, OInt(a_3, a_2, buyFor200)))$	
$\langle a_3.request(buyFor50, a_2); a_3.inform(done(a_2.refuse)?;$	(4)
$a_3.inform(\neg OInt(a_3, a_2, buyFor200), a_1) \rangle$	
$OInt(a_3, a_2, buyFor50) \wedge OInt(a_3, a_2, done(done(a_2.refuse)?;$	
$a_3.inform(\neg OInt(a_3, a_2, buyFor200), a_1)) \rangle$	
$\wedge \neg Int(a_3, done(a_3.inform(\neg OInt(a_3, a_2, buyFor200), a_1))) \rangle$	

Table 1. CAL formalisation of a sequence of dialogues, involving speech acts *inform*, *request*, *confirm*, and *refuse*.

but this would be mere speculation. For example, a_2 may just have tried to provoke the reaction of Step 4 and then denounce a_3 as an extortionist. The example further highlights the ability of ostensible attitudes to model mutual inconsistencies between information circulating in a group of agents and in one of its subgroups, where after Steps 1b and 1c we simultaneously have $Bel(a_3, reliable(a_1))$, $Op(a_3, a_2, \neg reliable(a_1))$, and $Op(a_3, \{a_2, a_1\}, reliable(a_1))$.

2.2 Semantics

The model theory of \mathcal{L} is that of a first-order linear time temporal logic with modal operators for gradual belief and for intention. For belief, we use (a linear time extension of) the probabilistic semantics proposed in [1], which has been shown to include a KD45 modal operator for full belief as a special case. Intention is modelled by a KD modal operator. We further include two modal operators for the CAs of opinion and ostensible intention. Their individual Kripke-style semantics is roughly equivalent to that of beliefs or intentions, a possible axiomatisation will be discussed in more detail in Section 2.3.

Definition 2 A model is a tuple $M = (\Theta, E, W, A, (\mu_a)_{a \in A}, (I_a)_{a \in A}, (O_{A_1, A_2})_{A_1, A_2 \subseteq A}, (J_{a_1, A_2})_{a_1 \in A, A_2 \subseteq A}, \Phi)$ where Θ is a universe of discourse, E is a set of primitive event types, $W \subseteq \{w : [n] \mapsto E \mid n \in \mathbb{N}\}$ is a set of possible courses of events (or worlds) specified as a total function from the non-negative integers up to n to elements of E . A is a set of agents, and for all $a \in A$, $\mu_a : S \mapsto [0, 1]$ is a discrete probability distribution over situations (i.e., worlds at a particular time step, defined as $S = \{(w, i) \mid w : [n] \mapsto E, n \in \mathbb{N}, 1 \leq i \leq n\}$) for gradual belief, and $I_a \subseteq S \times W$ is a serial accessibility relation for intentions. For all $A_1, A_2 \subseteq A$, $a_1 \in A$, $O_{A_1, A_2} \subseteq S \times W$ is a serial, transitive, Euclidean accessibility relation for opinions, and $J_{a_1, A_2} \subseteq S \times W$ is a serial accessibility relation for ostensible intentions. Φ interprets predicates.

Since S contains at most a denumerable number of situations, μ can be naturally extended to a probability distribution over subsets $T \subseteq S$ by $\mu(T) = \sum_{s \in T} \mu(s)$. In particular, we have $\mu(S) = 1$.

Formulas of the logical language \mathcal{L} are interpreted with respect to a tuple (M, v, σ, i) , consisting of a model M , a variable assignment v (mapping variables to elements of Θ), a possible world (i.e., possible course of events) σ , and a time step i in this particular world. The interpretation of formulas is given by the standard interpretation rules

for first-order formulas and for the action-related modal operators *happens* and *done*. We refer to [2] for formal definitions of these rules. The gradual belief operator Bel_p , the intention operator Int , the opinion operator Op , and the ostensible intention operator $OInt$ are interpreted as follows:

$(M, v, \sigma, i) \models Bel_p(a, \varphi)$	iff $\mu_a(\{s' \mid (M, v, s', i) \models \varphi\}) = p$
$(M, v, \sigma, i) \models Int(a, \varphi)$	iff for all σ' such that $(\sigma, i, \sigma') \in I_a$, $(M, v, \sigma', n) \models \varphi$
$(M, v, \sigma, i) \models Op(A_1, A_2, \varphi)$	iff for all σ' such that $(\sigma, i, \sigma') \in O_{A_1, A_2}$, $(M, v, \sigma', n) \models \varphi$
$(M, v, \sigma, i) \models OInt(a_1, A_2, \varphi)$	iff for all σ' such that $(\sigma, i, \sigma') \in J_{a_1, A_2}$, $(M, v, \sigma', n) \models \varphi$

That is, φ is *gradually believed* by agent a with strength p iff the measure μ_a of all situations where φ holds true is at least p , and *intended* by a iff it holds in all situations that are accessible via I_a . φ is *ostensibly believed* (*ostensibly intended*) by A_1 facing A_2 (a_1 facing A_2) iff it holds in all situations that are accessible via O_{A_1, A_2} (J_{a_1, A_2}). While an agent would usually relate the strength of belief to past events (i.e., frequency) in some way, we will not commit to a particular way this is done in the context of this paper (e.g., by giving axioms that relate μ to past events).

2.3 Communication Attitudes

Even though agents are fully autonomous, CAs should be governed by a set of axioms that separate rational and irrational communicative behaviour. As we have already outlined above, violation of these axioms would, in the most extreme case, disqualify an agent from taking part in (rational) interaction with other agents. The following axioms describe (the consistency of a set of) CAs in a way that is similar to a KD45 logic of belief and a KD logic of intention, but cleanly separated from these mental attitudes:

1. $Op(A_1, A_2, \varphi \rightarrow \psi) \rightarrow (Op(A_1, A_2, \varphi) \rightarrow Op(A_1, A_2, \psi))$
2. $Op(A_1, A_2, \varphi) \rightarrow \neg Op(A_1, A_2, \neg \varphi)$
3. $Op(A_1, A_2, \varphi) \rightarrow Op(A_1, A_2, Op(A_1, A_2, \varphi))$
4. $\neg Op(A_1, A_2, \varphi) \rightarrow Op(A_1, A_2, \neg Op(A_1, A_2, \varphi))$
5. $OInt(a_1, A_2, \varphi \rightarrow \psi) \rightarrow (OInt(a_1, A_2, \varphi) \rightarrow OInt(a_1, A_2, \psi))$
6. $OInt(a_1, A_2, \varphi) \rightarrow \neg OInt(a_1, A_2, \neg \varphi)$
7. $OInt(a_1, A_2, \varphi) \leftrightarrow Op(a_1, A_2, OInt(a_1, A_2, \varphi))$
8. $OInt(a_1, A_2, \varphi) \leftrightarrow Op(A_2, a_1, OInt(a_1, A_2, \varphi))$
9. $\neg OInt(a_1, A_2, \varphi) \leftrightarrow Op(a_1, A_2, \neg OInt(a_1, A_2, \varphi))$
10. $\neg OInt(a_1, A_2, \varphi) \leftrightarrow Op(A_2, a_1, \neg OInt(a_1, A_2, \varphi))$
11. $OInt(a_1, A_2, \varphi) \rightarrow \neg Op(a_1, A_2, \varphi)$
12. $OInt(a_1, A_2, Op(A_2, a_1, \varphi)) \rightarrow Op(a_1, A_2, \varphi)$
13. $Op(a_1, A_2, \varphi) \rightarrow \langle A_2.query(a_1, \varphi); a_1.reply(A_2, \varphi) \rangle \top$

Axioms 1 to 6 correspond to the usual axioms of a KD45 modal operator of belief and to that of a KD operator of intention, and are additionally contextualised with both sender and addressee. The remaining axioms concern additional properties of opinions, ostensible intentions, and the relationship between them. Axiom 13 states that agents (have to) admit their opinions at least upon request, if this request is observed by the opinion addressees. In practice, the above axioms, which provide a basic, abstract set of social norms, could be augmented by additional rules concerning “etiquette” in social interaction and emergent social norms (e.g., under what circumstances it is socially acceptable to retract an assertion or drop an intention).

For opinions that are not just held and uttered on request (like in an opinion poll), but actively asserted facing other agents, we can

define a special kind of *active opinion*, denoted Op^a . Since the latter includes the ostensible intention to spread the opinion among the respective addressees, its semantics can directly be given in terms of ostensible intentions, i.e.,

$$Op^a(a_1, A_2, \varphi) \equiv_{\text{def}} OInt(a_1, A_2, Op(A_2, a_1, \varphi)).$$

By Axiom 12, we have $Op^a(a_1, A_2, \varphi) \rightarrow Op(a_1, A_2, \varphi)$, i.e., *passive opinions* form the consequential closure of those pro-actively put forward in terms of communication. By Axioms 8 and 12, we further have $Op^a(a_1, A_2, \varphi) \rightarrow Op(A_2, a_1, Op^a(a_1, A_2, \varphi))$, a variation of Axiom 3 for the addressee. We do not distinguish between active and passive ostensible intentions, because in this case consequential closure mainly concerns functional decomposition and side-effects of actions, of which an agent should be aware if he has actively announced them.

We further propose the following axioms to bridge the gap between mental and communication attitudes. In most cases, however, these will not be needed to reason about communication processes.

14. $OInt(a_1, A_2, \varphi) \leftrightarrow Bel(a_1, OInt(a_1, A_2, \varphi))$
15. $OInt(a_1, A_2, \varphi) \leftrightarrow Bel(A_2, OInt(a_1, A_2, \varphi))$
16. $Op(A_1, A_2, \varphi) \leftrightarrow Bel(A_1, Op(A_1, A_2, \varphi))$
17. $Op(A_1, A_2, \varphi) \leftarrow Bel(A_2, Op(A_1, A_2, \varphi))$
18. $Op(a_1, a_1, \varphi) \leftrightarrow Bel(a_1, \varphi)$
19. $OInt(a_1, a_1, \varphi) \leftrightarrow Int(a_1, \varphi)$

According to Axiom 17, (passive) opinions don't necessarily have to be visible, but if we come to believe that someone holds an opinion, this belief is always justified. Axioms 18 and 19 allow us to write (full) belief and intention as special cases of opinion and ostensible intention, respectively.

2.4 Communication Attitudes and Communication

Having separated CAs from mental attitudes, the natural next step is to interpret communication in terms of CAs. In the context of this paper, we do not aim at an axiomatisation of a comprehensive set of speech acts like that of FIPA ACL [4], hence giving them an alternative social (but not commitment-based) semantics in terms of CAs. Instead, we provide a minimal set of four communicative acts, and relate CAs directly to actual communications using these communicative acts. *inform* asserts that a particular logical formula currently holds true, *request* declares the intention to make a formula true (note that in our framework, intentionality may include bringing about a certain state or action indirectly “using” other agents), *retract* and *dismiss* cancel a previous statement. Communicative acts are denoted $sender.act(content, addressee)$.

The following *trigger axioms* describe the functional relationship between these communicative acts on the one hand and opinions and ostensible intentions on the other (we use a binary *weak until* operator which can be defined as $\psi W \psi' \equiv_{\text{def}} \text{happens}((\psi?)^*; \psi') \vee \square \psi$):

20. $(Op) done(a_1.inform(\varphi, A_2)) \rightarrow (Op(a_1, A_2, \varphi) W done(a_1.retract(\varphi, A_2)))$
21. $(OInt) done(a_1.request(\varphi, A_2)) \rightarrow (OInt(a_1, A_2, \varphi) W done(a_1.dismiss(\varphi, A_2)))$

As we have already said, additional rules will be necessary to restrict the use of *retract* and *dismiss* to situations in which it is socially acceptable to retract an assertion or drop an intention. Again, such rules are not to prevent an autonomous agent from uttering certain communication primitives in a given context, but rather define what is considered rational communication and what is not.

3 TRUSTABILITY

Kripke-style semantics are widely used to model rational attitudes [see, e.g., 19], and we have pointed out that we consider CAs rational at least to some degree. Yet, they are not very helpful when it comes to determining the actual consequences of someone holding a certain CA (e.g., in terms of reliability). This is crucial because communication is, from an observers point of view, much about decision, behavioural expectation and prediction. As an example for such a *consequentialist semantics* of opinions and ostensible intentions, one might expect that holding a certain ostensible intention means to act “in accordance” with this attitude at least for a limited amount of time, i.e.,

$$OInt(a_1, A_2, done(\alpha_1; \dots; \alpha_n)) \rightarrow \exists h \geq 0. Int(a_1, done(\alpha_1; \dots; \alpha_h))$$

That is, an ostensible intention regarding a sequence of actions implies that the agent *truly* intends a (possibly empty) prefix of this sequence. A similar assumption could be made for opinions. As a matter of rationality in communication, a prefix should truly be intended if it needs to be performed by a_1 alone and under observation by A_2 (i.e., $h \geq j$ instead of $h \geq 0$ if $\alpha_i = a_1.\alpha_i$ and is observable by A_2 for $i \leq j$). Here, h can be seen as the *sphere of trustability* of the respective CA, i.e., the length of the largest sequence of actions that are truly intended. Due to the mental opacity of a_1 , the value of h would in practice have to be determined in a context-dependent way via empirical observation of past ostensible intentions and their consequences in terms of actions actually executed by a_1 . Such a mapping of ostensible to mental attitudes would already provide a consequentialist semantics for ostensible intentions and beliefs, but would come at the price of grounding CAs in mental attitudes. Moreover, it is not at all clear whether and how the extent of the sphere could be computed from past observations, given that intentions denote an earnest self-commitment [17]. To reflect this insight and still allow an observer of a CA to derive information regarding static and dynamic aspects of the world, we propose a consequentialist semantics of CAs that is based on the observer's *trust* that a particular CA does indeed describe (part of) the worlds current state and future evolution.

Trust is commonly defined as a belief that another party will do what it says it will, i.e., be honest and reliable, or reciprocate, i.e., return an advance action for the common good of both, given an opportunity to defect to get higher payoff [see, e.g., 16]. Hence, trust provides an agent a_1 with a means to derive expectations about a certain issue (proposition) φ from CAs regarding φ directed toward him by other agents A_2 . This kind of trust may become crucial when a_1 himself is uncertain about φ , but forced to take impromptu action depending on φ . We give a formal definition.

Definition 3 Let a_1 be an agent, A_2 a set of agents, φ a proposition. Then trusting with regard to φ and with degree p in light of a necessary decision is defined as

$$\begin{aligned} DTrust_p(a_1, A_2, \varphi) &\equiv_{\text{def}} \\ &(happens(a_1.(\alpha \cup \beta)) \\ &\wedge Int(a_1, done(Bel(a_1, \varphi)?; a_1.\alpha \cup Bel(a_1, \neg\varphi)?; a_1.\beta))) \\ &\wedge Bel_q(a_1, \varphi) \wedge (q < 1) \wedge (p + q = 1) \\ &\wedge Op(A_2, a_1, \varphi)) \leftrightarrow Int(a_1, done(a_1.\alpha)). \end{aligned}$$

That is, if (i) agent a_1 is forced to choose between actions α and β and intends to do so depending on whether or not φ holds, (ii) a_1 believes in φ with degree $q < 1$, and (iii) some other agents A_2 hold the opinion against a_1 that φ , then a_1 is said to trust A_2 with respect

to φ and with degree p if he takes action α if and only if $p + q = 1$. A similar definition could be given for ostensible intentions.

Current research on trust in the area of artificial agents mainly focuses on *trust metrics*, which determine how trust and reputation of different dimensions and from various sources are aggregated to form a single notion of trust [see, e.g., 9, 6]. A major weakness of these purely numerical approaches, especially when a precise justification or motivation is required, is the lack of a formal semantics. Existing logical models of trust, on the other hand, including those used in the context of belief revision to assess new information, ground these semantics in mental attitudes of the participating agents, particularly those of the *trustee* [see, e.g., 11, 3]. Like a mentalistic agent communication semantics, this is likely to impede any process by which trust is inferred and used in open environments where agents are mentally opaque. Definition 3 further differs from most existing approaches in that it considers trust at the level of contextualised behavioural expectations or (communicative) assertions rather than entire agents, which results in a more fine-grained and precise model. Since communication is the primary means of interaction among intelligent, autonomous agents, communicative events should constitute the natural, basic subject of trust among such agents. This is in line with the prevailing sociological view of trust as confidence in ones expectations, providing a solution to the problem of acting based on contextualised and gradual (i.e., possibly uncertain) expectations and reducing the inherent complexity of social interaction [12].

While describing precisely (i) what actions need to be taken by an agent who trusts a CA, and (ii) how trust can be recognised ex post, Definition 3 does not provide any additional insights regarding when a CA should or should not be trusted. This underlines the observation of [11] that trust cannot fully be defined as a derived concept. The only available information regarding a decision to trust are past interactions that have taken place in a similar social context or, more precisely, behavioural expectations derived from these interactions. Procedures of arbitrary complexity and sophistication could be imagined to derive trust and hence decisions regarding further action from such expectations. For example, one might want to infer trust (of degree p) in agents A_2 regarding proposition φ from gradual belief (of the same degree) that an opinion held by A_2 that φ does indeed mean φ , i.e., $Bel_p(a_1, Op(A_2, a_1, \varphi) \rightarrow \varphi) \Rightarrow DTrust_p(a_1, A_2, \varphi)$. The left hand side of this rule resembles a special case of *adaptive expectations*, i.e., expectations that are revised in case of a disappointment [15]. A particular algorithm by which adaptive expectations can be learned and updated from actual interactions is given in [14]. For reasons of limited space, we refer to the original publications for details. In any case, this process might involve dealing incompatible beliefs, and will hence have to be combined with appropriate mechanisms for belief update or belief revision.

4 CONCLUSION

Information in open environments emerges from a potentially large number of competing goals and viewpoints and can be both unreliable and inconsistent. Moreover, a commonly agreed “truth”, or the most basic laws governing reasonable ways to come to an agreement, might not exist. Moving towards a semantically rich formalisation of *opinions* must therefore be a core concern of a strictly communication-oriented paradigm of knowledge representation and distributed AI. This has been the motivation underlying the work described here. Future research will have to concentrate on the application of our approach in real-world domains, and on the integration with the closely related approach of *grounding* in discourse and dialogue games [5].

ACKNOWLEDGEMENTS

We would like to thank Andreas Herzig for valuable discussions on the topic of this paper and the anonymous reviewers for helpful comments. Part of this material is based upon work supported by the Deutsche Forschungsgemeinschaft under grant BR 609/13-1.

A New Semantics for the FIPA Agent Communication Language based on Social Attitudes

Benoit Gaudou¹ and Andreas Herzig¹ and Dominique Longin¹ and Matthias Nickles²

Abstract. One of the most important aspects of the research on agent interaction is the definition of *agent communication languages* (ACLs), and the specification of a proper formal semantics of such languages is a crucial prerequisite for the usefulness and acceptance of artificial agency. Nevertheless, those ACLs which are still mostly used, especially the standard FIPA-ACL, have a communication act semantics in terms of the participating agents' *mental attitudes* (viz. beliefs and intentions), which are in general undeterminable from an external point of view due to agent autonomy. In contrast, semantics of ACLs based on *commitments* are fully verifiable, but not sufficiently formalized and understood yet. In order to overcome this situation, we propose a FIPA-ACL semantics which is fully verifiable, fully formalized, lean and easily applicable. It is based on *social attitudes* represented using a *logic of grounding* in straightforward extension of the BDI agent model.

1 Introduction

The design of agent communication languages (ACLs) has attracted a lot of attention during the last years. Such languages are mostly based on Searle and Vanderveken's speech act theory [9], and are not only relevant for applications involving real software agents or robots, but also for other software entities which need to communicate, like web services.

Among the different existing ACLs, FIPA-ACL is still the most important standard, subsets of which are widely used in agent interaction protocols. FIPA-ACL is semantically rich, and the concepts involved are quite intuitive.

Nevertheless, FIPA-ACL has a feature that has often been criticized in the literature, viz. that the semantics of communication acts (CAs) is defined in terms of the agents' mental states. For example, when agent i informs agent j that φ , then the (rational) effect is that agent j starts to believe φ . In order for such an effect to obtain some hypotheses have to be made; but even in such contexts j is autonomous and might not adopt φ , and in any case i or other agents and the system designer can never verify whether this is the case or not. This is especially felt as being too strong in open environments with black- or gray-box agents where we don't even want to ascribe mental attitudes to other agents.

In contrast, those semantics based on the concept of social commitments [10] is verifiable because they are only based on what has been communicated and the commitments the agents have made by doing that (instead of the beliefs and intentions that are "behind"

these commitments and that have caused them). The drawback here is that the existing approaches are only semi-formal, in particular because there is no consensus on what "being committed" actually means. As a consequence, they are rarely used in practice up to now.

The aim of this paper is to resolve the problems of FIPA's CA semantics without loosing its benefits. We propose a novel semantics avoiding the strong hypotheses of the original semantics by "lifting" the BDI-based FIPA semantics to the social level. We do so by replacing the usual private mental attitudes of BDI logics by *public* mental attitudes, i.e. attitudes that have been made public through communication (*social attitudes*). More precisely, our semantics is based on an unified and extended approach to the concept of *communication attitudes (ostensible beliefs and intentions)* [7] and the more or less equivalent concept of *grounding*³ [5]. For example, the effect of an informing-that- p act is that it is public that the sender believes that p . This does not mean that the sender really believes that p , but only hinders him to subsequently inform that $\neg p$, or to inform that he ignores whether p .

The major benefits of our new semantics are the following:

- It is verifiable, and suitable even for truly autonomous, possibly malevolent agents.
- It is fully formalized.
- It is based on a straightforward extension of BDI, and therefore relatively lightweight.
- It can easily be adapted to similar ACLs, e.g. the widely used KQML/KIF.
- It generalizes the single-addressee FIPA acts to groups of agents, and it distinguishes the group of addressees from the group of bystanders (overhears), and thus refines FIPA's acts.

All in all, we aim at an agent communication semantics that eliminates the major shortcomings of the still predominant mentalist approaches to ACL semantics while being "upward compatible" to the standard FIPA semantics and similar approaches, lean, and formally well founded.

The remainder of this paper is organized as follows: The next section provides a short account of the logical framework that we have chosen as a formal foundation of our approach. Section 3 presents the new semantics, and Section 4 illustrates our approach by means of a case study. Section 5 concludes.

2 A logic of grounding

In this section we briefly present the logic of belief, intention, action, and grounding defined in [5], that is based on Cohen and

¹ Université Paul Sabatier, IRIT, Toulouse, email: gaudou.herzig.longin@irit.fr

² Technical University of Munich, email: nickles@informatik.tu-muenchen.de

³ We use the term *grounding* as Traum [11], i.e. it refers to "the process of adding to the common ground between conversational agent".

Levesque's [2]. AGT is a finite set of agents, ACT is a set of actions, $ATM = \{p, q, \dots\}$ is the set of atomic formulas. Complex formulas are denoted by φ, ψ, \dots . A model \mathcal{M} is a 5-tuple that is made up of: a set of possible worlds W ; a mapping

$$\mathcal{V} : W \longrightarrow (ATM \longrightarrow \{0, 1\})$$

associating a valuation \mathcal{V}_w to every $w \in W$; a mapping

$$\mathcal{A} : ACT \longrightarrow (W \longrightarrow 2^W)$$

associating actions $\alpha \in ACT$ and worlds $w \in W$ with the set of worlds resulting from the execution of α in w ; a mapping

$$\mathcal{G} : (2^{AGT} \setminus \emptyset) \longrightarrow (W \longrightarrow 2^W)$$

associating sets of agents $I \subseteq AGT$ and worlds $w \in W$ with the set of worlds that are publicly possible for the group I at w (the worlds that are compatible with what has been uttered in I 's presence); and finally the mapping

$$\mathcal{I} : AGT \longrightarrow (W \longrightarrow 2^{2^W})$$

associating every $i \in AGT$ and world w with the set of propositions (alias sets of worlds) that are intended by i . (The \mathcal{I}_i are neighborhood functions in Chellas' sense [1].)

The logical language contains modal operators of action $After_\alpha$ and $Before_\alpha$, for every $\alpha \in ACT$, modal operators of groundedness G_I for every group I , and modal operators of intention Int_i for every agent $i \in AGT$.

The formula $After_\alpha \varphi$ reads “ φ is true after every execution of the action α ”, and $Before_\alpha \varphi$ reads “ φ is true before every execution of the action α ”. Semantically, $w \models After_\alpha \varphi$ iff $w' \models \varphi$ for each $w' \in \mathcal{A}_\alpha(w)$, and $w \models Before_\alpha \varphi$ iff $w' \models \varphi$ for each w' such that $w \in \mathcal{A}_\alpha(w')$. The logic of $After_\alpha$ and $Before_\alpha$ is the tense logic K^t, i.e. standard normal modal logic K plus the conversion axioms $\varphi \rightarrow Before_\alpha \neg After_\alpha \neg \varphi$ and $\varphi \rightarrow After_\alpha \neg Before_\alpha \neg \varphi$. The abbreviation $Done_\alpha \varphi \stackrel{\text{def}}{=} \neg Before_\alpha \neg \varphi$ reads “ α has just been done before which φ was true”. We note $Done(\alpha) \stackrel{\text{def}}{=} Done_\alpha \top$ for convenience. Moreover, $Before_{\alpha \cup \alpha'} \varphi$ abbreviates $Before_\alpha \varphi \wedge Before_{\alpha'} \varphi$. (Hence $Done(\alpha \cup \alpha')$ stands for $Done(\alpha) \vee Done(\alpha')$.)

$G_I \varphi$ reads “it is grounded for group I that φ is true”, or for short: “ φ is grounded for I ”. When I is a singleton, $G_{\{i\}} \varphi$ means that for agent i , φ is grounded. In this (and only in this) degenerated case ‘public’ grounding is the same as private belief. We write $G_i \varphi$ for $G_{\{i\}} \varphi$. The accessibility relations of grounding operators must satisfy the constraints for the standard normal modal logic KD (seriality), plus the following, for groups I, I' such that $I' \subseteq I$:

- (i) if $u\mathcal{G}_{I'}v$ and $v\mathcal{G}_Iw$ then $u\mathcal{G}_Iw$
- (ii) if $u\mathcal{G}_{I'}v$ and $u\mathcal{G}_Iw$ then $v\mathcal{G}_Iw$
- (iii) if $u\mathcal{G}_Iv$ and $v\mathcal{G}_{I'}w_1$ then there is w_2 such that $u\mathcal{G}_Iw_2$ and $V(w_1) = V(w_2)$
- (iv) $\mathcal{G}_I \subseteq \bigcup_{i \in I} \mathcal{G}_i \circ \mathcal{G}_i$

Constraint (i) stipulates that subgroups are aware of what is grounded in the group: whenever w is a world for which it is grounded for I' that all I -grounded propositions hold in w , then all I -grounded propositions indeed hold in w . This is a kind of *attention* property: each subgroup participating in a conversation is aware of what is grounded in the group. Similarly (ii) expresses that subgroups are aware of what is ungrounded in the group, too. (i) and (ii) correspond to the axioms of strong rationality (SR+) and (SR-):

$$G_I \varphi \rightarrow G_{I'} G_I \varphi \quad (\text{SR+})$$

$$\neg G_I \varphi \rightarrow G_{I'} \neg G_I \varphi \quad (\text{SR-})$$

which express that if a proposition φ is grounded (resp. ungrounded) for a group I then it is grounded for each subgroup that φ is grounded

(resp. ungrounded) for I ⁴.

(iii) stipulates that for every objective proposition grounded for I it is publicly established for I that each subgroup of I is grounded on it (which does not imply that it is grounded for the latter): whenever w is a world for which all propositions grounded for I' are grounded for I , then all those propositions are indeed grounded for I in w . It validates the axiom (WR)

$$G_I \varphi \rightarrow G_I G_{I'} \varphi, \text{ for } \varphi \text{ objective} \quad (\text{WR})$$

which says that if the objective formula φ is grounded for a group K then it is necessarily grounded for K that for each subgroup K' the formula is grounded.⁵ Note that this does not imply that for every subgroup φ is actually grounded, i.e. (WR) does not entail $G_K \varphi \rightarrow G_{K'} \varphi$. In particular, the fact that φ is grounded for group K does not imply that the members of K believe that φ .

(iv) expresses that if it is grounded for a set I that a proposition is established for every agent then it is grounded for I , too. This corresponds to axiom (CG)

$$\left(\bigwedge_{i \in I} G_I G_i \varphi \right) \rightarrow G_I \varphi \quad (\text{CG})$$

which says that if a proposition is established for every agent in I , then it is established for the whole group I . Together, (WR) and (CG) stipulate that for objective φ we have $(\bigwedge_{k \in K} G_K G_k \varphi) \leftrightarrow G_K \varphi$. Note that $G_K \varphi$ does NOT imply $G_k \varphi$ where $k \in K$. Indeed, a proposition can be grounded in a group independently of the private belief of each agent of the group about this proposition: there is thus no sincerity hypothesis.

$Int_i \varphi$ reads “agent i intends that φ be true”. The Int_i are non-normal modal operators which only validate the rule of equivalence: $\frac{\varphi \leftrightarrow \psi}{Int_i \varphi \leftrightarrow Int_i \psi}$. They neither validate $Int_i(\varphi \wedge \varphi') \rightarrow (Int_i \varphi \wedge Int_i \varphi')$ nor $(Int_i \varphi \wedge Int_i \varphi') \rightarrow Int_i(\varphi \wedge \varphi')$.

Intentions and actions are related by the principle of intentional action saying that if α has just been performed by agent i then i had the intention to do so immediately before.

$$Before_{i:\alpha} Int_i Done(i:\alpha) \quad (\text{IA})$$

where $i:\alpha$ denotes that action α is performed by agent i .

To highlight our proposal for the semantics of grounding consider the following example. There are three agents $AGT = \{0, 1, 2\}$. Let agent 0 (privately) believe that 2 sells high-quality products, formally written $G_0 q_2$. Now suppose that in private conversation agent 0 tells 1 that the contrary is the case (for example to trigger some attitude of 1 that benefits 0). The (illocutionary) effect is $G_{\{0, 1\}} G_0 \neg q_2$. Then agent 2 joins in the conversation, and later on 0 informs 1 and 2 that q_2 : The illocutionary effect is $G_{\{0, 1, 2\}} G_0 q_2$. This illustrates that even for nested groups $\{0\} \subset \{0, 1\} \subset \{0, 1, 2\}$, mutually inconsistent states of public group belief might hold simultaneously.

3 Communication act semantics

Following and extending the ACL syntax used in [4], a single communication act (CA) is denoted as $\langle i, \text{ActName}(J, \varphi), K \rangle$, where i

⁴ In particular, we have the modal axioms (4) and (5) for G_I operators as theorems of our logic.

⁵ (WR) concerns only objective formulas, i.e. formula that does not contain any modality. If we applied (WR) to some mental states, we would restrict the agents' autonomy. For example, when an agent performs the speech act $\langle i, \text{Inform}(J, p), K \rangle$, he expresses publicly that he believes p . Thus if agent i expresses: $\langle i, \text{Inform}(J, G_J p), K \rangle$ the formula $G_K G_i G_J p$ holds, and the agents $j \in J$ cannot afterwards express that they believe $\neg p$. If he made this speech acts, the formulae $G_K G_J \neg p$ and, thanks to (WR), $G_K G_i G_J \neg p$ would hold, which is inconsistent with the above formula $G_K G_i G_J p$.

is the performing agent, J is a group of recipients (whereas FIPA only allows one addressee). $ActName$ is the name of the act (in our model not necessarily corresponding to exactly one speech act type, see below). φ is the propositional content of the act. K , which is missing in FIPA, denotes a group of attending agents who overhear the respective utterance, with $i \in K$, $J \subseteq K \setminus \{i\}$ and $J \neq \emptyset$. For a dialogue of only two agents i and j we have $J = \{j\}$ and $K = \{i, j\}$.

In the standard semantics of FIPA CAs [4] (henceforth called FIPA-S), semantics is specified by providing the *feasibility preconditions* (FPs) and the *rational effects* (REs) of single CAs. The former denote which logical conditions need to be fulfilled in order to execute the respective act, and the latter specify which conditions hold after the successful performance of that act. FPs characterize both the ability of the speaker to perform the act and the context-dependent relevance of the act (i.e., that performing the act is relevant given a certain dialogue context). In contrast, REs specify the desired and rationally-expectable direct perlocutionary effect of the utterance, i.e. what becomes true in case the perlocutionary act succeeds.

We think there are at least three reasons not to qualify a CA by its rational effect. Firstly, it is possible to desire and expect different kinds of RE of the same CA; secondly, Searle shows in [9, Sec. 2.1] that the effect of a speech act cannot be a rational (or perlocutionary) effect simply because a lot of speech acts just do not have any perlocutionary effect. He also shows that even if a speech act can have a perlocutionary effect, we can always exhibit a context where the speaker does not intend this perlocutionary effect. Thirdly, strong hypotheses (such as sincerity, competence, credibility...) must be made about the agents to enable the inference of the expected RE, which is too restrictive in our context of open multi-agent systems, possibly with conflicts and malevolent, egocentric agents...

In contrast to FIPA-S, the FPs and IEs (for illocutionary effects) in our model do not make any statement about mental attitudes, but specify the preconditions and effects in terms of groundings of group K (the public, so to say). They are chosen such that the respective communication act is both executable given all realistic preconditions, and succeeds reliably with a publicly verifiable effect. The only (self-evident) exception follows from the bridge axioms (SR_+) and (SR_-) given in the previous section, stating that an agent or subgroup of a certain group knows about the existence of the respective grounded beliefs or intentions of their group — this means merely that the agents keep track of the ongoing course of communication in terms of FPs and IEs.

In the sequel we use the term *Social Attitudes Based Semantics* (SABS) for our modelling, and will define the SABS semantics of the four primitive CAs of FIPA-ACL: *Inform*, *Request*, *Confirm* and *Disconfirm*, and we will also present the respective FIPA-S specifications for comparison. All other FIPA-CAs are macros composed of these primitives in a more or less straightforward manner.

3.1 Inform: Asserting information

We start with the FIPA-S version of the semantics:

$$\langle i, \text{Inform}_{\text{FIPA}}(j, \varphi), K \rangle$$

FP: $\text{Bel}_i \varphi \wedge \neg \text{Bel}_i (\text{Bel}_j \varphi \vee \text{Bel}_j \neg \varphi \vee U_j \varphi \vee U_j \neg \varphi)$

RE: $\text{Bel}_j \varphi$

At this, $U_j \varphi$ denotes that agent j is uncertain about φ , but thinks that φ is more likely than $\neg \varphi$. The terms “uncertain” and “more likely” are not precisely defined in [4]. The essential preconditions of *Inform* in the FIPA-S are thus that agent i truthfully believes what he asserts,

and that the receiver does not have any definite opinion about the asserted proposition. Whereas the former condition is obviously unrealistic given a truly autonomous agent i , the latter disallows (problematically) the use of *Inform* to convince the addressee. We consider the latter usage as crucial e.g. in the context of computational argumentation and argumentation-based negotiation. We could introduce an additional conviction-act extending the syntax, or try to emulate it with a construct like *Request(Inform(φ))*, but this would not only be unnecessary and inelegant, but would also blur the fact that there exists a continual transition from “pure information” to conviction. It is also not clear why the absence of an opinion shall be a realistic precondition for the success of an information act, or, conversely, why the existence of an opinion (which could be very weak, or “by default” only) shall hinder the receiver to adopt the asserted information (e.g., consider that the addressee might trust the sender more than herself).

The rational effect of *Inform* in FIPA-S is simply that the addressed agent believes what she has been told (in case the act succeeds). Of course, this effect cannot be verified with autonomous agents. Even if it could be verified, it would be too strong and unlikely. Moreover it is not verifiable that the informing agent (truthfully) intends the adoption of a certain belief.

These concerns lead to the following SABS semantics:

$$\langle i, \text{Inform}(J, \varphi), K \rangle$$

FP: $\neg G_K G_J \varphi \wedge \neg G_K \text{Int}_i G_J \varphi \wedge \neg G_K \neg G_i \varphi$

IE: $G_K G_i \varphi$

In the FP, $\neg G_K G_J \varphi$ specifies that the addressed agent has not expressed φ before (with group K attending), corresponding to the $\neg \text{Bel}_i \text{Bel}_j \varphi$ part of the FIPA-S FP (the *relevance precondition*). It simply expresses that asserting an information would be unnecessary if the receiver has already expressed its belief in it. However, our new FP does not demand that group J has no opinion at all about φ , allowing to use *Inform* also to *convince* J in case this group has already expressed its disbelief in φ earlier. $\neg G_K \text{Int}_i G_J \varphi$ in FP effectively demands that agent i did not assert this information using an assertive communication act before, which is also an aspect of the relevance precondition. $\neg G_K \neg G_i \varphi$ ensures that the asserted opinions of agent i are mutually consistent. (The latter is a precondition of *rationality*).

In the IE, $G_K G_i \varphi$ denotes that with asserting φ , it becomes grounded that agent i believes that φ , regardless if she does so privately (i.e., mentally) or not.

As usual we define $\langle i, \text{InformIf}(J, p), K \rangle$ as an abbreviation of $\langle i, \text{Inform}(J, p), K \rangle \cup \langle i, \text{Inform}(J, \neg p), K \rangle$. Hence $\text{Done}(\langle i, \text{InformIf}(J, p), K \rangle) \equiv \text{Done}(\langle i, \text{Inform}(J, p), K \rangle) \vee \text{Done}(\langle i, \text{Inform}(J, \neg p), K \rangle)$.

However, in many cases, we can safely assume that group J immediately starts to publicly believe the asserted information, namely when this group apparently trusts the uttering agent in regard to this information. (A notorious exception are exam situations.) An important particular case is expressed by the following axiom, for $J \subseteq K$ and $\alpha = \langle i, \text{InformIf}(J, \varphi), K \rangle$:⁶

$$(G_K \text{Done}_\alpha \bigwedge_{j \in J} \text{Int}_j \text{Done}(\alpha)) \rightarrow G_K G_J \varphi \quad (1)$$

This specifies that if an agent has requested a certain information before from agent i in form of a closed question (like with “Is it raining

⁶ We here consider that the group J have asked i to publicly declare that φ . (And not each j , as it would be the case if α was $\langle i, \text{InformIf}(\{j\}, \varphi), K \rangle$ in (1).)

outside?"'), it becomes grounded that she believes the answer.⁷

3.2 Request: Requesting an action to be done

Again, we state the FIPA version of the semantics first:

$$\langle i, \text{Request}_{\text{FIPA}}(j, \alpha), K \rangle$$

FP: $FP(\alpha)[i \setminus j] \wedge Bel_i \text{Agent}(j, \alpha) \wedge Bel_i \neg PG_j \text{Done}(\alpha)$

RE: $\text{Done}(\alpha)$

Here, α is an action expression, $FP(\alpha)[i \setminus j]$ denotes the part of the feasibility preconditions of action α where the mental attitudes are those of agent i . $\text{Agent}(j, \alpha)$ states that j is the only agent that ever performs, has performed or will perform α , and $PG_j \text{Done}(\alpha)$ denotes that $\text{Done}(\alpha)$ (i.e., action α has just been performed successfully) is a *persistent goal* [8] of agent j . The RE just specifies that the intended perlocutionary effect of this communication act is to get α done.

Obviously, these specifications again require strong assumptions about mental properties, which are equally problematic as in the case of *Inform*. In addition, $\text{Agent}(j, \alpha)$ reduces the scope of this communication act unnecessarily, disallowing concurrent intention of j to perform the same action herself.

As in our formalism the propositional content of a CA is a formula, a request to do action α is defined as a request that $\text{Done}(\alpha)$ be true. Furthermore, in our case the addressee of a speech act is a group of agents. Thus a request is addressed to each agent of the group in the aim that either at least one agent of the group do the requested action ("open that door"), or each agent of the group do it ("clean that room", addressed to a group of children). $i : \alpha$: denotes that i is the author of action α (making superfluous the FIPA *Agent* predicate). We thus have two kinds of request (whereas there is only one in FIPA):

$$\langle i, \text{RequestSome}(J, J:\alpha), K \rangle \stackrel{\text{def}}{=}$$

$$\langle i, \text{RequestSome}(J, \bigvee_{j \in J} \text{Done}(j:\alpha)), K \rangle$$

FP: $\left(\neg G_K \bigvee_{j \in J} \text{Int}_j \text{Done}(j:\alpha) \right) \wedge \neg G_K \neg \text{Int}_i \left(\bigvee_{j \in J} \text{Done}(j:\alpha) \right)$

IE: $G_K \text{Int}_i \left(\bigvee_{j \in J} \text{Done}(j:\alpha) \right) \wedge G_K \neg G_i \left(\bigvee_{j \in J} \text{Int}_j \text{Done}(j:\alpha) \right)$

So our FP specifies that is not grounded that at least one of the agents in J intends to achieve α already (relevance precondition), and that it is not grounded that agent i does not intend $\text{Done}(\alpha)$ (rationality precondition). The IE is also straightforward: the act results in the grounding that agent i intends that at least one agent in J intends $\text{Done}(\alpha)$ become true, and that i does not believe that one agent in J intends $\text{Done}(\alpha)$.

Second, we define:

$$\langle i, \text{RequestEach}(J, J:\alpha), K \rangle \stackrel{\text{def}}{=}$$

$$\langle i, \text{RequestEach}(J, \bigwedge_{j \in J} \text{Done}(j:\alpha)), K \rangle$$

FP: $\left(\neg G_K \bigwedge_{j \in J} \text{Int}_j \text{Done}(j:\alpha) \right) \wedge \neg G_K \neg \text{Int}_i \left(\bigwedge_{j \in J} \text{Done}(j:\alpha) \right)$

IE: $G_K \text{Int}_i \left(\bigwedge_{j \in J} \text{Done}(j:\alpha) \right) \wedge G_K \neg G_i \left(\bigwedge_{j \in J} \text{Int}_j \text{Done}(j:\alpha) \right)$

which specifies that i intends that each agent of J perform the requested action α . For compatibility reasons, we also define

$$\langle i, \text{Request}(J, \alpha), K \rangle \stackrel{\text{def}}{=}$$

$$\langle i, \text{RequestSome}(J, J:\alpha), K \rangle$$

FIPA also defines the acts *Confirm* (for the confirmation of an uncertain information) and its pendant *Disconfirm* as primitives. But since our *Inform* semantics has an adequately weakened FP that does not require that the asserted information is not uncertain, *Confirm* and *Disconfirm* simply map to *Inform* in our semantics.

4 Case study

In order to demonstrate the properties and the application of our approach, this section presents a brief case study in form of an *agent purchase negotiation* scenario. In particular, we aim to demonstrate the following crucial features of SABS, all not being present in FIPA-S or, by principle, any other BDI-based ACL semantics:

- Pre- and post-conditions of communication acts being only dependent from publicly observable agent behavior, thus being fully verifiable;
- Communication acts with contents being inconsistent with the beliefs and intentions of the participating agents;
- Communication acts addressing groups of agents;
- Multiple communication acts uttered by the same sender, but with mutually inconsistent contents (even towards nested groups);
- Persuasive Inform-acts.

In addition, the example shows how the logging of the grounding state of the negotiation dialogue can replace *commitment stores*, which are usually used to keep track of the various commitments arising during the course of an interaction (like to sell or buy a product). In contrast, by the use of our semantics we obtain the publicly available information about the state of commitment of the participating agents directly in terms of logical post-conditions of communication acts, namely publicly expressed intentions. As explained in Section 1, we consider this to be simpler and formally clear compared to the use of social commitments in the sense of [10].

The interaction roughly follows protocols for *purchase negotiation dialogue games* as known from, e.g., [6], but omitting several details of such protocols which are not relevant for our demonstrative purposes (like the specification of selling options in detail). Also, such protocols often make use of proprietary negotiation locutions, whereas we get along with FIPA-ACL constructs, since in our context, no acts not contained in FIPA-ACL (like the "Promise" and "Threaten" acts in protocols for argumentation-based negotiation) are required. Nevertheless, our scenario is clearly beyond FIPA's *contract net* specification [3].

Our scenario consists of four agents $MAS = \{s_1, s_2, b_1, b_2\}$, representing potential car sellers and customers. In the discourse universe exists two instances θ_1 and θ_2 of some car type θ (e.g., specimen of the Alfa Romeo 159).

We present now the interaction course, consisting of sequential steps in the following form. Note that the interaction course consists of multiple interlaced conversations among different sender/receiver pairs and different overhears (i.e., different "publics" so to say). In particular, agent b_2 is involved in two selling dialogues at the same time.

*Utterance no. sender→receiver: Descriptive act title
Message⁸*

⁷ The intention Int_j can be triggered with FIPA's *QueryIf* act. The schema would work analogously for $\langle i, \text{InformIf}(\{j\}, \neg\varphi), K \rangle$.

⁸ Using syntactical macros according to [4]. Only in case the message primitives are semantically relevant in our context, the respective macros are expanded.

Effect (optionally) gives the effect of the act in terms of grounded formulas, according to SABS and the axioms in Section 2 (so this may go beyond the direct IE).

In contrast, *Private information* (*PI*) optionally unveils relevant mental attitudes before or after an act has been uttered and understood by the respective agents. The PIs are not determined by preceding communication acts, due to agent autonomy. They are also of course usually not available to observers, and just given for explanatory purposes.

U1 $s_1 \rightarrow \{b_1, b_2\}$: Initialize dialogue

$\langle s_1, \text{RequestEach}(\{b_1, b_2\}, \text{enterDialogue}(\theta_1)), \{s_1, b_1, b_2\} \rangle$

U2 $b_1 \rightarrow \{s_1\}$: Enter dialogue

$\langle b_1, \text{Agree}(\{s_1\}, \text{enterDialogue}(\theta_1)), \{s_1, b_1, b_2\} \rangle$

U3 $b_2 \rightarrow \{s_1\}$: Enter dialogue

$\langle b_2, \text{Agree}(\{s_1\}, \text{enterDialogue}(\theta_1)), \{s_1, b_1, b_2\} \rangle$

U4 $s_2 \rightarrow \{b_2\}$: Initialize dialogue

$\langle s_2, \text{Request}(\{b_2\}, \text{enterDialogue}(\theta_2)), \{s_2, b_2\} \rangle$

U5 $b_2 \rightarrow \{s_2\}$: Enter dialogue

$\langle b_2, \text{Agree}(\{s_2\}, \text{enterDialogue}(\theta_2)), \{s_2, b_2\} \rangle$

$P_{I_{s_1}}$: Bel_{s₁} discounts

U6 $s_1 \rightarrow \{b_1, b_2\}$: Information about discount

$\langle s_1, \text{Inform}(\{b_1, b_2\}, \neg \text{discounts}), \{s_1, b_1, b_2\} \rangle$

Effect:

$G_{\{s_1, b_1, b_2\}} G_{s_1} \neg \text{discounts}$

$\wedge G_{\{s_1, b_1, b_2\}} \text{Int}_{s_1} G_{\{b_1, b_2\}} \neg \text{discount}$

Seller s_1 asserts that no discounts can be given while believing ($P_{I_{s_1}}$: Bel_{s₁} discount) that the opposite is true (there might be the company policy that discounts should be given, but that might reduce the seller's individual profit).

U7 $s_1 \rightarrow \{b_2\}$: Information about discount

$\langle s_1, \text{Inform}(\{b_2\}, \text{discounts}), \{s_1, b_2\} \rangle$

Effect:

$G_{\{s_1, b_2\}} G_{s_1} \text{discounts}$

$\wedge G_{\{s_1, b_2\}} \text{Int}_{s_1} G_{b_2} \text{discount}$

While seller s_1 informed group $\{b_1, b_2\}$ that there would be no price discounts, he informs customer b_2 that this is not true (likely because s_1 thinks that b_2 is a valued customer whereas b_1 is not).

U8 $b_2 \rightarrow \{s_1\}$: Query if car type has high accident rate

$\langle b_2, \text{Request}(\{s_1\}, \text{InformIfAccidentRateHigh}), \{s_1, b_2\} \rangle$

Effect:

$G_{\{s_1, b_2\}} \text{Int}_{b_2} \text{Done}(s_1 : \text{InformIfAccidentRateHigh}) \wedge$

$G_{\{s_1, b_2\}} \neg G_{b_2} \text{Int}_{s_1} \text{Done}(s_1 : \text{InformIfAccidentRateHigh}),$ with
 $\text{InformIfAccidentRateHigh} \stackrel{\text{def}}{=}$

$\langle s_1, \text{InformIf}(\{b_2\}, \text{accidentRateHigh}(\theta)), \{s_1, b_2\} \rangle$

$P_{I_{s_1}}$: Bel_{s₁} accidentRateHigh(θ_1)

U9 $s_1 \rightarrow \{b_2\}$: Information about accident rate

$\langle s_1, \text{Inform}(\{b_2\}, \neg \text{accidentRateHigh}(\theta)), \{s_1, b_2\} \rangle$

Effect:

$G_{\{s_1, b_2\}} G_{s_1} \neg \text{accidentRateHigh}(\theta)$

$\wedge G_{\{s_1, b_2\}} G_{b_2} \neg \text{accidentRateHigh}(\theta)$

Note that due to her closed question before and axiom 1 it becomes immediately grounded that b_2 believes the asserted information.

In addition, b_2 privately believes this information also (see PI_{b_2} below), but revises this later.

Seller s_1 asserted $\neg \text{accidentRateHigh}(\theta_1)$ though thinking the opposite.

PI_{b_2} : Bel_{b₂} $\neg \text{accidentRateHigh}(\theta)$

U10 $b_2 \rightarrow \{s_2\}$: Query if car type has high accident rate

$\langle b_2, \text{Request}(\{s_2\}, \text{InformIfAccidentRateHigh}), \{s_2, b_2\} \rangle$

U11 $s_2 \rightarrow \{b_2\}$: Information about accident-damage

$\langle s_2, \text{Inform}(\{b_2\}, \text{accidentRateHigh}(\theta)), \{s_2, b_2\} \rangle$

Again, b_2 publicly believes the information, and trusts it for some reason privately more than the information given by seller s_1 earlier. Nevertheless, $G_{\{s_1, b_2\}} G_{b_2} \neg \text{accidentRateHigh}(\theta_1)$ remains true.

PI_{b_2} : Bel_{b₂} accidentRateHigh(θ)

U12 $b_2 \rightarrow \{s_2\}$: Propose to buy at a certain price

$\langle b_2, \text{Propose}(\{s_2\}, \text{buy}(\theta_2, 10000\mathcal{L})), \{s_2, b_2\} \rangle$

U13 $s_2 \rightarrow \{b_2\}$: Accept proposal

$\langle s_2, \text{AcceptProposal}(\{b_2\}, \text{buy}(\theta_2, 10000\mathcal{L})), \{s_2, b_2\} \rangle$

Effect (with the previous act):

$G_{\{s_2, b_2\}} \text{Int}_{b_2} \text{buy}(\theta_2, 10000\mathcal{L})$ (i.e., b_2 is publicly committed to buy θ_2 at the price of $10000\mathcal{L}$ now).

5 Conclusion

We've proposed a novel approach to the semantics of agent communication, based on verifiable social attitudes which are triggered by observable communication acts. We believe that this approach is more adequate for open systems in comparison both to traditional mentalistic and commitment-based semantics, as it allows to analyze the meaning of messages on the social level without the need to know about mental agent properties or architectural details, while being easily comprehensible, downward compatible to BDI, and fully formalized. A subject of future work in this respect will be the practical application of our approach in the field of interaction protocols, and argumentation and negotiation frameworks.

Contouring of Knowledge for Intelligent Searching for Arguments

Anthony Hunter¹

Abstract. A common assumption for logic-based argumentation is that an argument is a pair $\langle \Phi, \alpha \rangle$ where Φ is a minimal subset of the knowledgebase such that Φ is consistent and Φ entails the claim α . Different logics are based on different definitions for entailment and consistency, and these give us different options for argumentation. For a variety of logics, in particular for classical logic, there is a need to develop intelligent techniques for generating arguments. Since building a constellation of arguments and counterarguments involves repeatedly querying a knowledgebase, we propose a framework based on what we call “contours” for storing information about a knowledgebase that provides boundaries on what is provable in the knowledgebase. Using contours allows for more intelligent searching of a knowledgebase for arguments and counterarguments.

1 INTRODUCTION

Argumentation is a vital aspect of intelligent behaviour by humans. To capture this, there are a number of proposals for logic-based formalisations of argumentation (for reviews see [14, 7]). These proposals allow for the representation of arguments for and against some conclusion, and for attack relationships between arguments. In a number of key examples of argumentation systems, an argument is a pair where the first item in the pair (the support) is a minimal consistent set of formulae that proves the second item (the claim) which is a formula (see for example [3, 10, 4, 1, 11, 5]).

Problemsatically, finding arguments and counterarguments involves much searching of a knowledgebase to ensure they are all found (exhaustiveness), and to ensure each of them has a minimal consistent set of premises entailing the claim (correctness). Proof procedures and algorithms have been developed for finding preferred arguments from a knowledgebase following for example Dung’s preferred semantics (see for example [13, 12, 6, 8, 9]). However, these procedures and algorithms do not offer any ways of ameliorating the cost of repeatedly querying a knowledgebase as part of the process of ensuring exhaustiveness and correctness. In this paper, we address this computational inefficiency by presenting a new technique for intelligently searching a knowledgebase for arguments and counterarguments.

2 LOGICAL ARGUMENTATION

In this section we review an existing proposal for logic-based argumentation [4]. We consider a classical propositional language with deduction denoted by \vdash . We use $\alpha, \beta, \gamma, \dots$ to denote formulae and $\Delta, \Phi, \Psi, \dots$ to denote sets of formulae.

For the following definitions, we first assume a knowledgebase Δ (a finite set of formulae) and use this Δ throughout. We further assume that every subset of Δ is given an enumeration $\langle \alpha_1, \dots, \alpha_n \rangle$ of its elements, which we call its canonical enumeration. This really is not a demanding constraint: In particular, the constraint is satisfied whenever we impose an arbitrary total ordering over Δ . Importantly, the order has no meaning and is not meant to represent any respective importance of formulae in Δ . It is only a convenient way to indicate the order in which we assume the formulae in any subset of Δ are conjoined to make a formula logically equivalent to that subset.

The paradigm for the approach is a large repository of information, represented by Δ , from which arguments can be constructed for and against arbitrary claims. Apart from information being understood as declarative statements, there is no a priori restriction on the contents, and the pieces of information in the repository can be of arbitrary complexity. Therefore, Δ is not expected to be consistent. It need even not be the case that every single formula in Δ is consistent.

The framework adopts a very common intuitive notion of an argument. Essentially, an argument is a set of relevant formulae that can be used to classically prove some claim, together with that claim. Each claim is represented by a formula.

Definition 1. An argument is a pair $\langle \Phi, \alpha \rangle$ such that: (1) $\Phi \subseteq \Delta$; (2) $\Phi \not\vdash \perp$; (3) $\Phi \vdash \alpha$; and (4) there is no $\Phi' \subset \Phi$ such that $\Phi' \vdash \alpha$. We say that $\langle \Phi, \alpha \rangle$ is an argument for α . We call α the **claim** of the argument and Φ the **support** of the argument (we also say that Φ is a support for α).

Example 1. Let $\Delta = \{\alpha, \alpha \rightarrow \beta, \gamma \rightarrow \neg\beta, \gamma, \delta, \delta \rightarrow \beta, \neg\alpha, \neg\gamma\}$. Some arguments are $\langle \{\alpha, \alpha \rightarrow \beta\}, \beta \rangle$, $\langle \{\neg\alpha\}, \neg\alpha \rangle$, $\langle \{\alpha \rightarrow \beta\}, \neg\alpha \vee \beta \rangle$, and $\langle \{\neg\gamma\}, \delta \rightarrow \neg\gamma \rangle$.

Arguments are not independent. In a sense, some encompass others (possibly up to some form of equivalence). To clarify this requires a few definitions as follows.

Definition 2. An argument $\langle \Phi, \alpha \rangle$ is **more conservative** than an argument $\langle \Psi, \beta \rangle$ iff $\Phi \subseteq \Psi$ and $\beta \vdash \alpha$.

Example 2. $\langle \{\alpha\}, \alpha \vee \beta \rangle$ is more conservative than $\langle \{\alpha, \alpha \rightarrow \beta\}, \beta \rangle$.

Some arguments directly oppose the support of others, which amounts to the notion of an undercut.

Definition 3. An **undercut** for an argument $\langle \Phi, \alpha \rangle$ is an argument $\langle \Psi, \neg(\phi_1 \wedge \dots \wedge \phi_n) \rangle$ where $\{\phi_1, \dots, \phi_n\} \subseteq \Phi$.

Example 3. Let $\Delta = \{\alpha, \alpha \rightarrow \beta, \gamma, \gamma \rightarrow \neg\alpha\}$. Then, $\langle \{\gamma, \gamma \rightarrow \neg\alpha\}, \neg(\alpha \wedge (\alpha \rightarrow \beta)) \rangle$ is an undercut for $\langle \{\alpha, \alpha \rightarrow \beta\}, \beta \rangle$. A less conservative undercut for $\langle \{\alpha, \alpha \rightarrow \beta\}, \beta \rangle$ is $\langle \{\gamma, \gamma \rightarrow \neg\alpha\}, \neg\alpha \rangle$.

¹ UCL Department of Computer Science, London, UK. Email: a.hunter@cs.ucl.ac.uk

Definition 4. $\langle \Psi, \beta \rangle$ is a **maximally conservative undercut** of $\langle \Phi, \alpha \rangle$ iff $\langle \Psi, \beta \rangle$ is an undercut of $\langle \Phi, \alpha \rangle$ such that no undercuts of $\langle \Phi, \alpha \rangle$ are strictly more conservative than $\langle \Psi, \beta \rangle$ (that is, for all undercuts $\langle \Psi', \beta' \rangle$ of $\langle \Phi, \alpha \rangle$, if $\Psi' \subseteq \Psi$ and $\beta \vdash \beta'$ then $\Psi \subseteq \Psi'$ and $\beta' \vdash \beta$).

The value of the following definition of canonical undercut is that we only need to take the canonical undercuts into account. This means we can justifiably ignore the potentially very large number of non-canonical undercuts.

Definition 5. An argument $\langle \Psi, \neg(\phi_1 \wedge \dots \wedge \phi_n) \rangle$ is a **canonical undercut** for $\langle \Phi, \alpha \rangle$ iff it is a maximally conservative undercut for $\langle \Phi, \alpha \rangle$ and $\langle \phi_1, \dots, \phi_n \rangle$ is the canonical enumeration of Φ .

An argument tree describes the various ways an argument can be challenged, as well as how the counter-arguments to the initial argument can themselves be challenged, and so on recursively.

Definition 6. A complete argument tree for α is a tree where the nodes are arguments such that

1. The root is an argument for α .
2. For no node $\langle \Phi, \beta \rangle$ with ancestor nodes $\langle \Phi_1, \beta_1 \rangle, \dots, \langle \Phi_n, \beta_n \rangle$ is Φ a subset of $\Phi_1 \cup \dots \cup \Phi_n$.
3. The children nodes of a node N consist of all canonical undercuts for N that obey 2.

The second condition in Definition 6 ensures that each argument on a branch has to introduce at least one formula in its support that has not already been used by ancestor arguments. This is meant to avoid making explicit undercuts that simply repeat over and over the same reasoning pattern except for switching the role of some formulae (e.g. in mutual exclusion, stating that α together with $\neg\alpha \vee \neg\beta$ entails $\neg\beta$ is exactly the same reasoning as expressing that β together with $\neg\alpha \vee \neg\beta$ entail $\neg\alpha$, because in both cases, what is meant is that α and β exclude each other). As a notational convenience, in examples of argument trees the \diamond symbol is used to denote the claim of an argument when that argument is a canonical undercut (no ambiguity arises as proven in [4]).

Example 4. Let $\Delta = \{\alpha \vee \beta, \alpha \rightarrow \gamma, \neg\gamma, \neg\beta, \delta \leftrightarrow \beta\}$. For this, two argument trees for the claim $\alpha \vee \neg\delta$ are given.

$$\begin{array}{cc} \langle \{\alpha \vee \beta, \neg\beta\}, \alpha \vee \neg\delta \rangle & \langle \{\delta \leftrightarrow \beta, \neg\beta\}, \alpha \vee \neg\delta \rangle \\ \uparrow & \uparrow \\ \langle \{\alpha \rightarrow \gamma, \neg\gamma\}, \diamond \rangle & \langle \{\alpha \vee \beta, \alpha \rightarrow \gamma, \neg\gamma\}, \diamond \rangle \end{array}$$

A complete argument tree is an efficient representation of the counterarguments, counter-counterarguments, ... Furthermore, if Δ is finite, there is a finite number of argument trees with the root being an argument with consequent α that can be formed from Δ , and each of these trees has finite branching and a finite depth (the finite tree property). Note, also the definitions presented in this section can be used directly with first-order classical logic, so Δ and α are from the first-order classical language. Interestingly, the finite tree property also holds for the first-order case [5].

3 MOTIVATION FOR CONTOURING

We now turn to automating the construction of arguments and counterarguments. It is tempting to think that automated theorem proving technology can do more for us than it is guaranteed to. For each argument, we need a minimal set of formulae that proves the claim.

An automated theorem prover (an ATP) may use a “goal-directed” approach, bringing in extra premises when required, but they are not guaranteed to be minimal. For example, supposing we have a knowledgebase $\{\alpha, \alpha \wedge \beta\}$, for proving $\alpha \wedge \beta$, the ATP may start with the premise α , then to prove β , a second premise is required, which would be $\alpha \wedge \beta$, and so the net result is $\{\alpha, \alpha \wedge \beta\} \vdash \alpha \wedge \beta$, which does not involve a minimal set of premises. In addition, an ATP is not guaranteed to use a consistent set of premises since by classical logic it is valid to prove anything from an inconsistency.

So if we seek arguments for a particular claim δ , we need to post queries to an ATP to ensure that a particular set of premises entails δ , that the set of premises is minimal for this, and that it is consistent. So finding arguments for a claim α involves considering subsets Φ of Δ and testing them with the ATP to ascertain whether $\Phi \vdash \alpha$ and $\Phi \not\vdash \perp$ hold. For $\Phi \subseteq \Delta$, and a formula α , let $\Phi?\alpha$ denote a call (a query) to an ATP. If Φ classically entails α , then we get the answer $\Phi \vdash \alpha$, otherwise we get the answer $\Phi \not\vdash \alpha$. In this way, we do not give the whole of Δ to the ATP. Rather we call it with particular subsets of Δ . So for example, if we want to know if $\langle \Phi, \alpha \rangle$ is an argument, then we have a series of calls $\Phi?\alpha, \Phi?\perp, \Phi \setminus \{\phi_1\}?\alpha, \dots, \Phi \setminus \{\phi_k\}?\alpha$, where $\Phi = \{\phi_1, \dots, \phi_k\}$. So the first call is to ensure that $\Phi \vdash \alpha$, the second call is to ensure that $\Phi \not\vdash \perp$, the remaining calls are to ensure that there is no subset Φ' of Φ such that $\Phi' \vdash \alpha$.

We can now summarise all the queries that are posted to the ATP for finding all the arguments for α from the knowledgebase Δ . We summarise it by the set $\text{NaiveQuerying}(\Delta, \alpha)$ defined next.

Definition 7. For a knowledgebase Δ and a formula α ,

$$\text{NaiveQuerying}(\Delta, \alpha) = \{(\Phi?\alpha) \mid \Phi \subseteq \Delta\} \cup \{(\Phi?\perp) \mid \Phi \subseteq \Delta\}$$

Proposition 1. For Δ and α , if $|\Delta| = n$, then $|\text{NaiveQuerying}(\Delta, \alpha)| = 2^{n+1}$.

Clearly, by using all the queries in $\text{NaiveQuerying}(\Delta, \alpha)$, we are taking no account of any of the results that we have gained at any intermediate stage. In other words, we are not being intelligent. Yet if we want to harness automated reasoning, we need principled means for intelligently querying an ATP in order to search a knowledgebase for arguments.

Now when we think of the more difficult problem of not just finding all arguments for α , but then finding all undercuts to these arguments, and by recursion, undercuts to these undercuts. During the course of building an argument tree, there will be repeated attempts to ask the same query, and there will be repeated attempts to ask a query with the same support set. But, importantly, each time a particular subset is tested for a particular claim, we gain more information about Δ . So instead of taking the naive approach of always throwing the result of querying away, we see that this information can be collated about subsets to help guide the search for further arguments and counterarguments. For example, if we know that a particular subset Φ is such that $\Phi \not\vdash \alpha$, and we are looking for an argument with claim $\alpha \wedge \beta$, then we can infer that $\Phi \not\vdash \alpha \wedge \beta$, and there is no need to test Φ for this claim (i.e. it is not useful to make the call $\Phi?\alpha \wedge \beta$).

So as we undertake more tests of Δ for various subsets of Δ and for various claims, we build up a picture of Δ . We can consider these being stored as contours on the (cartographical) map of $\wp(\Delta)$. We formalise this in Section 4.

To make our presentation more concise, from now on, we refer to each subset of Δ by a binary number. Suppose Δ has cardinality n , then we adopt the arbitrary enumeration $\langle \alpha_1, \dots, \alpha_n \rangle$ of Δ , presented in Section 2. Using this, we can then represent any subset Φ of Δ by

a n digit binary number of the form d_1, \dots, d_n . For the i th formula (i.e. α_i) in $\langle \alpha_1, \dots, \alpha_n \rangle$, if α_i is in Φ , then the i th digit (i.e. d_i) in d_1, \dots, d_n is 1, and if α_i is not in Φ , then the i th digit (i.e. d_i) in d_1, \dots, d_n is 0. For example, for the enumeration $\langle \alpha, \beta \wedge \neg\gamma, \gamma \vee \epsilon \rangle$, 000 is $\{\}$, 100 is $\{\alpha\}$, 010 is $\{\beta \wedge \neg\gamma\}$, 001 is $\{\gamma \vee \epsilon\}$, 110 is $\{\alpha, \beta \wedge \neg\gamma\}$, 111 is $\{\alpha, \beta \wedge \neg\gamma, \gamma \vee \epsilon\}$, etc.

Since we will be considering the power set of a knowledgebase, the following definition of the MaxWidth function will be useful for us: If n is $|\Delta|$ and m is $\lfloor n/2 \rfloor$ (i.e. m is the greatest integer less than or equal to $n/2$), then $\text{MaxWidth}(n)$ is $n!/(n-m)!m!$. In other words, of all cardinalities for subsets of Δ , the most numerous are those of cardinality $\lfloor n/2 \rfloor$, and so the MaxWidth function gives the number of subsets of Δ of cardinality $\lfloor n/2 \rfloor$.

4 FRAMEWORK FOR CONTOURING

We start with the ideal situation where we have substantial information about the knowledgebase Δ .

Definition 8. The **contour** for α is $C(\alpha) = \{\Phi \subseteq \Delta \mid \Phi \vdash \alpha \text{ and there is no } \Psi \subset \Phi \text{ such that } \Psi \vdash \alpha\}$, the **uppercontour** for α is $U(\alpha) = \{\Phi \subseteq \Delta \mid \Phi \vdash \alpha\}$, and the **lowercontour** for α , is $L(\alpha) = \{\Phi \subseteq \Delta \mid \Phi \not\vdash \alpha\}$.

Clearly, $C(\alpha) \subseteq U(\alpha)$, and $L(\alpha) \cup U(\alpha)$ is $\wp(\Delta)$, and $L(\alpha) \cap U(\alpha)$ is \emptyset . Furthermore, it is possible that any set in $L(\alpha)$, $C(\alpha)$, or $U(\alpha)$ is inconsistent. Obviously, all the sets in $U(\perp)$ are inconsistent, and none in $L(\perp)$ is inconsistent.

Proposition 2. For any $\Phi \subseteq \Delta$, $\Phi \in C(\alpha)$ iff (1) for all $\Psi \in U(\alpha)$, $\Psi \not\subseteq \Phi$, and (2) for all $\Psi \in L(\alpha)$, $\Phi \not\subseteq \Psi$.

Example 5. For $\langle \alpha \wedge \neg\alpha, \beta, \neg\beta \rangle$, $U(\perp) = \{100, 110, 101, 011, 111\}$, $C(\perp) = \{100, 011\}$, $L(\perp) = \{000, 010, 001\}$, $U(\alpha \vee \beta) = \{100, 010, 101, 110, 011, 111\}$, $C(\alpha \vee \beta) = \{100, 010\}$, and $L(\alpha \vee \beta) = \{000, 001\}$.

We can use contours directly to generate arguments. For this, we obtain $L(\perp)$ from $C(\perp)$ as follows: $L(\perp) = \{\Phi \subseteq \Delta \mid \Phi \subseteq \Psi \text{ and } \Psi \in C(\perp)\}$.

Proposition 3. For any Φ and α , $\Phi \in C(\alpha) \cap L(\perp)$ iff $\langle \Phi, \alpha \rangle$ is an argument.

This means that if we have $C(\alpha)$ and $C(\perp)$, we have all the knowledge we require to generate all arguments for α . By this we mean, we do not need to use the ATP.

However, we may be in a position where we have some γ for which we want to generate arguments, but for which we do not have $C(\gamma)$. In general, we cannot expect to have a contour for every possible claim for which we may wish to construct an argument. To address this, we will require an ATP, but we can focus our search for the arguments, so that we can reduce the number of calls that we make to the ATP. For this we can identify Boolean constituents of γ for which we do have the contours. To support this, we require the following definition.

Definition 9. For any α, β , the **contour conjunction** and **contour disjunction** operators, denoted \oplus and \otimes respectively, are defined as follows.

$$\begin{aligned} C(\alpha) \oplus C(\beta) &= C(\alpha) \cup C(\beta) \cup \{\Phi \cup \Psi \mid \Phi \in C(\alpha) \& \Psi \in C(\beta)\} \\ C(\alpha) \otimes C(\beta) &= C(\alpha) \cup C(\beta) \cup \{\Phi \cap \Psi \mid \Phi \in C(\alpha) \& \Psi \in C(\beta)\} \end{aligned}$$

Example 6. Consider $\langle \alpha, \beta, \alpha \vee \beta \rightarrow \gamma, \alpha \vee \beta \rightarrow \delta \rangle$. So $C(\gamma) = \{1010, 0110\}$ and $C(\delta) = \{1001, 0101\}$. Hence,

$$\begin{aligned} C(\gamma) \oplus C(\delta) &= \{1011, 0111, 1111, 1010, 0110, 1001, 0101\} \\ C(\gamma) \otimes C(\delta) &= \{1000, 0000, 0100, 1010, 0110, 1001, 0101\} \end{aligned}$$

Note, $C(\gamma \wedge \delta) = \{1011, 0111\}$ and $C(\gamma \vee \delta) = \{1010, 0110, 1001, 0101\}$.

Clearly, the \oplus and \otimes operators are associative and commutative. We also obtain the following containment results.

Proposition 4. For any α, β , $C(\alpha \wedge \beta) \subseteq (C(\alpha) \oplus C(\beta))$

Proposition 5. For any α, β , $C(\alpha \vee \beta) \subseteq (C(\alpha) \otimes C(\beta))$

So if we are looking for an argument for $\alpha \wedge \beta$, we look in the set $C(\alpha) \oplus C(\beta)$. Similarly if we are looking for an argument for $\alpha \vee \beta$, we look in the set $C(\alpha) \otimes C(\beta)$. Furthermore, the number of sets to consider in $C(\alpha) \oplus C(\beta)$, and similarly in $C(\alpha) \otimes C(\beta)$, is a quadratic function of the number of sets in each of $C(\alpha)$ and $C(\beta)$.

Proposition 6. For any α and β , if $|C(\alpha)| = p$ and $|C(\beta)| = q$, then $|C(\alpha) \oplus C(\beta)| \leq pq + p + q$ and $|C(\alpha) \otimes C(\beta)| \leq pq + p + q$.

Now we consider an operator to facilitate the use of a contour $C(\alpha)$ to find arguments with the claim $\neg\alpha$.

Definition 10. For any $X \subseteq \wp(\Delta)$, the **shift** operator, denoted \div , is defined as follows.

$$\div X = \{\Phi \subseteq \Delta \mid \text{for all } \Psi \in X, \Phi \not\subseteq \Psi \text{ and } \Psi \not\subseteq \Phi\}$$

Example 7. Consider $\langle \alpha \vee \beta, \neg\alpha, \neg\beta, \neg\gamma \wedge \delta, \neg\delta \wedge \beta \rangle$. So $C(\beta)$ is $\{11000, 00001\}$. Hence, $\div C(\beta)$ is $\{10100, 10010, 10110, 01100, 01010, 01110, 00100, 00010, 00110\}$. By comparison, $C(\neg\beta)$ is $\{00100\}$.

Whilst \div is, in a weak sense, a kind of complementation operator, properties such as $\div(\div C(\alpha)) = C(\alpha)$ do not hold. But we do have the following useful property which shows how given $C(\alpha)$, we can use $\div C(\alpha)$ to focus our search for an argument for $\neg\alpha$.

Proposition 7. For any α , $(C(\neg\alpha) \cap L(\perp)) \subseteq (\div C(\alpha) \cap L(\perp))$

We conclude this section by considering undercuts. For any undercut, the claim is the negation of the support of its parent, and the support of the parent is some subset of Δ . Suppose the support of the parent is $\{\delta_1, \dots, \delta_k\}$, so the claim of any undercut is $\neg(\delta_1 \wedge \dots \wedge \delta_k)$. This claim is equivalent to $\neg\delta_1 \vee \dots \vee \neg\delta_k$. So, if we have contours for each of $\neg\delta_1, \dots, \neg\delta_k$, we can focus our search for any these undercut in the space delineated by $C(\neg\delta_1) \otimes \dots \otimes C(\neg\delta_k)$. So we may consider keeping a contour for the negation of each element in Δ .

5 USING CONTOURS

We now consider how contours can improve our use of an ATP by using fewer queries than NaiveQuerying(Δ, α). For a knowledgebase Δ , a formula α , and a set of contours Θ , if $C(\alpha) \in \Theta$, then we know it is not necessary to make any calls to the ATP.

If we are looking for arguments with a claim that is a conjunction of formulae for which we have contours, the queries to the ATP are delineated by the following function.

$$\begin{aligned} \text{ConjunctionQuerying}(\{C(\alpha), C(\beta), C(\perp)\}, \alpha \wedge \beta) \\ = \{(\Phi? \alpha) \mid \Phi \in C(\alpha) \oplus C(\beta) \text{ and } \Phi \in L(\perp)\} \end{aligned}$$

Similarly, if we are looking for arguments with a claim that is a disjunction of formulae for which we have contours, the queries to the ATP are delineated by the following function.

$$\begin{aligned} \text{DisjunctionQuerying}(\{\mathcal{C}(\alpha), \mathcal{C}(\beta), \mathcal{C}(\perp)\}, \alpha \vee \beta) \\ = \{(\Phi? \alpha) \mid \Phi \in \mathcal{C}(\alpha) \otimes \mathcal{C}(\beta) \text{ and } \Phi \in \mathcal{L}(\perp)\} \end{aligned}$$

Proposition 8. For Δ , $\alpha \wedge \beta$, and $\alpha \vee \beta$, if $|\mathcal{C}(\alpha)| = p$ and $|\mathcal{C}(\beta)| = q$ and $r = pq + p + q$ then

$$\begin{aligned} |\text{ConjunctionQuerying}(\{\mathcal{C}(\alpha), \mathcal{C}(\beta), \mathcal{C}(\perp)\}, \alpha \wedge \beta)| \leq r \\ |\text{DisjunctionQuerying}(\{\mathcal{C}(\alpha), \mathcal{C}(\beta), \mathcal{C}(\perp)\}, \alpha \vee \beta)| \leq r \end{aligned}$$

Now we turn to finding undercuts which can be a substantial part of the cost of constructing an argument tree, and indeed can involve many times more work than just finding the root of an argument tree. If we have a contour for the negation of each formula in Δ , then we can use the following delineation on queries.

$$\begin{aligned} \text{UndercutQuerying}(\{\mathcal{C}(\neg\delta_1), \dots, \mathcal{C}(\neg\delta_k), \mathcal{C}(\perp)\}, \neg\delta_1 \vee \dots \vee \neg\delta_k) \\ = \{(\Phi? \alpha) \mid \Phi \in \mathcal{C}(\neg\delta_1) \otimes \dots \otimes \mathcal{C}(\neg\delta_k) \text{ and } \Phi \in \mathcal{L}(\perp)\} \end{aligned}$$

Example 8. For $\langle \alpha, \beta, \delta \rightarrow (\neg\alpha \vee \neg\beta), \delta, \gamma, \gamma \rightarrow \neg\delta \rangle$, $\mathcal{C}(\neg\alpha) = \{011100, 000111\}$, $\mathcal{C}(\neg\beta) = \{101100, 000111\}$, $\mathcal{C}(\neg(\delta \rightarrow (\neg\alpha \vee \neg\beta))) = \{110100, 000111\}$, $\mathcal{C}(\neg\delta) = \{000011\}$, $\mathcal{C}(\neg\gamma) = \{111100, 000101\}$, $\mathcal{C}(\neg(\gamma \rightarrow \neg\delta)) = \{111100, 000110\}$, and $\mathcal{C}(\perp) = \{111100, 000111\}$. Consider undercuts for $\langle 110000, \alpha \wedge \beta \rangle$, i.e. those with the claim $\neg\alpha \vee \neg\beta$. So $\text{UndercutQuerying}(\{\mathcal{C}(\neg\alpha), \mathcal{C}(\neg\beta), \mathcal{C}(\perp)\}, \neg\alpha \vee \neg\beta) = \{001100? \neg\alpha \vee \neg\beta, 011100? \neg\alpha \vee \neg\beta, 101100? \neg\alpha \vee \neg\beta\}$. By comparison, $\mathcal{C}(\neg\alpha \vee \neg\beta) = \{001100\}$.

Proposition 9. For Δ and α , if $|\Delta| = n$, then $0 \leq |\text{UndercutQuerying}(\{\mathcal{C}(\neg\delta_1), \dots, \mathcal{C}(\neg\delta_k), \mathcal{C}(\perp)\}, \neg\delta_1 \vee \dots \vee \neg\delta_k)| \leq 2^{n-2} + 1$.

The best case for the UndercutQuerying function is when $k = 1$. This is when the argument being undercut has a support with just one premise. So the undercut has to just undercut this premise, and therefore, the undercut can be obtained directly from the relevant contour $\mathcal{C}(\neg\delta_1)$ without recourse to the ATP. The worst case for the UndercutQuerying function is when $|\Delta| = n$ and $k = (\text{MaxWidth}(n) - 1)$, and there is a $\Phi_1 \in \mathcal{C}(\neg\delta_1)$ and .. and a $\Phi_k \in \mathcal{C}(\neg\delta_k)$ such that for each $\Phi_i \in \{\Phi_1, \dots, \Phi_k\}$, $|\Phi_i| = \lfloor n/2 \rfloor$, and for all $\Phi_i, \Phi_j \in \{\Phi_1, \dots, \Phi_k\}$, $\Phi_i \neq \Phi_j$. The worst case is clearly an extreme situation and it would seem that on average the number of queries raised by the UndercutQuerying function would be significantly lower, as can be seen for lower values of k using iterated applications of Proposition 8.

6 PARTIAL CONTOURS

Let Π be a set of answers to queries to the ATP. In other words, for a series of queries $(\Phi_1? \alpha_1), \dots, (\Phi_n? \alpha_n)$, we have obtained a set of answers $\Pi = \{\pi_1, \dots, \pi_n\}$, where for each $\pi_i \in \Pi$, the answer is either of the form $\Phi_i \vdash \alpha_i$ or of the form $\Phi_i \not\vdash \alpha_i$. Using Π , we want to generate a partial contour $\mathcal{C}(\Pi, \alpha)$ for α . We will define it so that $\mathcal{C}(\Pi, \alpha)$ is a subset of $\mathcal{C}(\alpha)$ calculated on the basis of Π .

Definition 11. For Π and α , the **partial uppercontour**, is $\mathcal{U}(\Pi, \alpha) = \{\Phi \subseteq \Delta \mid \Psi \subseteq \Phi \text{ and } (\Psi \vdash \alpha) \in \Pi\}$ and the **partial lowercontour**, is $\mathcal{L}(\Pi, \alpha) = \{\Phi \subseteq \Delta \mid \Phi \subseteq \Psi \text{ and } (\Psi \not\vdash \alpha) \in \Pi\}$.

For $\Pi \subseteq \Pi'$, $\mathcal{U}(\Pi, \alpha) \subseteq \mathcal{U}(\Pi', \alpha)$ and $\mathcal{L}(\Pi, \alpha) \subseteq \mathcal{L}(\Pi', \alpha)$.

Definition 12. For Π , the **partial contour** for $\mathcal{C}(\Pi, \alpha)$ is $\mathcal{C}(\Pi, \alpha) = \{\Phi \in \mathcal{U}(\Pi, \alpha) \mid \text{for all } \phi \in \Phi, (\Phi \setminus \{\phi\}) \in \mathcal{L}(\Pi, \alpha)\}$.

So from Π , we construct the partial uppercontour and the partial lowercontour for some α , and then from these we can construct the partial contour for α .

Example 9. For $\langle \alpha, \neg\alpha, \beta \rangle$, let $\Pi = \{(111 \vdash \perp), (101 \not\vdash \perp), (011 \not\vdash \perp), (100 \not\vdash \perp), (110 \vdash \perp), (010 \not\vdash \perp)\}$. Hence, $\mathcal{C}(\Pi, \perp) = \{110\}$.

We use partial contours in the same way as we use full contours. The only proviso is that with partial contours, we have incomplete information about the knowledgebase. So for example, since $\mathcal{C}(\Pi, \alpha) \subseteq \mathcal{C}(\alpha)$, we are not guaranteed to obtain all arguments for α from just using $\mathcal{C}(\Pi, \alpha)$. However, for any $\Phi \in \mathcal{C}(\Pi, \alpha)$, we know that Φ or any superset of Φ implies α , and any proper subset does not imply Φ . So any element in $\mathcal{C}(\Pi, \alpha)$ can have a profound effect on searching for arguments. We use the shift operator to formalise this.

Proposition 10. If $\langle \Phi, \alpha \rangle$ is an argument, then $\Phi \in ((\mathcal{C}(\Pi, \alpha) \cup \div\mathcal{C}(\Pi, \alpha))$.

Proposition 11. If $\Phi \in \mathcal{C}(\Pi, \alpha) \cap \mathcal{L}(\perp)$, then $\langle \Phi, \alpha \rangle$ is an argument.

We can delineate the queries sent to the ATP when searching for an argument for α , with a partial contour $\mathcal{C}(\Pi, \alpha)$, using the following definition, where $\mathcal{M}(\Pi, \perp)$ is $\mathcal{L}(\Pi, \perp) \cup \mathcal{U}(\Pi, \perp)$.

$$\begin{aligned} \text{PartialQuerying}(\{\mathcal{C}(\Pi, \alpha), \mathcal{C}(\Pi, \perp)\}, \alpha) = \\ \{(\Phi? \alpha) \mid \Phi \in \div\mathcal{C}(\Pi, \alpha) \text{ and } \Phi \notin \mathcal{U}(\Pi, \perp)\} \\ \cup \{(\Phi? \perp) \mid \Phi \in (\div\mathcal{C}(\Pi, \alpha) \cup \mathcal{C}(\Pi, \alpha)) \text{ and } \Phi \notin \mathcal{M}(\Pi, \perp)\} \end{aligned}$$

The utility of a partial contour is dependent on the membership of Π . However, we do have $\text{PartialQuerying}(\{\mathcal{C}(\Pi, \alpha), \mathcal{C}(\Pi, \perp)\}, \alpha)$ being a subset of $\text{SimpleQuerying}(\Delta, \mathcal{C}(\perp), \alpha)$ and as Π increases, the difference is increasingly marked. So in any case, whatever is in a partial contour can reduce the number of calls to the ATP.

Now we turn to the question of what are the bounds on the number of queries (i.e. size of Π) to build a contour. In the worst case, for any α , to ensure $\mathcal{C}(\Pi, \alpha) = \mathcal{C}(\alpha)$, it is necessary for Π to have 2^n queries where $\Pi = \{(\Phi? \alpha) \mid \Phi \subseteq \Delta\}$. However, we can take a more intelligent approach to decrease Π . For example, if we generate Π dynamically, once we have enough information from Π to add a particular $\Phi \subseteq \Delta$ to a particular contour, we have no need to seek supersets or subsets of Φ for that contour. Furthermore, we can envisage that the contours are built over time, as a by-product of using a knowledgebase. So each time the ATP is queried, the answer to the query is added to Π . As items are added to Π , the contours are constructed incrementally. We can therefore think of contours as being formed by a kind of lemma generation.

Finally, if we use partial contours, we do not even need to assume that the knowledgebase is fixed, since every partial contour of a knowledgebase Δ is a partial contour of a knowledgebase $\Delta \cup \Delta'$ for any Δ' .

7 STORING CONTOURS

So far we have made a case for the value of using contours. Even in the worst case, they offer an improvement over naive searching for arguments and counterarguments. By maintaining appropriate contours, the numbers of calls to the ATP is always decreased. The downside to maintaining contours, or even partial contours, is the amount of information that needs to be kept about the knowledgebase over time.

Proposition 12. For any α , if $|\Delta| = n$, then $1 \leq C(\alpha) \leq \text{MaxWidth}(n)$.

So for example, if the cardinality of our knowledgebase is 10, we may in the worst case, have a cardinality for $C(\perp)$ of 252. This is not surprising given that $C(\perp)$ is the set of minimally inconsistent subsets of Δ . Of course, this is a worst case scenario, and it would indicate a remarkably inconsistent knowledgebase for which it would be difficult to imagine arising in the real-world. Nonetheless, it raises the question of whether we could compromise on the information we retain from Π , and yet still reduce the number of queries to the ATP. We address this next.

The following result suggests that a simple solution is that when a contour or partial contour is being constructed, it appears to be too large to be manageable, it may be better to erase it, and construct the elements of the contour as and when required, and furthermore, if it is sufficiently large, it is relatively straightforward to find them because they are the subsets of Δ of cardinality $\lfloor n/2 \rfloor$.

Proposition 13. Let $|\Delta| = n$. For any α , as the cardinality of $C(\alpha)$ increases towards $\text{MaxWidth}(n)$, the average size of the elements of $C(\alpha)$ approaches $\lfloor n/2 \rfloor$.

As another alternative to storing all the precise information we have about the contours, given some Π , we propose using outline contours. To do this, we require the subsidiary notion of a **k -partition**: For a set $\Lambda = \{\Phi_1, \dots, \Phi_n\}$, where $k \leq n$, a k -partition is a partitioning of Λ into k disjoint subsets of Λ such that the partition with most members has at most one member more than the partition with fewest members. So a k -partition is as close as possible to a partitioning with partitions of equal size. Because a k -partition is a partitioning, each element of Λ is in exactly one partition. We also require the subsidiary notion of a **serial union**: For a set $\Lambda = \{\Phi_1, \dots, \Phi_n\}$, where $k \leq n$, suppose $(\Lambda_1, \dots, \Lambda_k)$ is a k -partitioning of Λ . Then the serial union of $(\Lambda_1, \dots, \Lambda_k)$ is $(\cup(\Lambda_1), \dots, \cup(\Lambda_k))$.

Definition 13. For a set of answers Π , a formula α , and a threshold $k \in \mathbb{N}$, an **outline contour** $C(\Pi, \alpha, k)$ is defined as follows: If $|C(\Pi, \alpha)| < k$, then $C(\Pi, \alpha, k) = C(\Pi, \alpha)$, otherwise let $C(\Pi, \alpha, k)$ be the serial union of a k -partitioning of $C(\Pi, \alpha)$.

So if $C(\Pi, \alpha, k)$ is $C(\Pi, \alpha)$, then we are keeping the explicit information we have about the contour. But, if $|C(\Pi, \alpha)| > k$, then we merge sets in $C(\Pi, \alpha)$ so that we never have more than k sets. In any case, we can recover the contours from each outline contour.

Proposition 14. If $C(\Pi, \alpha) = C(\alpha)$, and $k = 1$, then $C(\Pi, \alpha, k) = \{\cup C(\alpha)\}$.

Example 10. For $\langle \alpha, \neg\alpha, \beta \wedge \neg\beta, \neg\alpha \wedge \gamma, \alpha \vee \beta, \neg\beta \rangle$,

$$C(\perp) = \{110000, 001000, 100100, 010011\}$$

Let Π be such that $C(\Pi, \perp) = C(\perp)$ and let $k = 2$. So there are four possibilities for $C(\Pi, \perp, k)$. One of them is $\{111000, 110111\}$.

Proposition 15. Let Π be such that $C(\Pi, \alpha) = C(\alpha)$. For any k , if $\langle \Phi, \alpha \rangle$ is an argument, then there is a $\Psi \in C(\Pi, \alpha, k)$, such that $\Phi \subseteq \Psi$.

So outline contours involve more queries to the ATP than contours, but less space is required to store them.

8 DISCUSSION

Much progress has been made in developing formalisms for argumentation. Some algorithms for argumentation have been developed (for example [12, 6, 2, 11]). However, relatively little progress has been made in developing techniques for overcoming the computational challenges of constructing arguments, and in particular for intelligent searching for arguments.

In this paper, we have (1) clarified the need to manage the querying of an ATP when constructing arguments and counterarguments; (2) introduced contours as a way of representing information about a knowledgebase obtained by querying with an ATP; (3) shown how we can construct arguments and counterarguments using contours and shown how this is more efficient than naively using the knowledgebase with the ATP to search for arguments; (4) shown how we can construct contours incrementally; and (5) considered a couple of simple strategies for offsetting the cost of maintaining larger contours. From the theoretical framework for contouring presented in this paper, it should be straightforward to develop algorithms for harnessing an ATP and undertaking empirical evaluation.

Whilst our presentation is based on a particular approach to logic-based argumentation, we believe the proposal could easily be adapted for a range of other logic-based approaches to argumentation (for example [11, 1, 9]).

On the Inability of Gathering by Asynchronous Mobile Robots with Initial Movements¹

Branislav Katreňiak² and Jana Katreňiaková²

Abstract. Consider a community of simple autonomous robots freely moving in the plane. The robots are decentralized, asynchronous, deterministic without the common coordination system, identities, direct communication, memory of the past, but with the ability to sense the positions of the other robots. Existing results show the inability of gathering in this model and solve the gathering problem in the model extended by the multiplicity detection capability. However, the previous results rely on the fact that the robots are initially not moving. We prove that the gathering problem is unsolvable in the model with initial movement vectors even with the multiplicity detection capability.

1 INTRODUCTION

We consider a distributed system populated by a set of autonomous mobile robots. The robots are anonymous, have no common knowledge, no common sense of the direction (e.g. compass), no central coordination and no means of direct communication. The behavior of these robots is quite simple, each of them idles, senses, computes and moves in a cycle. In particular, each robot is capable of sensing the positions of the other robots with respect to its local coordination system, performing local computations on the observed data and moving towards the computed destination. The local computation is done according to a deterministic algorithm that takes only the sensed robots' positions as input and returns a destination point towards which the executing robot moves. All robots perform the same algorithm. The main research in this area is focused on understanding under which conditions are these robots able to complete given tasks, e.g. exploring the plane, forming particular patterns, gathering in a single point, etc.

The convergence problem [4] (robots have to converge together) and the problem of forming the biangular circle [7] can be solved in this basic model, however the gathering problem cannot [8]. Various extensions of the model have been proposed to increase its power. Adding the common sense of the orientation (compass) made the problem of arbitrary pattern formation solvable [6] and the gathering problem (robots have to meet at one point in finite time) became solvable even when robots were restricted to the limited visibility [5]. Another studied extension was the multiplicity detection and the gathering problem became solvable with this capability [2].

However, all the previous results supposed that the robots are initially not moving. Especially the algorithms in [2], [7] used the assumption very extensively to prevent certain configurations (robots'

positions together with their movement vectors) in order to infer properties about the robots' movement from the observed robots' positions.

In this paper we relax this assumption and allow the robots to have arbitrary initial movement vectors. This assumption allows for better sequential composition of algorithms and makes the model even more selfstabilizing – it does not only simulate errors causing robots to stop but also a finite number of errors causing robots to miss the destination point computed by the algorithm e.g. by external push (Theorem 2).

After the model definition in Section 2 we mention some basic properties of the introduced model. In Section 4 we analyze the solvability of the convergence problem and in Section 5 we present the proof that the gathering problem is insolvable for three robots even with the multiplicity detection capability and conclude that the basic model with the multiplicity detection and the model with initial vectors and the multiplicity detection are different.

2 MODEL

We use the model introduced in [6] weakened by canceling the implicit zero initial vectors assumption. The robots do not start synchronously from the waiting state but in the moving phase with some arbitrary initial destination point. Such a model will be called model with initial vectors.

2.1 Model definition

Each robot is viewed as a point in a plane equipped with sensors. It can observe the set of all points which are occupied by at least one other robot. Note that the robot only knows whether there are any other robots at a specific point, but it has no knowledge about their number (i.e. it cannot tell how many robots are at a given location). The *local view* of each robot consists of a unit of length, an origin (w.l.o.g. the position of the robot in its current observation), an orientation of angles and the coordinates of the observed points. No kind of agreement on the unit of length, the origin or the orientation of angles is assumed among the robots.

A robot is initially *moving* towards some initial destination point. When the robot reaches this destination, it switches to the basic *waiting* state (*Wait*). Asynchronously and independently from the other robots, it *observes* the environment (*Look*) by activating its sensors. The sensors return a snapshot of the world, i.e. the set of all points occupied by at least one other robot, with respect to the local coordinate system. Then, based only on its local view of the world, the robot *calculates* its destination point (*Compute*) according to its deterministic algorithm (the same for all robots). After the computation

² Department of Computer Science, Faculty of Mathematics, Physics and Informatics, Comenius University, Bratislava
e-mail {katreňiak, katreňiaková}@dcs.fmph.uniba.sk

the robot *moves* towards its destination point (*Move*); if the destination point is the current location, the robot stays on its place. A move may stop before the robot reaches its destination (e.g. because of limits to the robot's motion energy). The robot then returns to the waiting state. The sequence *Wait – Look – Compute – Move* forms a *cycle* of a robot.

The robots are *fully asynchronous*, the amount of time spent in each phase of a cycle (even in the movement towards the initial destination point) is finite but otherwise unpredictable. In particular, the robots do not have a common notion of time. As a result, robots can be seen by the other robots while moving, and thus computations can be made based on obsolete observations. The robots are *oblivious*, meaning that they do not remember any previous observations nor computations performed in any previous cycles. The robots are *anonymous*, meaning that they are indistinguishable by their appearance, and they do not have any kind of identifiers that can be used during the computation. Finally, the robots have *no means of direct communication*: any communication occurs in a totally implicit manner, by observing the other robots' positions.

There are two limiting assumptions concerning *infinity*:

Assumption 1: The amount of time required by a robot to complete a cycle is finite and bounded from above by a fixed constant.

Assumption 2: The distance traveled by a robot in a cycle is bounded from below by a fixed ε (or the robot gets to the destination point).

As no other assumptions on space exist, the distance traveled by a robot in a cycle is unpredictable.

One considered capability of robots' sensors is the multiplicity detection capability. Sensors of such robots do not return only the set of occupied positions but also the information about the multiplicity at each occupied position. The multiplicity can be expressed either as a number of robots at particular position or only as a binary information one robot/more robots. We will consider the stronger variant with full information.

3 MODEL PROPERTIES

We defined the initial movement of robots as uninterruptable. But the model does not change if we allow them to be interruptable.

Theorem 1 *The model with initial vectors is equal to its modification where the initial movements can be interrupted as the movements in the live cycles.*

From the point of view of any robot's algorithm, the initial destination point is unpredictable. If the initial movement has to be interrupted at some point P , the initial destination point could be defined as this point P .

We define a *push* as an asynchronous event which sets some robot into the moving state towards an arbitrary destination point.

We define the model with finite number of pushes as the model in which finite number of pushes is allowed.

Theorem 2 *The model with the initial vectors is equal to its extension with finite number of pushes and is also equal to the basic model (with zero initial vectors) with finite number of pushes.*

In the models with finite number of pushes we execute the computation until the last push occurs. At this point we construct exactly the same configuration (robots' algorithms, positions and movement vectors) as in the model with initial vectors. Computation will continue exactly the same way because no more pushes can occur.

Models with finite number of pushes can simulate the model with initial vectors by pushing the robots at the start to give them the same initial vectors.

4 CONVERGENCE

Convergence problem orders robots to converge together but they don't have to meet at one point in finite time.

[Convergence] Given is a group of n robots in the plane. Find an algorithm for the robots such that for every $\varepsilon > 0$ there exist time t that after this time the distance of every two robots will be at most ε .

The convergence problem can be solved by easy center of gravity algorithm. Denote by $r_i[t]$ the location of robot i at time t . The algorithm *Center.Of.Gravity* is very simple. After observing the current configuration at some time t , the robot i computes as its goal point ($c_i[t]$) the average location of all robot positions (including its own) and moves towards the calculated goal point. A formal definition of this algorithm follows.

Algorithm Center.Of.Gravity (code for robot i at time t)

1. Calculate the center of gravity $c_i[t] = \frac{1}{N} \sum_j r_j[t]$
2. Move to the point $c_i[t]$

It was proved in [4] that the algorithm *Center.Of.Gravity* solves the convergence problem in the basic model and also in the model with initial vectors.

5 GATHERING

Gathering problem orders robots to meet at any point in the plane in finite time.

[Gathering] Given is a group of n robots in the plane. Find an algorithm for the robots in order to gather all robots at one point in finite time. The gathering point is not determined before.

It was shown in [8] that gathering is unsolvable in the basic model without any extensions. If we give robots the multiplicity detection capability, gathering becomes solvable for at least three robots [2],[3]. We show that in the model with initial vectors the multiplicity detection capability does not help and gathering stays unsolvable for three robots even with multiplicity detection extension.

To show the insolvability of the gathering problem, we will choose for every possible (fixed) algorithm such initial robots' positions, initial robots' vectors, robots' local coordination systems and the scheduler that prevent the robots from gathering (in finite time). As many events and actions in the model are asynchronous from the robots' algorithms' point of view, we can schedule them arbitrary (only restricted by Assumptions 1 and 2) in our scheduler.

We define a *similar projection* as the projection that preserves ratios of distances and angles. Two configurations are similar when one can be obtained from the other by a similar projection. Similar configurations are indistinguishable from the robots' algorithms' point of view (assuming the robots' positions and movement vectors being projected too).

Usual way of preventing the robots from gathering is to force them to repeat any similar configuration during the model computation. Then the sequence between the two similar configurations can be repeated indefinitely many times and robots will never gather at one point in finite time. Scheduler can arbitrary slower and fasten the robots' movement but it cannot interrupt the movement (Assumption 2).

The symmetrical configuration forces the algorithms to act equally (all the same) in some situations.

Theorem 3 For every algorithm solving the gathering problem holds that if the equilateral triangle configuration is observed, algorithm has to choose the center of the triangle as the destination point.

Suppose that for the equilateral triangle the algorithm does not choose the center of the triangle as the destination point. We choose the initial robots' positions as the equilateral triangle, zero initial vectors, and synchronous scheduler. Local coordination system are chosen such that all robots observe the same situation (we use the symmetry of the situation).

As the robots are indistinguishable, every robot must choose the same (symmetrical) destination vector. After one step of the synchronous scheduler we get a similar configuration.

Note that Theorem 3 holds even when robots are equipped with the multiplicity detection capability.

Having Theorem 3 in mind we are going to find the mentioned initial positions, initial vectors and scheduler that will force the robots to reach the similar positions again.

We represent the robots positions (points in the plane) by complex numbers. We choose the initial positions of robots to form an equilateral triangle $A = 1 + 0i$, $B = -\frac{1}{2} - \frac{\sqrt{3}}{2}i$, $C = -\frac{1}{2} + \frac{\sqrt{3}}{2}i$ with center $S = 0 + 0i$ and mark the initial movement vector of robot A as \vec{a} , robot B as \vec{b} and robot C as \vec{c} (see Fig.1).

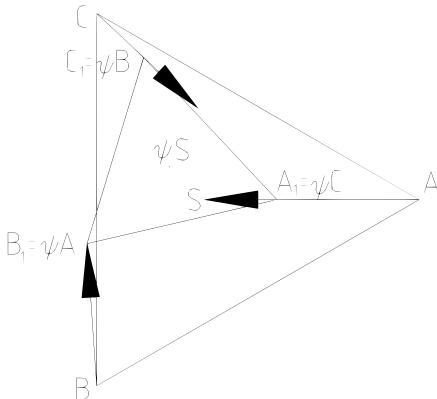

Figure 1. Initial positions, initial vectors, positions after one scheduler's step

We set initial vector \vec{a} to zero. According to the Theorem 3, robot A has to choose S as its destination point, so the vector of movement \vec{a} becomes $\vec{a} = S - A = -1 + 0i$. We program one step of the scheduler to let robot B move to its destination $B_1 = B + \vec{b}$ and to pause robots' A, C movement at the points $A_1 = A + k\vec{a}$, $C_1 = C + l\vec{c}$; $k, l \in (0, 1)$. We are going to find such initial vectors \vec{b}, \vec{c} and constants k, l that the configuration after one scheduler's step will be similar to the starting configuration. The similar projection (we mark it as ψ) must fulfill following equations (see Fig.1):

$$\begin{aligned}\psi A &= B_1 \\ \psi B &= C_1 \\ \psi C &= A_1\end{aligned}$$

Having the projection ψ , all other parameters are just a function of it:

$$\begin{aligned}\vec{b} &= \psi A - B \\ \psi \vec{c} &= S - \psi C\end{aligned}$$

$$\begin{aligned}k &= \frac{|\psi C - A|}{|\vec{a}|} \\ l &= \frac{|\psi B - C|}{|\vec{c}|}\end{aligned}$$

Projection ψ keeps the robots in the equilateral triangle situation.

In i -th scheduler's step, the i -th projection of robot A (i.e. $\psi^i A$) is the robot that has just finished its movement, observes the equilateral triangle situation and computes its destination vector towards the center of the current equilateral triangle – $\psi^i S$. Analogously robot $\psi^i B$ is the one that gets to its destination in the next scheduler step and becomes $\psi^{i+1} A$. Robot $\psi^i C$ is the one that will be paused in the next scheduler's step, becomes $\psi^{i+1} B$, and get to its destination in the second scheduler's step, becomes $\psi^{i+2} A$. When we formalize these properties, we get the following equations and restrictions: insolvable

$$\mathcal{I}(\psi C) = 0 \quad (1)$$

$$\mathcal{I}(\psi^2 B) = 0 \quad (2)$$

$$\psi^3 A = 0 + 0i \quad (3)$$

$$\mathcal{R}(\psi C) \in (0, 1) \quad (4)$$

$$\mathcal{R}(\psi^2 B) \in (0, \mathcal{R}(\psi C)) \quad (5)$$

where $\mathcal{I}(x)$ is the imaginary part of the complex number x and $\mathcal{R}(x)$ is its real part.

Equations 1, 2 and Restrictions 4, 5 formalizes the fact, that robot A is in the next two scheduler's steps on its way from point $1 + 0i$ to the point $0 + 0i$. Equations 3 means that robot A gets to the point $0 + 0i$ in the third scheduler's step.

Now, let us define the mentioned projection ψ . It is characterized by two complex numbers \vec{p} (scaling and rotation) and \vec{q} (movement). Let W be any point, $\psi(W) = \vec{p}W + \vec{q}$. Let \vec{w} by any vector, $\psi(\vec{w}) = \vec{p}\vec{w}$.

From Equation 3 we get

$$\psi^3(1 + 0i) = 0 + 0i \Rightarrow \vec{q} = -\frac{\vec{p}^3}{\vec{p}^2 + \vec{p} + 1}$$

Let $\vec{p} = x + yi; x, y \in \mathbb{R}$.

By adjustment of Equation 1 we get

$$\mathcal{I}(\psi C) = \mathcal{I}\left(\vec{p}\left(-\frac{1}{2} + \frac{\sqrt{3}}{2}i\right) - \frac{\vec{p}^3}{\vec{p}^2 + \vec{p} + 1}\right) = 0$$

By further adjustment in real numbers we get:

$$\begin{aligned}\left(\frac{\sqrt{3}}{2}x - \frac{3}{2}y\right)((x^2 - y^2 + x + 1)^2 + (2xy + y)^2) + \\ + 2xy + y = 0\end{aligned}$$

By adjustment of Equation 2 we get

$$\mathcal{I}(\psi^2 B) = \mathcal{I}\left(\vec{p}^2\left(-\frac{1}{2} - \frac{\sqrt{3}}{2}i\right) - \frac{\vec{p}^3(\vec{p} + 1)}{\vec{p}^2 + \vec{p} + 1}\right) = 0$$

By further adjustment in real numbers we get:

$$\begin{aligned}\left(-3xy - \frac{\sqrt{3}}{2}(x^2 - y^2)\right)((x^2 - y^2 + x + 1)^2 + (2xy + y)^2) - \\ - y(x^2 - y^2 + x + 1) + (x + 1)(2xy + y) = 0\end{aligned}$$

In general, our problem can be seen as solving a system of two equations or finding a common root of functions

$$\begin{aligned} f(x, y) &= \left(\frac{\sqrt{3}}{2}x - \frac{3}{2}y \right) \\ &\cdot ((x^2 - y^2 + x + 1)^2 + (2xy + y)^2) + \\ &+ 2xy + y \end{aligned} \quad (6)$$

$$\begin{aligned} g(x, y) &= \left(-3xy - \frac{\sqrt{3}}{2}(x^2 - y^2) \right) \\ &\cdot ((x^2 - y^2 + x + 1)^2 + (2xy + y)^2) - \\ &- y(x^2 - y^2 + x + 1) + (x + 1)(2xy + y) \end{aligned} \quad (7)$$

Not all roots of these functions are correct solutions of our problem (because we ignored the Restrictions 4, 5), but one of the correct approximate solutions we have found by an numeric algorithm is

$$\begin{aligned} \vec{p} &= -0.381503871916 - 0.357088906042i \\ \vec{q} &= -0.162229750616 + 0.1518475917i \\ \vec{b} &= -0.043733622532 + 0.660784089442i \\ \vec{c} &= 0.4719173352574 - 0.441716211537i \\ k &= 0.6622297506162 \\ l &= 0.4646451929566 \end{aligned}$$

Simulation of this solution is pictured in Figure 2. See appendix A for the proof that there exists an exact solution near the approximate one.

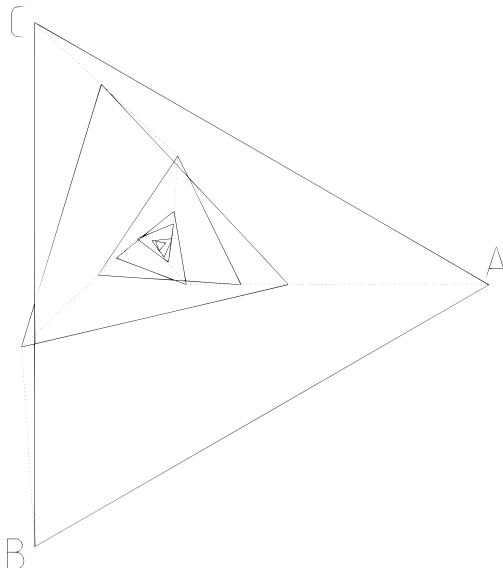

Figure 2. Simulation of the solution

Theorem 4 *The gathering problem is unsolvable for three robots in the model with initial vectors even with the multiplicity detection capability.*

If the robots' algorithm does not choose for the equilateral triangle observation the center of that triangle, we use the Theorem 3. In the

other case we have constructed the initial robots' positions, initial robots' vectors and the scheduler such that after three scheduler's steps we get the configuration similar (projection ψ^3) to the initial one (robots positions are projected too).

If we relax the never mentioned assumption, that robots are on distinct positions at the start, we easily get the following corollary.

Theorem 5 *The gathering problem is unsolvable for $3k$ robots in the model with initial vectors even with the multiplicity detection capability.*

Repeat the proof of the Theorem 4 with k robots starting at point A , k robots at point B and k robots at point C . Scheduler will schedule all robots starting at one point totally synchronously and thus robots will be moving together and do not get any more valuable input than in the original proof.

Theorem 6 *Basic model with multiplicity detection capability and the model with initial vectors and multiplicity detection capability are different.*

Gathering problem is solvable for at least 3 robots in the basic model with multiplicity detection capability and is unsolvable for 3 robots in the model with initial vectors even with multiplicity detection capability.

6 CONCLUSIONS AND OPEN PROBLEMS

We have introduced the model of asynchronous mobile robots with initial vectors and showed some of its basic properties. Then we proved that the gathering problem is unsolvable for three robots in this model even with the multiplicity detection capability and thus that the basic model with multiplicity detection and the model with initial vectors and multiplicity detection are different.

The gathering problem remains open in the model with initial vectors and the multiplicity detection for more than three robots.

Other problems studied in the basic model with zero initial vectors can be investigated in the introduced model with nonzero initial vectors.

A Existence of Exact Solution

One of the approximate solutions of the Equations 6, 7 is

$$p = x + yi = -0,381503871916 - 0,357088906042i$$

We are going to prove that there exist an exact solution in its surrounding – in interval $\langle -0.382, -0.381 \rangle \times \langle -0.358, -0.356 \rangle$.

In the beginning we mention some assertions from function analysis, which we use later in the proof.

Theorem 7 Let $h : \langle a, b \rangle \rightarrow \mathbf{R}$ be a continuous function. If h is decreasing (resp. increasing) on $\langle a, b \rangle$ and $h(a) \cdot h(b) < 0$, then exists exactly one $c \in \langle a, b \rangle$, such that $h(c) = 0$.

Theorem 8 Let $h_1, h_2 : \langle a, b \rangle \rightarrow \mathbf{R}$ be continuous functions. If $h_1(a) < h_2(a)$ and $h_1(b) > h_2(b)$ then there is $c \in \langle a, b \rangle$ such that $h_1(c) = h_2(c)$.

Now we are able to prove the main theorem. In further text, we denote $x_1 = -0.382, x_2 = -0.381, y_1 = -0.358, y_2 = -0.356, y_0 = -0.357$ and $J = \langle x_1, x_2 \rangle, I = \langle y_1, y_2 \rangle$. Refer to the Figure 3 for the depicted behavior of functions $f(x, y)$ and $g(x, y)$ on the interval $J \times I$.

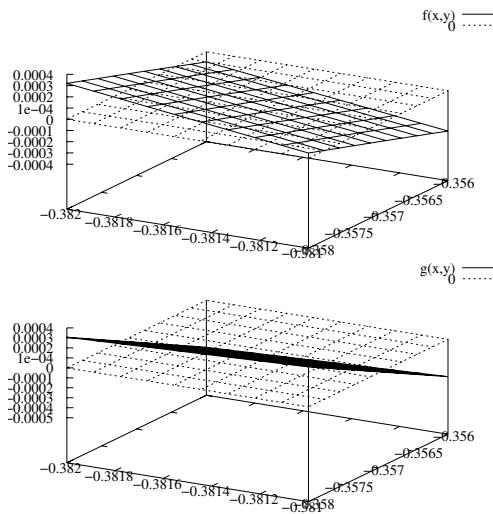

Figure 3. Functions $f(x, y)$ and $g(x, y)$ near the approximate solution

Theorem 9 Let $f(x, y)$ and $g(x, y)$ be functions as defined earlier in Equations (6), (7). There exists $x \in \langle x_1, x_2 \rangle, y \in \langle y_1, y_2 \rangle$ such that $f(x, y) = g(x, y) = 0$.

After substituting in functions f and g we get

- $f(x_1, y_0) > 0$ and $f(x_1, y_2) < 0$ and from Mean-value Theorem there exists $y'_f \in (y_0, y_2)$ such that $f(x_1, y'_f) = 0$
- $f(x_2, y_1) > 0$ and $f(x_2, y_0) < 0$ and from Mean-value Theorem there exists $y''_f \in (y_1, y_0)$ such that $f(x_2, y''_f) = 0$
- $g(x_1, y_1) > 0$ and $g(x_1, y_0) < 0$ and from Mean-value Theorem there exists $y'_g \in (y_1, y_0)$ such that $g(x_1, y'_g) = 0$
- $g(x_2, y_0) > 0$ and $g(x_2, y_2) < 0$ and from Mean-value Theorem there exists $y''_g \in (y_0, y_2)$ such that $g(x_2, y''_g) = 0$

Let define functions on interval $\langle x_1, x_2 \rangle$ as $h_f(x) = y \iff f(x, y) = 0$ and $h_g(x) = y \iff g(x, y) = 0$. Since the function f is decreasing on $\langle y_1, y_2 \rangle$ for every fixed $x \in \langle x_1, x_2 \rangle$ (proved later in Theorem 10), from Theorem 7 for every x there exists exactly one $y \in \langle y_1, y_2 \rangle$ such that $f(x, y) = 0$. Thus the function h_f is well defined. The same holds for h_g (since g is decreasing on $\langle y_1, y_2 \rangle$, too). Moreover both h_f and h_g are continuous, since they are product of intersection of continuous function f (resp. g) and a plane.

Since easily holds $y'_f = h_f(x_1) > h_g(x_1) = y'_g$ and $y''_f = h_f(x_2) > h_g(x_2) = y''_g$ and both h_f and h_g are continuous, from Theorem 8 there exists $x \in (x_1, x_2)$ and $y \in (y_1, y_2)$ such that $h_f(x) = h_g(x) = y$ i.e. $f(x, y) = g(x, y) = 0$.

Theorem 10 The function $f(x, y)$ is on interval I decreasing for every fixed $x \in J$.

The function $f(x, y)$ on the interval I is decreasing for every fixed x iff $\frac{\partial f(x, y)}{\partial y}$ is defined and negative for every $y \in I$.

The function $\frac{\partial f(x, y)}{\partial y}$ is defined for every $(x, y) \in J \times I$ and since $y_1 \leq y \leq y_2$ and $x_1 \leq x \leq x_2$, the inequality

$$\begin{aligned} -7.5y^4 &+ 2\sqrt{3}xy^3 &- 9x^2y^2 &- 9xy^2 &+ \\ &+ 4.5y^2 &+ 2\sqrt{3}x^3y &- \sqrt{3}x^2y &- \\ &- \sqrt{3}xy &+ 2y &+ 1.5x^4 &- \\ &- 3x^3 &- 4.5x^2 &- x - 0.5 &\leq \\ -7.5y_2^4 &+ 2\sqrt{3}x_1y_1^3 &- 9x_2^2y_2^2 &- 9x_1y_1^2 &+ \\ &+ 4.5y_1^2 &+ 2\sqrt{3}x_1^3y_1 &- \sqrt{3}x_1^2y_1 &- \\ &- \sqrt{3}x_2y_2 &+ 2y_2 &+ 1.5x_1^4 &- \\ &- 3x_1^3 &- 4.5x_2^2 &- x_1 - 0.5 &\doteq \\ \doteq -0.349586 & \text{ holds and } \frac{\partial f(x, y)}{\partial y} < 0 \text{ for each } (x, y) \in J \times I. \end{aligned}$$

Testing the limits of emergent behavior in MAS using learning of cooperative behavior

Jordan Kidney and Jörg Denzinger¹

Abstract. We present a method to test a group of agents for (unwanted) emergent behavior by using techniques from learning of cooperative behavior. The general idea is to mimick users or other systems interacting with the tested agents by a group of tester agents and to evolve the actions of these tester agents. The goal of this evolutionary learning is to get the tested agents to exhibit the (unwanted) emergent behavior. We used our method to test the emergent properties of a team of agents written by students for an assignment in a basic MAS class. Our method produced tester agents that helped the tested agents to perform at their best and another configuration of our system showed how much the tested agents could hold their own against very competitive agents, which revealed breakdowns in the tested agents' cooperation.

1 Introduction

Emergent behavior has become a hot research topic in both the multi-agent systems (MAS) and the artificial life communities. Having a group of agents that –by working together– achieve goals that are beyond what can be expected from them by just adding up their individual abilities is naturally a very desirable goal (especially given that the computer “world” is getting more and more distributed), so that even researchers from areas like software engineering and computer security have become interested in this phenomenon. While there are quite a few examples for the synergetic effects that emergent behavior can achieve (see, for example, [2]), there are still many aspects of emergent behavior that are not well understood. Current research mostly focuses on finding concepts for agent cooperation or interaction that result in some intended emergent behavior.

An aspect of emergent behavior that has not been addressed very much, so far, is the fact that the interactions of a set of agents might not always produce only wanted emergent behavior (which is naturally known, but not much written of) and how to identify situations for a set of agents when unwanted behavior surfaces. Traditionally, finding unwanted behavior of a system is the task of testing the system. But software testing in general struggles to keep up with the growing complexity of todays software systems and there have been very few approaches to deal with testing of multi-agent systems beyond the standard techniques developed decades ago. Following test case scripts, testing of individual system components and visualization of agent interactions help with testing of multi-agent systems, but finding unwanted emergent behavior of these systems requires much more than these techniques. The growing number of cases of users abusing systems by providing unexpected inputs or exploiting bugs in the systems is a clear proof of that (see [13]).

In this work, we propose to tackle this problem by making use of techniques that helped creating the problem in the first place: *learning of cooperative behavior* of agents. The general idea is to employ a group of cooperating agents that interact with the multi-agent system that we want to test in order to get this multi-agent system to produce an unwanted (emergent) behavior. Learning methods are used by the group of tester agents to adapt their behavior based upon observations made about the tested system. This process is done to get the tested system closer and closer to the unwanted behavior we are looking for. More precisely, we propose to use ideas from evolutionary learning of behavior (see [3]) to develop a set of tester agent strategies that forces the tested system to show the unwanted behavior we are looking for.

We used our method to test the emergent behavior of a set of agents created by students for their assignment in our multi-agent systems course. The tested agents act within the ARES 2 simulator (see [4]) that is a disaster simulation in which the tested agents have to find and rescue survivors buried under rubble. With our testing method we are able to evaluate the limits of the emergent behavior of the student teams. This testing on one hand works at creating a team of tester agents that tries to help the tested agents as much as possible, boosting the number of survivors rescued by the tested agents. On the other side it works to also create tester agents that keep the score of the tested agents as low as possible, revealing weaknesses in the cooperation strategies employed by the students. Our experimental evaluation shows that our testing method allows us to reveal quite well the (positive and negative) limits of the tested student team to help us in our evaluation (and grading) of the tested team. Additionally, our agents revealed confusion in the behavior of the tested agents in some circumstances, clearly unwanted emergent behavior.

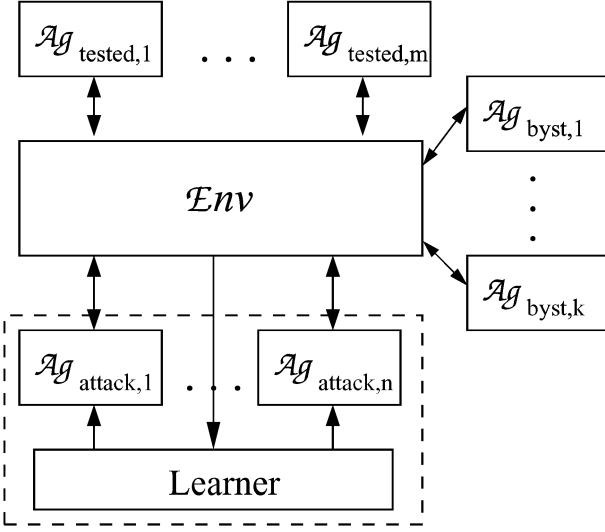

2 Basic definitions

A general definition that can be instantiated to most of the views of agents in literature sees an agent Ag as a quadruple $Ag = (Sit, Act, Dat, f_{Ag})$. Sit is a set of situations the agent can be in, Act is the set of actions that Ag can perform and Dat is the set of possible values that Ag 's internal data areas can have. In order to determine its next action, Ag uses $f_{Ag} : Sit \times Dat \rightarrow Act$ applied to the current situation and the current values of its internal data areas.

In order to interact, a group of agents has to share an environment or at least parts of it. Therefore, a multi-agent system MAS on a very high level is a pair $MAS = (A, Env)$, with A a set of agents and Env the environment. Env consists of a set of environment states. Based on this view of a multi-agent system, the first 3 components of an agent can be more structured by distinguishing between parts dealing with other agents and parts dealing with the

Figure 1. General setting of our approach

agent in the environment, but we do not need this distinction in this paper. Note that communication between agents is modeled by having on the one side actions and on the other side the communication “channels” provided by the environment. Note also that the set Sit of an agent can be just a view on the environment, i.e. an element of Sit can contain less information than an element of $\mathcal{E}nv$.

3 Testing by evolutionary learning

The method we propose for testing for unwanted emergent behavior of a group of agents A_{tested} uses a set of (learning) tester (or attack²) agents A_{attack} that interact with the agents in A_{tested} by playing the role of entities that the agents in A_{tested} usually interact with in their environment. The agents in A_{attack} can play the role of “team members” of the agents in A_{tested} or the role of users or other systems that use/interact with the agents in A_{tested} . Depending on the circumstances, there can be a third set A_{byst} of agents, the bystander agents, which are agents that are not part of the set of tested agents, but interact with them in the environment, and are also not under control of the tester. Figure 1 presents a view of the general setting just described, i.e. all 3 types of agents act in the environment $\mathcal{E}nv$ and by doing that they interact with each other.

Figure 1 also indicates that the agents in A_{attack} are learning, but how learning is organized is indicated rather vague, we only see that the learning gets feedback by observing the environment. There are many different ways how learning of a behavior for a group of agents can be accomplished (see [8] for an overview). We can have one learner that learns off-line and creates a team of attack agents that are not doing any learning while they “work”. The other extreme is that each agent $Ag_{attack,i}$ in A_{attack} has as part of it a learning component and the agent is learning on-line. And, as pointed out in [5], there are many other possibilities in between those extremes. We think that different combinations of A_{tested} and $\mathcal{E}nv$ will require different learning methods for A_{attack} .

In this paper, we propose a central off-line learning approach, i.e. the first extreme mentioned above. Naturally, learning is strongly connected with the agent architecture (Sit, Act, Dat, f_{Ag}) of an agent

² We use the term attack in the following, since “tester” and “tested” are very difficult to distinguish

and what architecture to choose depends a lot on the task agents have to perform. From the point of view of testing the limits of emergent behavior of agents in A_{tested} , the task of the agents in A_{attack} is to provoke the agents in A_{tested} into showing a particular behavior (that the human tester would like to know about).

More precisely, from the point of view of an outside observer, each agent $Ag_{attack,i} \in A_{attack}$ has to perform a sequence of actions $a_{i,1}, \dots, a_{i,l_i}$ ($a_{i,j} \in Act_{attack,i}$) that results in a sequence e_0, e_1, \dots, e_x of (enhanced) environment states, such that some condition $\mathcal{G}_{emerge}((e_0, e_1, \dots, e_x))$ is true. By an (enhanced) environment state, we mean a view on $\mathcal{E}nv \times \bigcup_{Ag \in A_{tested}} Dat_{Ag}$, i.e. we allow on the one side that internal data of the tested agents can be made available to our learning agents and on the other side we might not even make everything that is observable in the environment available to our attack agents (and the learner for them). If all agents interact with the environment in a synchronous fashion, then the length of the action sequences of the attack agents is the same and this length is also the number of environment states that we observe after starting from e_0 , i.e. $l_i = l_j$ and $l_i = x$ for all i, j .

In the case of the agents interacting asynchronously, we need to record the (enhanced) environmental state every time a change takes place. Then x obviously cannot easily be connected to the l_i s. In the asynchronous case, it often can be necessary to add timing information to the action sequence of an $Ag_{attack,i}$, resulting in a sequence $(t_{i,1}, a_{i,1}), \dots, (t_{i,l_i}, a_{i,l_i})$ of timed actions, with the $t_{i,j}$ indicating time units and $a_{i,j} \in Act_{attack,i}$ as before. Then $Ag_{attack,i}$ lets $t_{i,j}$ time units pass between performing $a_{i,j-1}$ and $a_{i,j}$.

Based on this action sequence oriented view on the agents in A_{attack} , the learning task for these agents is to come up with an action sequence for each agent that results in a sequence of environment states fulfilling \mathcal{G}_{emerge} . Evolutionary learning methods have proven to be quite successful for such settings (see [3], [1]). An evolutionary algorithm works on a set of so-called individuals (the set being called a population). The individuals in a population are evaluated using a fitness measure fit and so-called genetic operators are applied to selected individuals to create new individuals. The selection process usually contains both a fitness-oriented and a random component. The new individuals replace the worst fit individuals in the old population and this process is repeated until an end condition is fulfilled.

We instantiate this very general scheme in the following manner to learn the action sequences for the agents in A_{attack} . An individual consists of an action sequence $a_{i,1}, \dots, a_{i,l_i}$ for each of the agents $Ag_{attack,i} \in A_{attack}$ (or $(t_{i,1}, a_{i,1}), \dots, (t_{i,l_i}, a_{i,l_i})$ if we have an asynchronous system). The fitness of an individual $((a_{1,1}, \dots, a_{1,l_1}), \dots, (a_{n,1}, \dots, a_{n,l_n}))$ is based on evaluating the success of the individual when applied as the strategy for the agents in A_{attack} in one or several runs. This means we feed the action sequences to the agents they are intended for, let these agents interact with the other agents, i.e. the agents in A_{tested} and A_{byst} , and the environment and produce the sequence e_0, e_1, \dots, e_x of (enhanced) environment states that is the consequence of executing the individual. Due to having bystanders, an individual might not produce the same environment states every time the attack agents use this individual (other reasons for this can be random elements in the tested agents or random events occurring in the environment). If this is the case, we perform several runs to evaluate an individual and sum up the fitness of these runs.

To evaluate a run of an individual, we want to measure how near this run came to fulfilling the condition \mathcal{G}_{emerge} . Obviously, this depends on \mathcal{G}_{emerge} and on what information is represented in an en-

hanced environment state. But we found it very useful to base the fitness of a single run *single_fit* on an evaluation of the environment state sequence after every new state (see also [1]). Thus we have

$$\text{single_fit}((e_0, \dots, e_x)) = \begin{cases} j, & \text{if } \mathcal{G}_{\text{emerge}}((e_0, \dots, e_j)) = \text{true} \\ & \text{and } \mathcal{G}_{\text{emerge}}((e_0, \dots, e_i)) \\ & = \text{false for all } i < j \\ \sum_{i=1}^x \text{near_emerge}((e_0, \dots, e_i)), & \text{else.} \end{cases}$$

As the name *near_emerge* suggests, this function is supposed to measure how near its argument state sequence comes to fulfilling the predicate $\mathcal{G}_{\text{emerge}}$ (so, small *near_emerge* values indicate good individuals). We will provide an example for how to create such a function for an application in Section 4.2.

There are several schemata for genetic operators that can be used for creating new individuals out of individuals of the form we are using. Here we present four such schemata that we used in our application. Our *standard crossover* needs two individuals $((a_{1,1}, \dots, a_{1,l_1}), \dots, (a_{n,1}, \dots, a_{n,l_n}))$ and $((b_{1,1}, \dots, b_{1,l_1}), \dots, (b_{n,1}, \dots, b_{n,l_n}))$. The operator selects randomly a position j in the action sequence of all agents and performs then a standard crossover on each of the strings. The result is then $((a_{1,1}, \dots, a_{1,j}, b_{1,j+1}, \dots, b_{1,l_1}), \dots, (a_{n,1}, \dots, a_{n,j}, b_{n,j+1}, \dots, b_{n,l_n}))$.

A *standard mutation* also selects a position j in one individual randomly and changes the action there of every agent to another one, resulting in $((a_{1,1}, \dots, a_{1,j-1}, a'_{1,j}, a_{1,j+1}, \dots, a_{1,l_1}), \dots, (a_{n,1}, \dots, a_{n,j-1}, a'_{n,j}, a_{n,j+1}, \dots, a_{n,l_n}))$ with $a'_{i,j} \in \text{Act}_{\text{attack},i}$ and $a_{i,j} \neq a'_{i,j}$.

We also have so-called targeted genetic operators. Instead of selecting a random position in an action sequence, these operators make use of the fitness of the parent individuals to determine “good” positions. More precisely, we look at the *near_emerge* values for all the starting state sequences and identify positions, where taking in the next state into the sequence results in a substantially higher *near_emerge* value for this new sequence (indicating that something happened that leads us away from our goal). If we change the actions of our attack agents before this happens, then there is a good chance that we can avoid this. So, for each individual we remember the first index j , such that

$$\text{near_emerge}((e_0, \dots, e_j)) \geq \text{near_emerge}((e_0, \dots, e_{j-1})) + \text{too_much_lost},$$

for a parameter *too_much_lost*. *Targeted crossover* then first identifies the agent indexes with actions in their sequences that are leading to an environment state between $e_{j-\text{cotarg}}$ and e_j (with *cotarg* being another parameter). Targeted crossover then performs a standard crossover, but selects the agent index and the action sequence position only out of the ones identified in the first step. *Targeted mutation* does the same using standard mutations (with a parameter *muttarg*).

4 Experimental evaluation: testing student teams in ARES 2

In this section, we present our experiences in applying our concept from the last section to testing a student team written for the ARES 2 simulator. Our concept allowed us on the one side to test how well this team can make use of agents that try everything to help the team, while we also used the concept to create teams of attack agents that tried to achieve a very bad performance of the tested agent team.

4.1 ARES 2

ARES is a system that simulates a city struck by an earthquake and rescue robots that work together to locate and dig out survivors of the earthquake. In contrast to the RoboCupRescue simulator (see [10]) that provides the same general scenario, the goal in developing ARES was not to be as realistic as possible to allow the development of robot controls that can be used in the real world, the goal was to provide abstractions and simplifications of the real world that allow a team of students in an introductory class on multi-agent systems to enhance their learning experience by creating controls for the robots/agents that rescue many survivors in various problem scenarios within ARES (see [4]). The last version of ARES, ARES 2, allows for the interaction of several student teams within one simulation, thus forcing the students to think about how their agents should interact with other rescue agents, allowing for many possibilities for emergent behavior.

Since ARES was developed as a teaching tool, it contains various parameters, so-called world rules, that produce rather different settings for the students (each semester, a different combination of world rule instantiations can be used to avoid too much “inspiration” from the last semester). For example, the two instantiations for the world rule that determines how agents can replenish their energy can either allow the students to mainly neglect planning around energy (if agents can simply sleep everywhere) or planning around resources becomes very important (if agents can only recharge at certain places in the world). As a consequence, instructors using ARES often do not know what the best concepts for a particular instantiation of the world rules are, which makes evaluating the teams of the students difficult. Especially evaluating how the students deal with other teams is very difficult, since using fixed teams that interact with a student team allows the students to optimize towards these teams instead of developing generally good concepts. Therefore this situation is a perfect test application for our concept for testing emergent behavior.

A simulation run in ARES consists of a sequence of rounds. In each round, ARES allows every rescue agent to submit a non-communication action and, depending on the world rules, either alternatively a communication action or one or several additional communication actions. Each agent is allotted a certain amount of CPU-time each round for making its decisions. ARES then computes out of all action requests the new world state and sends to each agent its new world view. An ARES world (or scenario) consists of a collection of connected grids and each grid contains a so-called stack, where each stack element is either a piece of rubble, requiring a certain number of agents to be removed, or a survivor or survivor group. Associated with each grid field is a move cost indicating the energy an agent loses when moving on the grid. In addition to standard grids, there are fire and instant death grids that “kill” an agent moving on them and there are also recharge grids.

Agents can move from grid to grid, observe the world, remove rubble by digging and rescue survivors. Additionally, agents can send messages to other agents in their team, allowing for planning and cooperation. In order to remove a piece of rubble, this piece has to be on top of the stack of a grid, at least the required number of agents has to perform digging in the same round and, naturally, these agents have to be located on the grid at that time. The agents can belong to different teams. To rescue survivors, they have to be on top of the stack and at least one agent has to perform the rescue survivor action. A world rule allows for different ways of scoring for rescuing survivors if several agents perform the rescue at the same time.

In addition to updating the world and doing the scoring, ARES

also keeps track of the energy levels of survivors and agents, letting them die if the level gets to zero or below. ARES also delivers the messages agents send to each other in the round after the round in which the message was sent.

4.2 Instantiating our method

The interaction of agents within ARES is organized in rounds, which means that we are dealing with the synchronous case of Section 3. For each scenario in ARES, there is a given number of rounds l in the simulation, which is then also the length of the action sequences of the agents in A_{attack} and the sequence of environment states. Obviously, ARES represents the environment \mathcal{E}_{nv} and the agents of the students are the agents in A_{tested} . In our experiments, the set A_{byst} was empty, but if we used a second student team, these agents could be the set A_{byst} .

While the agents in A_{tested} naturally used all the actions available to agents in ARES, our attack agents do not need to use any communication actions since their coordination is achieved by the learning process. An environment state is a state of ARES, i.e. the state of the world (all grids and their stacks, positions of all agents, energy levels of survivors and agents) and the scores of all teams. Naturally, we did not want to change the agents of the students to get internal information out of them. Therefore we did not require to enhance the environment states.

To evaluate the agent team of the students, we would like to know how good this team is if the other team, i.e. the agents in A_{attack} , tries to provide help and if this other team tries to actively work against the student team. This means that there is not exactly a particular behavior we are looking for that is shown or not. Instead of having a predicate G_{emerge} , we have a function f_{emerge} that on the one side we want to maximize and on the other side to minimize and this function just counts the survivors the student team got points for. So, within our general scheme of Section 3, G_{emerge} is always false and f_{emerge} will contribute to our function near_emerge .

Our near_emerge function that aims at producing agents in A_{attack} that boost the performance of the agents in A_{tested} is based on the ideas of having the agents in A_{attack} stay near the agents of A_{tested} , so that they can help dig, and of trying to get a high f_{emerge} value for the student team. More precisely, we have

$$\text{near_emerge}_{\text{pos}}((e_0, \dots, e_j)) = \sum_{i=1}^n \text{dist}(A_{g_{\text{attack}}, i}, e_j) - 2 * f_{\text{emerge}}(e_j)$$

where $\text{dist}(A_{g_{\text{attack}}, i}, e_j)$ is the distance between $A_{g_{\text{attack}}, i}$ and the closest agent from A_{tested} in state e_j .

For producing attack teams that show off the possible negative behavior of the student team, we just use the f_{emerge} value, i.e.

$$\text{near_emerge}_{\text{neg}}((e_0, \dots, e_j)) = f_{\text{emerge}}(e_j)$$

In our experiments, this simple function was already sufficient. Note that our algorithm tries to minimize the fitness, so that large near_emerge values make a strategy for A_{attack} bad.

We would like to point out that this instantiation of our general concept is independent of all the world rules in ARES, so that it can be used for all settings of these rules.

4.3 Experiments

For our experiments, we followed the advice in [4] and created two types of scenarios for ARES, the student team and our system: special scenarios that aim at evaluating special aspects of the students'

team and random scenarios that come nearer to what a real-live scenario usually might be. In each scenario/world we have 2 agents from the student team and 2 agents in A_{attack} . The time given to the teams is always 50 rounds and each team participating in a save gets the points for this save. Each agent is given 1 second per round to do its "thinking", which means that a single simulation run takes roughly 200 seconds.

The settings for the evolutionary learner were as follows: We used a very small population size of 7 and had 10 generations only, to account for the rather time consuming evaluation of each individual. Nevertheless, this still means that a complete run of our system (i.e. computing the entry for pos or neg in one entry of Table 1) takes around 5 hours. The selection of the parents for the genetic operators was done using a 3-tournament selection, i.e. each time we need a parent, we randomly select 3 individuals from the population and then select out of these 3 the one with the best (lowest) fitness value. *too_much_lost* was chosen so that a scored point for the tested team would create a targeted position (for the neg case). Then the other parameters for the targeted genetic operators were set so that the position in the sequence used by the operator was directly before the drop in *near_emerge* occurred.

Table 1. Points scored by A_{tested}

World	1×st	2×st	pos	neg
Spec1	6	5	7	2
Spec2	4	8	8	4
Spec3	8	6	9	1
Rand1	11	8	12	6
Rand2	12	9	13	8
Rand3	14	11	16	10

In the 5×5 world Spec1 we have 7 survivors that are buried under rubble, the ones at (1,3), (5,3) and (3,5) (with (1,1) being the upper left corner of the world) requiring 2 agents to dig them out, the ones at (1,1) and (5,1) needing 3 agents and the ones at (1,5) and (5,5) just one. Additionally, at (3,3) there is an unburied survivor. The 2 agents of the student team are at (3,1) and the attack agents flank the tested agents at (1,2) and (5,2). The world Spec2 is a 7×7 world with a survivor in each corner that needs 2 agents to be dug out, 6 survivors placed into the corners of the 3×3 square in the center of the world with 2 survivors in each of the left corners and 1 survivor in each of the right corners, a survivor requiring 3 agents in the center of the world, a survivor requiring 4 agents 2 grid fields below this center and one survivor requiring 3 agents two fields above the center. One tester and one attack agent start at (1,4) and the other two agents start at (7,4). Spec3 is another 5×5 world with buried survivors requiring 2 agents at (2,2), (3,2), (4,2), (2,4), (3,4) and (4,4), a survivor requiring 3 agents in the center of the world and a survivor in the open at (1,3) and (5,3). One agent from each team starts at (3,1) and (3,5).

The worlds Rand1, Rand2, and Rand3 were generated using ARES 2's functionality for creating random worlds. All 3 worlds are 7×7 and require at a maximum 3 agents to rescue a survivor (and naturally not all of the time so many). In contrast to the special worlds, different grid fields can have different move costs. The start positions for the agents were random, but we required that always one tested agent and one attack agent started together at the same grid. All random worlds had 99 survivors in them, with random amounts of energy to start with.

In Table 1, the column $1 \times st$ reports on the success of the students' team when working alone in a world, while column $2 \times st$ gives the results of two incarnations of the students' team. Note that we report in column $2 \times st$ the better score of the two teams. The columns pos, respectively neg report on the scores of the tested team when

working with the best teams our learning system came up with to help the team (pos) and to hinder the team (neg). With the exception of Spec2, we see for all worlds that the learner could produce teams that increased, often substantially, the score of the students' team and also with teams that made it really tough for the tested team. Especially for Spec1 and Spec3 the results of the tested team are much less than in all other test series. The difference for the random worlds is not so big, because in these worlds there are many possibilities for the tested agents, too many to block them all.

While from an instructor's perspective, the information in Table 1 is already very useful for grading different students' teams, because it shows the spectrum a particular team can achieve, a closer look at the runs of the evolved attack teams producing the highlights in this table will show the usefulness of our approach for finding unwanted emergent behavior. Looking at the ARES 2 runs of the final attack teams for column pos, we can not report any surprising things. The attack agents stayed within close range of the tested agents, although they did not always occupy the same grid field. The attack agents learned to dig whenever the tested agents expected them to do this and as a result we got the good scores for the tested agents.

Of more interest are the ARES 2 runs that the attack agents for the neg case for Spec1 and Spec3 produce. Naturally, the attack agents did not do anything that helped the tested agents to get points, even if this meant that they also would not get points. While for the other scenarios the students' strategy for their team was able to realize that they do not get cooperation and from there on the tested agents planned only relying on themselves, the attack teams for Spec1 and Spec3 managed to get the tested agents into different kinds of weird behavior where the tested agents did not even try to dig out survivors (that they could dig out alone) when an attack agent came near and where the tested agents in fact stopped doing anything after a while although that had sufficient energy and time to rescue some more survivors. Essentially, our approach was able to produce evidence for problems in the tested agent design, evidence for clearly unwanted emergent behavior.

5 Related work

The current practice for testing for unwanted behavior in software testing is the use of random interaction sequences (see [6]), followed by human analysis and additional constructed sequences. Obviously, random sequences are just the starting point for our method. The efforts to accommodate the needs of multi-agent systems in testing, so far, either focus on developing graphical visualization tools that allow human testers to better observe the behaviors of the tested agents (see, for example, [7]) or develop special protocols and languages that provide a standard way for a developer to inspect the interactions of agents using them (see, for example, [9]).

The use of evolutionary methods to help with software testing has been suggested by several authors. For example, in [11] known (previous) errors of a system were slightly modified (and combined) by an evolutionary algorithm to create additional test cases around known problematic ones. In [12], evolutionary methods were used to develop tests covering the possible paths through a program. But, to our knowledge, there have been no works that deal with using any artificial intelligence concepts to detect unwanted emergent behavior.

6 Conclusion and future work

We presented a method to test the limits of emergent behavior in multi-agent systems that makes use of evolutionary methods to learn

the behavior of agents that are interacting with the agents to be tested. The goal of these tester/attack agents is to get the tested agents to exhibit a behavior that we are interested in, for example because we do not want the tested agents to show this behavior. We tested our method by testing a team of rescue agents developed by students to act in the ARES 2 system. For a collection of different rescue scenarios, we were able to evolve specific teams that showed off the ability of the tested student team to make use of very cooperative other agents and the inability of the student team to deal well with agents that work against their efforts in some rescue scenarios.

It should be noted that the evolved agents use a very primitive agent architecture, action sequences, and use implicit cooperation due to the learning process, so that these agents are clearly less complex than the agents that they are testing. This is due to the fact that the tester/attack agents can be much more focused and specialized than the agents they test, since they only have to produce a specific behavior and do not have to cover a lot of use scenarios, which naturally the tested agents have to. Given that the complexity of the systems to test is one of the major problems in today's testing efforts, this feature of our method is very promising!

Naturally, there is a lot of future research that we are interested in. In addition to additional applications, we see a lot of possibilities to improve the learning of the cooperative behavior of the tester/attack agents, especially with regard to building in additional knowledge about the application. This ranges from usage of more pre-defined structure in the action sequences, over more application specific fitness functions to additional genetic operators (for example to deal with the timing information). Also, we expect that more complex systems to test might require a little bit more sophisticated agent architectures.

Boolean games revisited

Elise Bonzon¹ and **Marie-Christine Lagasquie-Schiex¹** and **Jérôme Lang¹** and **Bruno Zanuttini²**

Abstract. Game theory is a widely used formal model for studying strategical interactions between agents. *Boolean games* [8] are two players, zero-sum static games where players' utility functions are binary and described by a single propositional formula, and the strategies available to a player consist of truth assignments to each of a given set of propositional variables (the variables *controlled* by the player.) We generalize the framework to n -players games which are not necessarily zero-sum. We give simple characterizations of Nash equilibria and dominated strategies, and investigate the computational complexity of the related problems.

1 Introduction

Game theory is the most successful formal model for the study of strategical interactions between agents. Informally, a game consists of a set of agents (or players), and for each agent, a set of possible strategies and an utility function mapping every possible combination of strategies to a real value. In this paper we consider only *static* games, where agents choose their strategies in parallel, without observing the others' choices. While game theory considers several formats for specifying a game (especially extended form and normal form, which coincide as far as static games are concerned), they usually consider that utility functions are represented explicitly, by listing the values for each combination of strategies.

In many real-world domains, the strategies available to an agent consist in assigning a value to each of a given set of variables. Now, representing utility functions explicitly leads to a description whose size is exponential both in the number of agents ($n \times 2^n$ values for n agents each with two available strategies) and in the number of variables controlled by the agents ($2 \times 2^p \times 2^p$ values for two agents each controlling p variables). Thus, in many cases explicitly specifying utility functions is unreasonable, as well as computing solution concepts (such as pure-strategy Nash equilibria) using a naive algorithm which enumerates combinations of strategies.

Now, specifying utilities, or more generally preferences, in a compact way, is an issue addressed by many AI researchers in the last years. Languages have been studied which allow for a concise representation of preference relations or utility functions on combinatorial domains, exploiting to a large extent the structural properties of preferences. In this paper, without much loss of generality we focus on the case where each agent has control over a set of propositional (binary) variables. Under this assumption, preferences can be represented within logic-based preference representation languages. Using propositional logic allies a rich expressivity to the possibility of using a wide variety of algorithms.

Since the specification of a static game needs the description of the agents' preferences, it seems natural to specify them using such lan-

guages for compact preference representation. Here, for the sake of simplicity we focus on the simplest possible way of using propositional logic for representing games (the extent to which it can be extended is discussed at the end of the paper), namely by using a revisited form of *Boolean games*. These games [8, 7, 5] are two-players zero-sum games where the players' utilities are binary and specified by a mere propositional formula φ (the *Boolean form* of the game). Some background is given in Section 2. In Section 3, we give a (simplified) description of Boolean games and generalize them so as to represent non zero-sum games with an arbitrary number of players (but we keep the assumption that each player's preferences are represented by a unique propositional formula, inducing a binary utility function). In Sections 4 and 5, we show how well-known tools from propositional logic can be used so as to give simple characterizations of two of the most important game-theoretic notions, namely pure-strategy Nash equilibria and dominated strategies, and so as to derive complexity results for their computation. Sections 6 and 7 respectively address related work and further issues.

2 Background

Let $V = \{a, b, \dots\}$ be a finite set of propositional variables and let L_V be the propositional language built from V and Boolean constants \top (*true*) and \perp (*false*) with the usual connectives. Formulas of L_V are denoted by φ, ψ etc. A *literal* is a variable x of V or the negation of one. A *term* is a consistent conjunction of literals. $\text{Lit}(\alpha)$ denotes the set of literals forming the term α . A formula φ is in DNF when it is written as a disjunction of terms.

2^V is the set of the interpretations for V , with the usual convention that for $M \in 2^V$ and $x \in V$, M gives the value *true* to x if $x \in M$ and *false* otherwise. \models denotes the classical logical consequence relation. Let $X \subseteq V$. 2^X is the set of X -interpretations. A *partial interpretation* (for V) is an X -interpretation for some $X \subseteq V$. Partial interpretations are denoted by listing all variables of X , with a $\bar{\cdot}$ symbol when the variable is set to false: for instance, let $X = \{a, b, d\}$, then the X -interpretation $M = \{a, d\}$ is denoted $\{a, \bar{b}, d\}$. If $\{V_1, \dots, V_p\}$ is a partition of V and $\{M_1, \dots, M_p\}$ are partial interpretations, where $M_i \in 2^{V_i}$, (M_1, \dots, M_p) denotes the interpretation $M_1 \cup \dots \cup M_p$. Let ψ be a propositional formula. A term α is an *implicant* of ψ iff $\alpha \models \psi$ holds. α is a *prime implicant* of ψ iff α is an implicant of ψ and for every implicant α' of ψ , if $\alpha \models \alpha'$ holds, then $\alpha' \models \alpha$ holds. $PI(\psi)$ denotes the set of all the prime implicants of ψ . If $X \subseteq V$, an X -prime implicant of ψ is a prime implicant of ψ such that $\text{Lit}(\alpha) \subseteq X$. $PI_X(\psi)$ denotes the set of all the X -prime implicants of ψ .

Let $\varphi \in L_V$ and $X \subseteq V$. The *forgetting* of X in φ [13], denoted by $\exists X : \varphi$, is defined inductively by: (i) $\exists \emptyset : \varphi = \varphi$; (ii) $\exists \{x\} : \varphi = \varphi_{x \leftarrow \top} \vee \varphi_{x \leftarrow \perp}$; (iii) $\exists (X \cup \{x\}) : \varphi = \exists X : (\exists \{x\} : \varphi)$. Note that $\exists X : \varphi$ is the logically weakest consequence of φ containing only variables from $V \setminus X$ [10, 12].

Finally, we denote the partial instantiation of a formula ϕ by an X -interpretation M_X by: $(\phi)_{M_X} = \Phi_{v \in M_X \leftarrow \top, v \in X \setminus M_X \leftarrow \perp}$.

3 Boolean games

Given a set of propositional variables V , a Boolean game on V [8, 7] is a zero-sum game with two players (1 and 2), where the actions available to each player consist in assigning a truth value to each variable in a given subset of V . The utility functions of the two players are represented by a propositional formula ϕ formed upon the variables in V and called *Boolean form* of the game. ϕ represents the goal of player 1: her payoff is 1 when ϕ is satisfied, and 0 otherwise. Since the game is zero-sum³, the goal of player 2 is $\neg\phi$.⁴

Example 1

Consider $V = \{a, b, c\}$. Player 1 controls a and c while 2 controls b . Player 1's goal is $\phi_1 = (a \leftrightarrow b) \vee (\neg a \wedge b \wedge \neg c)$ and therefore, 2's is $\phi_2 = \neg\phi_1 \equiv (\neg a \wedge b \wedge c) \vee (a \wedge \neg b)$. The normal form of this game is depicted on the right (in each (x, y) , x —resp. y —represents the payoff of player 1—resp. 2):

		2	$\{b\}$	$\{\bar{b}\}$
		1	$\{a, c\}$	$\{\bar{a}, c\}$
		2	$\{a, \bar{c}\}$	$\{\bar{a}, \bar{c}\}$
		$\{a, c\}$	(1, 0)	(0, 1)
		$\{a, \bar{c}\}$	(1, 0)	(0, 1)
		$\{\bar{a}, c\}$	(0, 1)	(1, 0)
		$\{\bar{a}, \bar{c}\}$	(1, 0)	(1, 0)

We now give a more general definition of a Boolean game, with any number of players and not necessarily zero-sum (we will see further that the original definition [8, 7] is a special case of this more general framework).

Definition 1 A Boolean game is a 4-tuple (A, V, π, Φ) , where $A = \{1, 2, \dots, n\}$ is a set of players, V is a set of propositional variables (called decision variables), $\pi : A \mapsto V$ is a control assignment function, and $\Phi = \{\phi_1, \dots, \phi_n\}$ is a collection of formulas of L_V .

The control assignment function π maps each player to the variables she controls. For the sake of notation, the set of all the variables controlled by i is written π_i instead of $\pi(i)$. We require that each variable be controlled by one and only one agent, i.e., $\{\pi_1, \dots, \pi_n\}$ forms a partition of V .

Definition 2 Let $G = (A, V, \pi, \Phi)$ be a Boolean game. A strategy s_i for a player i in G is a π_i -interpretation. A strategy profile S for G is an n -tuple $S = (s_1, s_2, \dots, s_n)$ where for all i , $s_i \in 2^{\pi_i}$.

In other words, a strategy for i is a truth assignment for all the variables i controls. Note that since $\{\pi_1, \dots, \pi_n\}$ forms a partition of V , a strategy profile S is an interpretation for V , i.e., $S \in 2^V$.

In the rest of the paper we make use of the following notation, which is standard in game theory. Let $G = (A, V, \pi, \Phi)$ be a Boolean game with $A = \{1, \dots, n\}$, and $S = (s_1, \dots, s_n)$, $S' = (s'_1, \dots, s'_n)$ be two strategy profiles. s_{-i} denotes the projection of S on $A \setminus \{i\}$: $s_{-i} = (s_1, s_2, \dots, s_{i-1}, s_{i+1}, \dots, s_n)$.

Similarly, π_{-i} denotes the set of the variables controlled by all players except i : $\pi_{-i} = V \setminus \pi_i$.

³ Stricto sensu, the obtained games are not zero-sum, but constant-sum (the sum of utilities being 1) – the difference is irrelevant and we use the terminology “zero-sum” nevertheless.

⁴ The original definition [8, 7] is inductive: a Boolean game consists of a finite dynamic game. We use here the equivalent, simpler definition of [5], who showed that this tree-like construction is unnecessary.

Finally, (s_{-i}, s'_i) denotes the strategy profile obtained from S by replacing s_i with s'_i without changing the other strategies: $(s_{-i}, s'_i) = (s_1, s_2, \dots, s_{i-1}, s'_i, s_{i+1}, \dots, s_n)$.

Players' utilities in Boolean games are binary: player i is satisfied by a strategy profile (and gets utility 1) if and only if her goal ϕ_i is satisfied, and she gets utility 0 otherwise. Therefore, the goals $\{\phi_i, i = 1, \dots, n\}$ play the role of the utility functions u_1, \dots, u_n .

Definition 3 For every player i and strategy profile S : $u_i(S) = 0$ if $S \models \neg\phi_i$ and $u_i(S) = 1$ if $S \models \phi_i$.

Example 2 We consider here a Boolean n -players version of the well-known prisoners' dilemma. n prisoners (denoted by $1, \dots, n$) are kept in separate cells. The same proposal is made to each of them: “Either you denounce your accomplices (denoted by D_i , $i = 1, \dots, n$) or you cover them (C_i , $i = 1, \dots, n$). Denouncing makes you freed while your partners will be sent to prison (except those who denounced you as well; these ones will also be freed). But if none of you chooses to denounce, everyone will be freed.”

Here is the representation of this game in normal form for $n = 3$:

		strategy of 3: C_3		strategy of 3: D_3			
		2	C_2	D_2	C_2	D_2	
		1	C_1	$(1, 1, 1)$	$(0, 1, 0)$	$(0, 0, 1)$	$(0, 1, 1)$
			C_1	$(1, 1, 1)$	$(0, 1, 0)$	$(0, 0, 1)$	$(0, 1, 1)$
			D_1	$(1, 0, 0)$	$(1, 1, 0)$	$(1, 0, 1)$	$(1, 1, 1)$

So, for n prisoners, we have an n -dimension matrix, therefore 2^n n -tuples must be specified. Now, this game can be expressed much more compactly by the following Boolean game $G = (A, V, \pi, \Phi)$: $A = \{1, 2, \dots, n\}$, $V = \{C_1, \dots, C_n\}$ (with $\neg C_i = D_i$ for every i), $\forall i \in \{1, \dots, n\}$, $\pi_i = \{C_i\}$, and $\forall i \in \{1, \dots, n\}$, $\phi_i = \{(C_1 \wedge C_2 \wedge \dots \wedge C_n) \vee \neg C_i\}$.

Here, each player i has two possible strategies: $s_i = \{C_i\}$ and $s'_i = \{\neg C_i\}$. There are 8 strategy profiles for G , including $S_1 = (C_1, C_2, C_3)$ and $S_2 = (\neg C_1, C_2, C_3)$. Under S_1 , players 1, 2 and 3 have their goal satisfied, while S_2 satisfies only the goal of player 1.

Note that this choice of binary utilities implies a loss of generality, but it is essentially a starting point for the study of Boolean games, which moreover will give us lower complexity bounds. See Section 7.

Definition 4 Let $G = (A, V, \pi, \Phi)$ be a Boolean game, with $\Phi = \{\phi_1, \dots, \phi_n\}$ and $A = \{1, \dots, n\}$. Strategy s_i is a winning strategy for i if $\forall s_{-i} \in 2^{\pi_{-i}}, (s_{-i}, s_i) \models \phi_i$.

Proposition 1 Let $G = (A, V, \pi, \Phi)$ be a Boolean game. Player $i \in A$ has a winning strategy iff $PI_{\pi_i}(\phi_i) \neq \emptyset$.

Clearly enough, deciding the existence of a winning strategy for a given player is an instance of the controllability problem [3, 11] and can be reduced to the resolution of a $\text{QBF}_{2,3}$ instance.

It is also easily seen that Boolean games as studied by Harrenstein et al [8, 7] are a special case of our n -players Boolean games, obtained by making the following two assumptions: $n = 2$ (two players) and $\phi_2 = \neg\phi_1$ (zero-sum).

4 Nash equilibria

Pure-strategy Nash equilibria (PNE) for n -players Boolean games are defined exactly as usual in game theory (see for instance [14]), having in mind that utility functions are induced from players' goals ϕ_1, \dots, ϕ_n . A PNE is a strategy profile such that each player's strategy is an optimum response to the other players' strategies.

Definition 5 Let $G = (A, V, \pi, \Phi)$ be a Boolean game with $A = \{1, \dots, n\}$. $S = \{s_1, \dots, s_n\}$ is a pure-strategy Nash equilibrium (PNE) if and only if $\forall i \in \{1, \dots, n\}, \forall s'_i \in 2^{\pi_i}, u_i(S) \geq u_i(s_{-i}, s'_i)$.

Example 3 Let $G = \{A, V, \pi, \Phi\}$ be the Boolean game defined by $V = \{a, b, c\}$, $A = \{1, 2, 3\}$, $\pi_1 = \{a\}$, $\pi_2 = \{b\}$, $\pi_3 = \{c\}$, $\varphi_1 = \neg a \vee (a \wedge b \wedge \neg c)$, $\varphi_2 = (a \leftrightarrow (b \leftrightarrow c))$ and $\varphi_3 = ((a \wedge \neg b \wedge \neg c) \vee (\neg a \wedge b \wedge c))$.

Player 1 has a winning strategy, namely setting a to false. It can be checked that the strategy profile $S = \{\bar{a}, \bar{b}, c\}$ is the only PNE of G .

In some examples, several PNE appear: in Ex. 1, the PNE are $\{\bar{a}\bar{b}\bar{c}\}$ and $\{\bar{a}\bar{b}\bar{c}\}$, and in Ex. 2, the PNE are $\{C_1C_2C_3\}$ and $\{\bar{C}_1\bar{C}_2\bar{C}_3\}$.

We now give simple characterizations of pure-strategy Nash equilibria in Boolean games, starting with the following one:

Proposition 2 Let $G = (A, V, \pi, \Phi)$ be a Boolean game and let $S \in 2^V$. S is a pure-strategy Nash equilibrium for G iff for all $i \in A$, either $S \models \varphi_i$ or $s_{-i} \models \neg \varphi_i$ holds.

Proof: S is a PNE for G iff $\forall i \in A, \forall s'_i \in 2^{\pi_i}, u_i(S) \geq u_i(s_{-i}, s'_i)$, i.e., $\forall i \in A, \forall s'_i \in 2^{\pi_i}, u_i(S) = 1$ or $u_i(s_{-i}, s'_i) = 0$, i.e., $\forall i \in A, u_i(S) = 1$ or $\forall s'_i \in 2^{\pi_i}, u_i(s_{-i}, s'_i) = 0$. Finally, $u_i(S) = 1 \Leftrightarrow S \models \varphi_i$, and $\forall s'_i \in 2^{\pi_i}, u_i(s_{-i}, s'_i) = 0 \Leftrightarrow \forall s'_i \in 2^{\pi_i}, (s_{-i}, s'_i) \models \neg \varphi_i$, i.e., $s_{-i} \models \neg \varphi_i$. ■

Since $s_{-i} \models \neg \varphi_i$ means that $\neg \varphi_i$ follows from s_{-i} whatever the instantiation of the variables controlled by player i , the previous characterization of PNE can be simplified again, using the forgetting operator.

Proposition 3 Let $S \in 2^V$. S is a pure-strategy Nash equilibrium for G if and only if $S \models \bigwedge_i (\varphi_i \vee (\neg \exists i : \varphi_i))$.

Proof: We have the following chain of equivalences: $s_{-i} \models \neg \varphi_i \Leftrightarrow s_{-i} \models \neg \exists i : \varphi_i \Leftrightarrow (s_i, s_{-i}) \models \neg \exists i : \varphi_i$ (because variables controlled by player i have disappeared from $\neg \exists i : \varphi_i$) $\Leftrightarrow S \models \neg \exists i : \varphi_i$. Putting everything together, we get: $(\forall i \in A, S \models \varphi_i \text{ or } s_{-i} \models \neg \varphi_i) \Leftrightarrow (\forall i \in A, S \models \varphi_i \text{ or } S \models \neg \exists i : \varphi_i) \Leftrightarrow \forall i \in A, S \models \varphi_i \vee (\neg \exists i : \varphi_i) \Leftrightarrow S \models \bigwedge_i (\varphi_i \vee (\neg \exists i : \varphi_i))$. ■

In the particular case of two-players zero-sum Boolean games, we recover the well-known fact that pure-strategy Nash equilibria coincide with winning strategies for one of the players.

Proposition 4 If G is a two-players zero-sum Boolean game, $S = (s_1, s_2)$ is a pure-strategy Nash equilibrium iff s_1 is a winning strategy for 1 or s_2 is a winning strategy for 2.

Proof: Let $S = (s_1, s_2)$ be a PNE. Assume $u_1(S) = 1$ (the case $u_2(S) = 1$ is symmetric). Since G is zero-sum, we have $u_2(S) = 0$. Now since S is a PNE, $\forall s'_2, u_2(S) \geq u_2(s_1, s'_2)$, which entails $\forall s'_2, u_2(s_1, s'_2) = 0$. It follows $\forall s'_2, (s_1, s'_2) \models \neg \varphi_2$, which entails that $\forall s'_2, (s_1, s'_2) \models \varphi_1$. Thus s_1 is a winning strategy for 1.

Conversely, assume that s_1 is a winning strategy for 1 (the case of 2 is symmetric). Then we have $\forall s_2, u_1(s_1, s_2) = 1$ and $\forall s_2, u_2(s_1, s_2) = 0$. Let $S = (s_1, s_2)$ where $s_2 \in 2^{\pi_2}$. We have $\forall s'_1, u_1(S) \geq u_1(s'_1, s_2)$ and $\forall s'_1, u_2(S) \geq u_2(s_1, s'_2)$. Thus S is a PNE. ■

This fact enables us to easily determine the complexity of deciding whether there is a pure-strategy Nash equilibrium in a given Boolean game. Recall that $\Sigma_2^P = \text{NP}^{\text{NP}}$ is the class of all the languages that can be recognized in polynomial time by a nondeterministic Turing machine equipped with NP oracles [15].

Proposition 5 Deciding whether there is a pure-strategy Nash equilibrium in a Boolean game is Σ_2^P -complete. Completeness holds even under the restriction to two-players zero-sum games.

Proof: Membership in Σ_2^P is immediate. Hardness is obtained by a reduction from the problem of deciding the validity of a QBF_{2,3}. Given $Q = \exists A, \forall B, \Phi$, we define a two-players zero-sum Boolean game by $\varphi_1 = \Phi \vee (x \leftrightarrow y)$, where x, y are new variables and $\pi_1 = A \cup \{x\}$. Obviously, this game can be built in polynomial time given Q . Clearly, if Q is valid with $M_A \in 2^A$ as a witness, then both (M_A, x) and (M_A, \bar{x}) are winning strategies for 1. Conversely, if Q is not valid, then whatever $M_A \in 2^A$ 1 plays, 2 can play $M_B \in 2^B$ such that $(M_A, M_B) \not\models \Phi$, and 2 can play \bar{y} (resp. y) if 1 plays x (resp. \bar{x}), resulting in both cases in 2 winning (so, 1 has no winning strategy). Now it is easily seen that 2 has no winning strategy. Finally, there is a winning strategy for 1 (or 2, vacuously) if and only if Q is valid, and Proposition 4 concludes. ■

The fact that this problem lies at the second level of the polynomial hierarchy can intuitively be explained by the presence of two independent sources of complexity: the search for the “good” strategy profiles, and the test whether this strategy profile is indeed a pure-strategy Nash equilibrium. Once again, this result is related to the complexity of controllability [11]. Actually, since the existence of a Nash equilibrium is a more general problem than controllability, the fact that it has the same complexity is rather good news.

We now briefly investigate syntactic restrictions on the formulas representing the players’ goals which make the problem easier. We are especially interested in DNF formulas. Recall that any Boolean function can be represented by such a formula, and thus that this is a syntactic but not a semantic restriction.

As far as 2-players zero-sum games are concerned, since deciding the validity of $\exists A, \forall B, \Phi$, a QBF_{2,3} formula, is Σ_2^P -complete even if Φ is restricted to be in DNF, Proposition 5 holds even if player 1’s goal is restricted to be in DNF (and player 2’s is implicit). However, when we explicitly represent the goals of each player in DNF, the complexity of the problem goes down to NP, as the next proposition shows.

Proposition 6 Let G be a Boolean game. If the goal φ_i of every player is in DNF, then deciding whether there is a pure-strategy Nash equilibrium is NP-complete. Completeness holds even if both we restrict the number of players to 2 and one player controls only one variable.

Proof: If φ_i is in DNF, then $\exists i : \varphi_i$ can be computed in linear time [10, Propositions 17–18]. Thus if every φ_i is in DNF, a formula $\psi \equiv \bigwedge_i (\varphi_i \vee (\neg \exists i : \varphi_i))$ can be computed in linear time. By Proposition 3 it is enough to guess a strategy profile S and check $S \models \psi$, thus the problem is in NP.

As for hardness, we give a reduction from (the complement of) the problem of deciding whether a DNF $\Phi = \bigvee_{i=1}^k T_i$ is tautological, a well-known coNP-complete problem. Write X for the set of variables of Φ and let $x, y \notin X$. Define a two-players game G by $\varphi_1 = \bigvee_{i=1}^k (T_i \wedge x \wedge \neg y) \vee (T_i \wedge \neg x \wedge y)$, $\pi_1 = \{y\}$, $\varphi_2 = (x \wedge y) \vee (\neg x \wedge \neg y)$, $\pi_2 = X \cup \{x\}$. Clearly, G can be built in linear time and φ_1, φ_2 are in DNF. Observe $\varphi_1 \equiv \Phi \wedge (x \neq y)$ and $\varphi_2 \equiv (x = y)$. By Proposition 3, there is a PNE in G if and only if $((\Phi \wedge (x \neq y)) \vee \neg \Phi) \wedge (x = y)$ is satisfiable. Indeed: (i) since y does not occur in Φ we have $\neg \exists y : (\Phi \wedge x \neq y) \equiv \neg (\Phi \wedge \exists y : x \neq y) \equiv \neg (\Phi \wedge \top) \equiv \neg \Phi$, and (ii) $\neg \exists X \cup \{x\} : (x = y) \equiv \perp$. Since $\Phi \wedge (x \neq y) \wedge (x = y)$ is unsatisfiable, there is a PNE in G iff $\neg \Phi \wedge (x = y)$ is satisfiable, i.e., iff $\neg \Phi$ is satisfiable since x and y do

not occur in Φ . Finally, there is a PNE in G iff Φ is not tautological. ■

When restricting to two-players games, the complexity of deciding whether a game has a PNE can even be lowered to P . This is the case if goals are represented in (i) Horn-renamable DNF, (ii) affine form, (iii) 2CNF or (iv) monotone CNF. This is ensured by tractability of projection in these cases, and the same proof as for abduction [17, Section 6] can be used. However, as far as we know the practical interest of these restrictions in our context has not been studied.

5 Dominated strategies

Another key concept in game theory is *dominance*. A strategy s_i for player i strictly dominates another strategy s'_i if it does strictly better than it against all possible combinations of other players' strategies, and weakly dominates it if it does at least as well against all possible combinations of other players' strategies, and strictly better against at least one. The key idea is that dominated strategies are not useful and can be eliminated (iteratively, until a fixpoint is reached). This process relies on the hypothesis that every player behaves in a rational way and knows that the other players are rational.

Definition 6 Let $s_i \in 2^{\pi_i}$ be a strategy for player i . s_i is strictly dominated if $\exists s'_i \in 2^{\pi_i}$ s.t. $\forall s_{-i} \in 2^{\pi_{-i}}$, $u_i(s_i, s_{-i}) < u_i(s'_i, s_{-i})$.

s_i is weakly dominated if $\exists s'_i \in 2^{\pi_i}$ s.t. $\forall s_{-i} \in 2^{\pi_{-i}}$, $u_i(s_i, s_{-i}) \leq u_i(s'_i, s_{-i})$ and $\exists s_{-i} \in 2^{\pi_{-i}}$ s.t. $u_i(s_i, s_{-i}) < u_i(s'_i, s_{-i})$.

The following simple example shows the interest of eliminating dominated strategies.

Example 4 Let $G = \{A, V, \pi, \Phi\}$ be the Boolean game defined by $V = \{a, b\}$, $A = \{1, 2\}$, $\pi_1 = \{a\}$, $\pi_2 = \{b\}$, $\varphi_1 = \varphi_2 = a \wedge \neg b$. This game has two PNE: strategy profiles $S_1 = \{a, \bar{b}\}$ and $S_2 = \{\bar{a}, b\}$. Nevertheless, only one of these equilibria is interesting. Indeed, if 1 and 2 are rational, they will both choose strategy profile S_1 , which makes both of them win. This result may be obtained by eliminating dominated strategies: for player 1 (resp. 2), strategy $\{a\}$ (resp. $\{\bar{b}\}$) weakly dominates strategy $\{\bar{a}\}$ (resp. $\{b\}$). ■

This interest also appears in Ex. 2 (the resulting strategy profile is $\{\overline{C_1 C_2 C_3}\}$), but not in Ex. 1 (the resulting strategy profiles are exactly the PNE). It is a well-known fact from game theory that a strictly dominated strategy is not present in any Nash equilibrium, whereas a weakly dominated strategy can be present in one (see for instance [9].) Moreover, the order of elimination of strictly dominated strategies does not affect the final result, which is no longer true for weakly dominated strategies. Since the latter negative result holds for general games (with no restriction on the players' utility functions), it is worth wondering whether it still holds for Boolean games. It actually does, as shown on the following example.

Example 5 $G = \{A, V, \pi, \Phi\}$, where $V = \{a, b\}$, $A = \{1, 2\}$, $\pi_1 = \{a\}$, $\pi_2 = \{b\}$, $\varphi_1 = a \wedge b$, $\varphi_2 = a \wedge \neg b$. For player 1 (resp. 2), strategy $\{a\}$ (resp. $\{\bar{b}\}$) weakly dominates strategy $\{\bar{a}\}$ (resp. $\{b\}$). If we first eliminate $\{\bar{a}\}$, then $\{\bar{b}\}$ weakly dominates $\{b\}$ and only one strategy profile remains, namely $\{a\bar{b}\}$. Now, if we first eliminate $\{b\}$, then $\{a\}$ no longer dominates $\{\bar{a}\}$ any more, and two strategy profiles remain, namely $\{a\bar{b}\}$ and $\{\bar{a}b\}$.

We now study properties and characterizations of dominating strategies. A first result, that we just state as a remark, is that in a Boolean

game, if strategy s_i strictly dominates strategy s'_i , then s_i is a winning strategy for i . Stated in more formal terms, s_i strictly dominates strategy s'_i if and only if: $s_i \models (\neg \exists -i : \neg \varphi_i)$ and $s'_i \models (\neg \exists -i : \varphi_i)$. This shows that, due to the restriction to binary utilities, the notion of strict dominance degenerates and loses its interest. This is however not the case for weak dominance. We have the following simple characterization of weak dominance:

Proposition 7 Strategy s_i weakly dominates strategy s'_i if and only if $(\varphi_i)_{s'_i} \models (\varphi_i)_{s_i}$ and $(\varphi_i)_{s_i} \not\models (\varphi_i)_{s'_i}$.

Proof: Strategy s_i weakly dominates s'_i iff (i) $\forall s_{-i} \in 2^{\pi_{-i}}, u_i(s_i, s_{-i}) \geq u_i(s'_i, s_{-i})$ and (ii) $\exists s_{-i} \in 2^{\pi_{-i}}, u_i(s_i, s_{-i}) > u_i(s'_i, s_{-i})$.

Now (i) $\Leftrightarrow \forall s_{-i} \in 2^{\pi_{-i}}, (u_i(s_i, s_{-i}) = 1 \text{ or } u_i(s'_i, s_{-i}) = 0) \Leftrightarrow \forall s_{-i} \in 2^{\pi_{-i}}$, if $(s'_i, s_{-i}) \models \varphi_i$ then $(s_i, s_{-i}) \models \varphi_i \Leftrightarrow \forall s_{-i} \in 2^{\pi_{-i}}$, if $s_{-i} \models (\varphi_i)_{s'_i}$ then $s_i \models (\varphi_i)_{s_i} \Leftrightarrow (\varphi_i)_{s'_i} \models (\varphi_i)_{s_i}$.

Finally, (ii) $\Leftrightarrow \neg(\text{i})$ if we swap s_i and s'_i ; thus (ii) $\Leftrightarrow (\varphi_i)_{s_i} \not\models (\varphi_i)_{s'_i}$. ■

Like for Nash equilibria, this characterization allows us to derive the complexity of deciding weak dominance.

Proposition 8 Deciding whether a given strategy s'_i is weakly dominated is Σ_2^P -complete. Hardness holds even if φ_i is restricted to be in DNF.

Proof: Membership in Σ_2^P is immediate. Hardness is obtained again by a reduction from the problem of deciding the validity of a QBF_{2,3}. Given $Q = \exists A, \forall B, \Phi$, let a, b be two new variables, and define $\varphi_1 = (a \wedge \Phi) \vee (\neg a \wedge b)$, $\pi_1 = A \cup \{a\}$, $\pi_2 = B \cup \{b\}$ (φ_2 does not matter). Let M'_A be any A -interpretation and s'_1 be (M'_A, \overline{a}) . We have $(\varphi_1)_{s'_1} \equiv (b)$.

Assume Q is valid with $M_A \in 2^A$ as a witness, and let $s_1 = (M_A, a)$. Then clearly s_1 is a winning strategy for 1 whereas s'_1 is not, thus s_1 weakly dominates s'_1 . Conversely, assume Q is not valid, and let $M_A \in 2^A$. Let $s_1 = (M_A, \overline{a})$. Then $(\varphi_1)_{s_1} \equiv (b) \equiv (\varphi_1)_{s'_1}$, thus by Proposition 7, s_1 does not weakly dominate s'_1 . Now let $s_1 = (M_A, a)$. Since Q is not valid, there is $M_B \in 2^B$ such that $(M_A, M_B) \not\models \Phi$. Thus $(M_B, b) \models (\varphi_1)_{s'_1}$ but $(M_B, b) \not\models (\varphi_1)_{s_1}$, and by Proposition 7, s_1 does not weakly dominate s'_1 . Finally, s'_1 is weakly dominated iff Q is valid. For goals in DNF, just note (i) if Φ is in DNF then $\exists A, \forall B, \Phi$ is still Σ_2^P -complete and (ii) a DNF for φ_1 can be built efficiently. ■

6 Related work

Our work is not the first one that gives a logical account to the study of concepts such as Nash equilibria and dominating strategies. Apart from Boolean games [8, 7, 5], a number of other works considered static games from the point of view of logic and AI.

Two recent lines of work allow for expressing games with *ordinal* preferences within well-developed AI frameworks.

In Foo et al [6], a game in normal form is mapped into a *logic program with ordered disjunction* (LPOD) where each player owns a set of clauses that encode the player's preference over her possible actions given every possible strategy profile of other players. It is then shown that pure-strategy Nash equilibria correspond exactly to the most preferred answer sets. The given translation suffers from a limitation, namely its size: the size of the LPOD is the same as that of the normal form of the game (since each player needs a number of clauses equal to the number of possible other strategy profiles for other players). However, this limitation is due to the way LPODs are

induced from games and could be overwhelmed by allowing to express the players' preferences by any LPODs (and prioritized goals), which then would allow for a possible much more compact representation.

In De Vos et al [4], a strategic game is represented using a *choice logic program*, where a set of rules express that a player will select a "best response" given the other players' choices. Then, for every strategic game, there exists a choice logic program such that the set of stable models of the program coincides with the set of Nash equilibria of the game. This property provides a systematic method to compute Nash equilibria for finite strategic games.

In Apt et al [1], CP-nets are viewed as games in normal form and vice versa. Each player i corresponds to a variable X_i of the CP-net, whose domain $D(X_i)$ is the set of available actions to the player. Preferences over a player's actions given the other players' strategies are then expressed in a conditional preference table. The CP-net expression of the game can sometimes be more compact than its normal form explicit representation, provided that some players' preferences depend only on the actions of a subset of other players. A first important difference with our framework is that we allow players to control an arbitrary set of variables, and thus we do not view players as variables; the only way of expressing in a CP-net that a player controls several variables would consist in introducing a new variable whose domain would be the set of all combination of values for these variables—and the size of the CP-net would then be exponential in the number of variables. A second important difference, which holds as well for the comparison with Foo et al [6] and De Vos et al [4], is that players can express arbitrary binary preferences, including extreme cases where the satisfaction of a player's goal may depend only of variables controlled by other players. A last (less technical and more foundational) difference with both lines of work, which actually explains the first two above, is that we do not map normal form games into anything but we *express* games using a logical language.

Admittedly, on the other hand, the restriction to binary preferences is a strong limitation, but our work can be viewed as a preliminary, but necessary step, and the extension of our notions, and of some of our results, to non-degenerated (ordinal or numerical) preferences do not present any particular problem (see Section 7).

In Section 4 we mentioned a relationship to propositional controllability, as studied by Boutilier [3] and Lang et al [11]. A recent line of work within this alley [16] studies a cooperation logic in which each agent is assumed to control a set of propositional variables. While we focus on preferences and solution concepts, van der Hoek and Wooldridge [16] focus on the effective power of agents, that is, they reason about the state of affairs that a group of agents can bring about.

7 Conclusion

In this paper we extended Boolean games to an arbitrary number of players and to arbitrary Boolean goals. Extended Boolean games are a first step towards a more general framework for expressing and reasoning with interacting agents when the set of strategy profiles has a combinatorial structure.

Clearly, the restriction to a single goal for each agent—and therefore to binary utilities—is a strong one. However, as often, proceeding by "building blocks" is valuable, for at least two reasons. First, once this Boolean games framework is defined, extending it so as to allow for more general preferences does not present any particular difficulty: the definition remains unchanged *except* the agents' goals $\varphi_1, \dots, \varphi_n$, which are replaced by more complex structures, expressed within

logical languages for compact representation. These frameworks allow for representing compactly either *numerical* preferences (utility functions on 2^V) or *ordinal* preferences (partial or complete orderings on 2^V). The companion paper [2] considers extended Boolean games with ordinal preferences represented by prioritized goals and CP-nets with binary variables.

Now, binary utilities are a degenerate case of both numerical and ordinal preferences. This implies that the complexity results identified in this paper provide *lower bounds* for complexity results in the aforementioned possible extensions of the framework⁵.

Apart of extensions to more expressive preferences as explained above, we plan to address the following two issues:

- computing *mixed strategy Nash equilibria* for Boolean games;
- defining and studying *dynamic Boolean games* (with complete or incomplete information).

⁵ For Proposition 5, this lower bound will also be an upper bound for most extensions of the framework.

An Automated Agent for Bilateral Negotiation with Bounded Rational Agents with Incomplete Information¹

Raz Lin² and Sarit Kraus^{2,3} and Jonathan Wilkenfeld^{3,4} and James Barry⁵

Abstract. Many day-to-day tasks require negotiation, mostly under conditions of incomplete information. In particular, the opponent's exact tradeoff between different offers is usually unknown. We propose a model of an automated negotiation agent capable of negotiating with a bounded rational agent (and in particular, against humans) under conditions of incomplete information. Although we test our agent in one specific domain, the agent's architecture is generic; thus it can be adapted to any domain as long as the negotiators' preferences can be expressed in additive utilities. Our results indicate that the agent played significantly better, including reaching a higher proportion of agreements, than human counterparts when playing one of the sides, while when playing the other side there was no significant difference between the results of the agent and the human players.

1 Introduction

Many day-to-day tasks require negotiation, often in a bilateral context. In this setting two agents are negotiating over one or several issues in order to reach consensus [4, 6, 7]. The sides might have conflicting interests, expressed in their utility functions, and they might also cooperate in order to reach beneficial agreements for both sides [1, 12]. While models for bilateral negotiations have been extensively explored, the setting of bilateral negotiation between an automated agent and a bounded rational agent is an open problem for which an adequate solution has not yet been found. Despite this, the advantages of succeeding in presenting an automated agent with such capabilities cannot be understated. Using such an agent could help in training people in negotiations and assist in e-commerce environments by representing humans and other activities in daily life. Our proposed automated agent makes a significant contribution in this respect. An even more difficult problem occurs when incomplete information is added into this environment. That is, there is also lack of information regarding some parameters of the negotiation.

We consider a setting of a finite horizon bilateral negotiation with incomplete information between an automated agent and a bounded rational agent. The incomplete information is expressed as uncertainty regarding the utility preferences of the opponent, and we assume that there is a finite set of different agent types. The negotiation itself consists of a finite set of multi-attribute issues and time-constraints. If no agreement is reached by the given deadline a status-

quo outcome is enforced. We propose a model of an automated agent for this type of negotiation by using a qualitative decision making approach [2, 13]. In our experiments we matched our automated agent against human negotiators. By analyzing the results of the experiments, we show that our agent is capable of negotiating efficiently and reaching multi-attribute agreements in such an environment. When playing one of the sides in the negotiation our agent reached significantly better results than the human players, and also allowed both sides to reach an agreement significantly faster. On the other hand, while our agent was playing the other side, though it did not reach significantly better results than the human player, it did not reach worse results. Also, there are no significant differences between the results reached by the human players and the automated agent playing that role.

The rest of the paper is organized as follows. Section 2 provides an overview of bilateral negotiation with incomplete information. Section 3 surveys related work done in the field of negotiation with incomplete information and bounded rational agents. Section 4 presents the design of our automated agent, including its beliefs updating and decision making mechanisms. Section 5 describes the experimental setting and methodology and reviews the results. Finally, Section 6 provides a summary and discusses future work.

2 Problem Description

We consider a bilateral negotiation in which two agents negotiate to reach an agreement on conflicting issues. The negotiation can end either when (a) the negotiators reach a full agreement, (b) one of the agents opts out, thus forcing the termination of the negotiation with an opt-out outcome denoted OPT , or (c) a predefined deadline is reached, denoted dl , in which, if a partial agreement was reached it is implemented or, if no agreement was reached, a status quo outcome, denoted SQ , is implemented. Let I denote the set of issues in the negotiation, o_i the finite set of values for each $i \in I$ and $O = o_1 \times o_2 \times \dots \times o_{|I|}$ a finite set of values for all issues. Since we allow partial agreements $\emptyset \in o_i$ for each $i \in I$. An offer is then denoted as a vector $\vec{o} \in O$. It is assumed that the agents can take actions during the negotiation process until it terminates. Let **Time** denote the set of time periods in the negotiation, that is **Time** = {0, 1, ..., dl }. Time also plays a factor and has an influence on the agents' utilities. Each agent is assigned with a time cost which influences his utility as time passes.

In each period $t \in \text{Time}$ of the negotiation, if the negotiation has not terminated earlier, each agent can propose a possible agreement, and the opponent can either accept or reject the offer. Each agent can either propose an agreement which consists of all the issues in the negotiation, or a partial agreement. In contrast to the model of

alternating offers [12], each agent can perform up to M interactions with the opponent agent in a given time period. Thus, an agent must worry that its opponent may opt out in any time period.

Since we deal with incomplete information, we assume that there is a finite set of agent types. These types are associated with different additive utility functions. Formally, we denote the possible types of the agents $\text{Types} = \{1, \dots, k\}$. We refer to an agent whose utility function is u_l as an agent of type l , and $u_l : \{(O \cup \{SQ\} \cup \{OPT\}) \times \text{Time}\} \rightarrow \mathbb{R}$. Each agent is given its exact utility function. The agent, and the subjects in the experiments described later in the paper, are also aware of the set of possible utility functions of the opponent. However, the exact utility function of the rival is private information. Our agent has some probabilistic belief about the type of the other agent. This belief may be updated over time during the negotiation process (for example, using Bayes formula).

3 Related Work

The problem of modeling an automated agent for bilateral negotiation is not new for researchers in the fields of Multi-Agent Systems and Game Theory. However, most research makes simplifying assumptions that do not necessarily apply in genuine negotiations, such as assuming complete information [3, 11] or the rationality of the opponent [3, 4, 5, 7]. None of the above researchers has looked into the negotiation process in which there is both incomplete information and the opponent is bounded rational. While their approaches might be appropriate in their context, they cannot be applied to our settings.

To deal with the opponent's bounded rationality, researchers suggested shifting from quantitative decision theory to qualitative decision theory [13]. In using such a model we do not necessarily assume that the opponent will follow the equilibrium strategy or try to be a utility maximizer. Also, this model is better suited for cases in which the utility or preferences are unknown but can be expressed in ordinal scales or as preference relations [2]. This approach seems appropriate in our settings, and using the maximin criteria, which is generally used in this context, enables our agent to follow a pessimistic approach regarding the probability that an offer will be accepted.

Another way to deal with bounded rationality was suggested by Luce [8], who introduced the notion of *Luce numbers*. A Luce number is a non-negative number that is attached to each offer. The Luce number of an offer $\vec{o}^* \in O$ is calculated using the following formula:

$$lu(o^*) = \frac{u(\vec{o}^*)}{\sum_{\vec{o} \in O} u(\vec{o})} \quad (1)$$

That is, the Luce numbers assign probabilistic beliefs regarding the acceptance of the offer by the opponent.

Several methods are proposed when dealing with the incomplete information regarding the preferences of an opponent. For example, Bayes theorem is the core component of the *Bayesian Nash equilibrium* ([12], p. 24-29), and it is used to deduce the current state given a certain signal. It allows us to compensate for incomplete information and enables good adaptation in a negotiation with time-constraints. In finite horizon negotiations there are no past interactions to learn from and not enough time periods to build a complete model. Thus this model supplies a good probabilistic tool to model the opponent, as opposed to neural networks [11] or genetic algorithms [7]. In our settings, Bayes theorem can be used to update the believed type of the opponent and at each time period act as if the opponent is of a certain type.

4 Agent Design

Our agent is built with two mechanisms: (a) a decision making mechanism, and (b) a mechanism for updating beliefs. We describe both mechanisms in the following subsections.

4.1 The Qualitative Decision Making Component (QDM)

The qualitative decision making component takes into account the agent's utility function, as well as the believed type of the opponent. This data is used both for deciding whether to accept or reject an offer and for generating an offer. In our settings, although several offers can be proposed in each time period, we restrict our agent to making a single offer in each period. This is done due to the fact that our mechanism for generating offers only produces one distinct offer at a given time period. The bounded rational agent, on the other hand, is free to propose several offers, and our agent can respond to all the offers, which indeed happened in the simulations. While we provide some theoretical foundations for our approach, we demonstrate its effectiveness using simulations with human subjects in an environment of incomplete information, as described in Section 5.

4.1.1 Generating Offers

The motivation behind the mechanism for generating offers is that the automated agent would like to propose an offer, which yields him the highest utility value. However, due to conflict of interests, there is a high probability that this agreement will be rejected by the opponent. To overcome this, our agent uses a qualitative decision strategy. Basically, the agent evaluates all possible offers based on its utility and the probability that the rival will accept them. *Luce numbers* are used to estimate this probability. We note that for every two offers x and y and agent j , where $lu_j(x)$ and $lu_j(y)$ denote the Luce numbers associated with offers x and y respectively for agent j , if $u_j(x) \geq u_j(y)$ then $lu_j(x) \geq lu_j(y)$. That is, the higher the Luce number of an offer, the greater the probability of it being accepted.

Since the opponent himself also tries to reason whether an offer will be accepted by our agent, we take the Luce numbers of both our agent and the opponent into account. That is, our agent tries to estimate, from the opponent's point of view, whether the opponent will accept the offer. This is done by calculating the sum of the Luce numbers of the agent and the opponent. This sum is used as an estimation for the acceptance of the offer, and is multiplied by the utility value of the opponent from that offer. Finally, our agent compares those values with its own utility values. Similarly to the qualitative decision theory, which uses the maximin value [2, 13], our agent selects the minimum value between those two values, under the pessimistic assumption that the probability that an offer is accepted is based on the agent that favors the offer the least. After calculating the minimum value between all the offers, our agent selects the offer with the maximum value among all the minima, in order to also try and maximize its own utility. Thus, our qualitative offer generation mechanism selects, intuitively, the best offer among the offers that the agent believes that might be accepted. In the rest of this section we describe this process formally.

We assume that, at each time period t , the automated agent has a belief about the type of its opponent. This believed type, denoted by $BT(t)$, is the one that the agent presumes to be the most probable for the opponent. The agent uses the utility function associated with that type in all of the calculations in that time period. In Section 4.2 we

describe in detail the elicitation of this belief. We denote by $u_{opp}^{BT(t)}$ the utility function associated with the believed type of the opponent at time t . From this utility function, our agent derives the *Luce numbers* [8]. Since the Luce number is calculated based on a given utility function, we denote the Luce number of an offer derived from the opponent's believed utility at time t , $BT(t)$, by $lu_{opp}(\text{offer} \mid BT(t))$, and the Luce number for an offer derived by the agent's own utility simply as $lu(\text{offer})$. We denote our function by $QO(t)$ (standing for Qualitative Offer), where $t \in \text{Time}$ is the time of the offer. If the current agent is j , the strategy selects an offer o in time t such that:

$$QO(t) = \arg \max_{o \in O} \min\{\alpha, \beta\} \quad (2)$$

$$\text{where } \alpha = u_j(o, t)$$

$$\text{and } \beta = [lu_{opp}(o \mid BT(t)) + lu(o)] \cdot u_{opp}^{BT(t)}(o, t)$$

Seemingly, our QO function is a non-classical method for generating offers. However, not only were we able to show its efficacy by empirical experiments, in which it was used in negotiations with bounded rational agents, as we describe in Section 5, we also showed (Section 4.1.3) that it also conforms to some properties from classical negotiation theory, which are mainly used by mediators. Note that the formula does not build on the bounded rationality of the opponent.

The next subsection deals with the question of when the agent should accept an incoming offer or reject it.

4.1.2 Accepting Offers

The agent needs to decide what to do when it receives an offer from its opponent, offer_{opp} , at time $t - 1$. If we refer to the automated agent as agent 1 and the bounded rational agent as agent 2, if $u_1(\text{offer}_{opp}) \geq u_1(QO(t))$ then our agent accepts the offer. Otherwise, our agent should not immediately rule out accepting the offer it has just received. Instead, it should take into consideration the probability that its counter-offer will be accepted or rejected by the opponent. This is done by comparing the believed utility of the opponent from the original offer as compared with the opponent's utility from our offer. If the difference is lower than a given threshold⁶ T , that is $|u_2(QO(t)) - u_2(\text{offer}_{opp})| \leq T$, then there is a high probability that the opponent will be indifferent between its original offer and our counter-offer, so our agent will reject the offer and propose a counter-offer (taking a risk that the offer will be rejected), since the counter-offer has a better utility value for our agent. If the difference is greater than the threshold, i.e., there is a higher probability that the opponent will not accept our counter-offer, our agent will accept the opponent's offer with a given probability, which is attached to each outcome. To this end we define the rank number, which is associated with each offer and a given utility function u , denoted *rank*(offer). The rank number of an offer is calculated by ordering all offers on an ordinal scale between 1 and $|O|$ according to their utility values, and dividing the offer's ordering number by $|O|$. That is, the agent will accept an offer with a probability $rank(\text{offer}_{opp})$ and reject and make a counter-offer $QO(t)$ with probability $1 - rank(\text{offer}_{opp})$. The intuition behind this is to enable the agent also to accept agreements based on their relative values, on an ordinal scale of $[0..1]$, and not based on their absolute values.

In the next subsection we demonstrate that our proposed solution also conforms to some properties of the *Nash bargaining solution*. This gives us the theoretical basis for the usage of our technique in

bilateral negotiation, and for the assumption that offers proposed by our agent will also be considered to be accepted by the opponent.

4.1.3 QO: An Alternative to Nash Bargaining Solution

We employ from Luce and Raiffa [9] the definitions of a bargaining problem and the Nash bargaining solution. We denote by $B = (u_1(\cdot), u_2(\cdot))$ the bargaining problem with two utilities, u_1 and u_2 . The Nash bargaining solution (note that the solution is not the offer itself, but rather the payoff of the offer) is defined by several characteristics and is usually designed for a mediator in an environment with complete information. A bargaining (or a negotiation) solution f should satisfy symmetry, efficiency, invariance and independence of irrelevant alternatives, wherein *symmetry* states that if both players have the same bargaining power, then neither player will have any reason to accept an agreement which yields a lower payoff for it than for its opponent. For example, for the solution to be symmetric, it should not depend on the agent who started the negotiation process. *Efficiency* states that two rational agents will not agree on an agreement if its utility is lower for both of them than another possible agreement. This solution is said to be Pareto-optimal. *Invariance* states that for all equivalent problems B and B' , that is $B' = (\alpha_1 + \beta_1 \cdot u_1(\cdot), \alpha_2 + \beta_2 \cdot u_2(\cdot))$, $\alpha_1, \alpha_2 \in \mathbb{R}$, $\beta_1, \beta_2 \in \mathbb{R}^+$, the solution is also the same, $f(B) = f(B')$. That is, two positive affine transformations can be applied on the utility functions of both agents and the solution will remain the same. Finally, *independence of irrelevant alternatives* asserts that the solution $f(B) = f(B')$ whenever $B' \subseteq B$ and $f(B) \subseteq B'$. That is, if new agreements are added to the problem in such a manner that the status quo remains unchanged, either the original solution is unchanged or it becomes one of the new agreements.

It was shown by Nash [10] that the only solution that satisfies all of these properties is the product maximizing of the agents' utilities. However, as we stated, the Nash solution is usually designed for a mediator. Since we propose a model for an automated agent which negotiates with bounded rational agents following the QO function (Equation 2), our solution cannot satisfy all of these properties. To this end, we modified the independence of irrelevant alternatives property to allow for a set of possible solutions instead of one unique solution:

- **PROPERTY 4A (Independence of irrelevant alternatives solutions)**
A negotiation solution f satisfies independence of irrelevant alternatives solutions if the set of all possible solutions of $f(B)$ is equal to the set of all possible solutions of $f(B')$ whenever $B' \subseteq B$ and $f(B) \subseteq B'$.

Proving that our agent's strategy for proposing offers conforms to those properties is important since although the agent should maximize its own utility, it should also find agreements that would be acceptable to its opponent.

Theorem 1 *The QO function satisfies the properties of symmetry, efficiency and independence of irrelevant alternatives solutions.*

Due to space limitations, we do not present the proof of the theorem. We also showed that in certain cases QO generates agreements which are better for the automated agent than agreements that would have been generated by following the Nash solution.

4.2 The Bayesian Updating Rule Component

The Bayesian updating rule (BUR) is based on Bayes Theorem described above and it provides a practical learning algorithm. We as-

⁶ In the simulations, T was set to 0.05.

sert that there are several types (or clusters) of possible agents. The bounded rational agent should be matched to one such type. In each time period, our agent consults the BUR component in order to update its belief regarding the opponent's type.

Recall that there are k possible types for an agent. At time $t = 0$ the prior probability of each type is equal, that is, $P(\text{type}) = \frac{1}{k}, \forall \text{type} \in \text{Types}$. Then, for each time period t we calculate the posteriori probability for each of the possible types, taking into account the history of the negotiation. This is done incrementally after each offer is received or accepted. Then, this value is assigned to $P(\text{type})$. Using the calculated probabilities, the agent selects the type whose probability is the highest and proposes an offer as if this is the opponent's type. Formally, at each time period $t \in \text{Time}$ and for each type $\in \text{Types}$ and offert _{t} (the offer at time period t) we compute:

$$P(\text{type}|offert_t) = \frac{P(\text{offert}_t|\text{type})P(\text{type})}{P(\text{offert}_t)} \quad (3)$$

where $P(\text{offert}_t) = \sum_{i=1}^{|\text{Types}|} P(\text{offert}_t|\text{type}_i) \cdot P(\text{type}_i)$. Since the Luce numbers actually assign probabilities to each offer, $P(\text{offert}_t|\text{type})$ is computed using the Luce numbers.

Now we can deduce the believed type of the opponent for each time period t , denoted as $BT(t)$, using the following equation:

$$BT(t) = \arg \max_{\text{type} \in \text{Types}} P(\text{type}|offert_t), \quad \forall t \in \text{Time} \quad (4)$$

Using this updating mechanism enables our updating component to conform to the following conditions, which are generally imposed on an agent's system of beliefs, and which are part of the conditions for a sequential Bayesian equilibrium [12]: (a) *consistency* and (b) *never dissuaded once convinced*. *Consistency* implies that agent j 's belief should be consistent with its initial belief and with the possible strategies of its opponents. These beliefs are updated whenever possible, while *never dissuaded once convinced* implies that once an agent is convinced of its opponent's type with a probability of 1, or convinced that its opponent cannot be of a specific type, it is never dissuaded from its view. The results of the simulation indeed show that in more than 70% of the simulations our agent believed that its opponent is of the correct type with a probability of 1 or with the highest probability amongst the other possible types.

5 Experiments

We developed a simulation environment which is adaptable such that any scenario and utility functions, expressed as multi-issue attributes, can be used, with no additional changes in the configuration of the interface of the simulations or the automated agent. Our agent can play either role in the negotiation, while the human counterpart accesses the negotiation interface via a web address. The negotiation itself is conducted using a semi-formal language. Each agent constructs an offer by choosing the different values constituting the offers. Then, the offer is constructed and sent in plain English to its counterpart.

To test the efficiency of our proposed agent, we have conducted experiments on a specific negotiation domain⁷. In the following subsections we describe our domain, the experimental methodology and review the results.

⁷ To show that our agent is capable of negotiating in other domains as well, we loaded another domain and tested the agent. As expected, the agent performs as well as in the specified domain. That is, only the utility functions play a role, and not the scenario or the domain.

5.1 Experimental Domain

The experimental domain adheres to the problem definitions described in Section 2. In our scenario England and Zimbabwe are negotiating in order to reach an agreement growing out of the World Health Organization's Framework Convention on Tobacco Control, the world's first public health treaty. The principal goal of the convention is "to protect present and future generations from the devastating health, social, environmental and economic consequences of tobacco consumption and exposure to tobacco smoke." There are three possible agent types, and thus a set of six different utility functions was created. This set describes the different types or approaches towards the negotiation process and the other party. For example, type (a) has a long term orientation regarding the final agreement, type (b) has a short term orientation, and type (c) has a compromise orientation.

Each negotiator was assigned a utility function at the beginning of the negotiation but had incomplete information regarding the opponent's utility. That is, the different possible types of the opponent were public knowledge, but the exact type of the opponent was unknown. The negotiation lasts at most 14 time periods, each with a duration of two minutes. If an agreement is not reached by the deadline then the negotiation terminates with a status quo outcome. Each party can also opt out of the negotiation if it decides that the negotiation is not proceeding in a favorable way. Opting out by England means trade sanctions imposed by England on Zimbabwe (including the ban on the import of tobacco from Zimbabwe), while if Zimbabwe opts out then it will boycott all British imports.

A total of 576 agreements exist, consisting of the following issues: (a) the total amount to be deposited into the Tobacco Fund to aid countries seeking to rid themselves of economic dependence on tobacco production, (b) impact on other aid programs, (c) trade issues, and (d) creation of a forum to explore comparable arrangements for other long-term health issues. While on the first two issues there are contradicting preferences for England and Zimbabwe, for the last two issues there are options which might be preferred by both sides.

5.2 Experimental Methodology

We tested our agent against human subjects, all of whom are computer science undergraduates. The experiment involved 44 simulations with human subjects, divided into 22 pairs. Each simulation was divided into two parts: (i) negotiating against another human subject, and (ii) negotiating against the automated agent. The subjects did not know in advance against whom they played. Also, in order not to bias the results as a consequence of the subjects getting familiar with the domain and the simulation, for exactly half of the subjects the first part of the simulation consisted of negotiating with a human opponent, while the other half negotiated first with the automated agent. The outcome of each negotiation is either the reaching of a full agreement, opting out, or reaching the deadline.

5.3 Experimental Results

The main goal of our proposed method was to enable the automated agent to achieve higher utility values at the end of the negotiation than the human negotiator, playing the same role, achieved, and to allow the negotiation process to end faster as compared to negotiations without our agent. Another secondary goal was to test whether our agent increased the social welfare of the outcome.

Table 1 summarizes the average utility values of all the negotiations and the average of the sums of utility values in all the experiments. HZ and HE denote the utility value gained by the human

playing the role of Zimbabwe or England, respectively, and QZ and QE denote the utility value gained by the *QO* agent playing either role. The utility values ranged from -575 to 895 for the England role and from -680 to 830 for the Zimbabwe role. The Status-Quo value in the beginning of the negotiation was 150 for England and -610 for Zimbabwe. England had a fixed gain of 12 points per time period, while Zimbabwe had a fixed loss of -16 points.

Table 1. Final negotiations utility values and sums of utility values

Parameter	Avg	Stdev
QZ vs. HE	-27.4	287.2
HZ vs. HE	-260	395.6
QE vs. HZ	150.5	270.8
HE vs. HZ	288.0	237.1
HZ vs. QE	113.09	353.23
HE vs. QZ	349.14	299.36
Sum - HE vs. QZ	321.7	223.4
Sum - HZ vs. QE	263.6	270.5
Sum - HE vs. HZ	27.86	449.9

First, we examined the final utility values of all the negotiations for each player, and the sums of the final utility values. The results show that when the automated agent played the role of Zimbabwe, it achieved significantly higher utility values as opposed to a human agent playing the same role (using paired *t-test*: $t(22) = 2.23, p < 0.03$). On the other hand, when playing the role of England, there is no significant difference between the utility values of our agent and the human player, though the average utility value for the human was higher than for the automated agent. The results also show that the average utility values when the human played against another human are lower than the average utility values when he played against our agent. However, these results are significant only when the human players played the role of Zimbabwe ($t(22) = -3.43, p < 0.003$). One explanation for the higher values achieved by the *QO* agent is that the *QO* agent is more eager to accept agreements than humans. When playing Zimbabwe side, which has a negative time cost, accepting agreements sooner, rather than later, allowed the agent to gain higher utility values than the human playing the same side.

Comparing the sum of utility values of both negotiators, based on the role our agent played, we show that this sum is significantly higher when the negotiations involved our agent (either when our agent played the role of Zimbabwe or England), as opposed to negotiations involving only human players (using 2-sample *t-test*: $t(22) = 2.74, p < 0.009$ and $t(22) = 2.11, p < 0.04$).

Another important aspect of the negotiation is the outcome - whether a full agreement was reached or whether the negotiation ended with no agreement (either status-quo or opting out) or with a partial agreement. While only 50% of the negotiations involving only humans ended with a full agreement, 80% of the negotiations involving the automated agent ended with a full agreement. Using *Fishers Exact test* we determined that there is a correlation between the kind of the opponent agent (be it our agent or the human) and the form of the final agreement (full, partial or none). The results show that there is a significantly higher probability of reaching a full agreement when playing against our agent ($p < 0.006$).

Then we examined the final time period of the negotiations. All of the test results showed that in negotiations in which our agent was involved the final time period was significantly lower than the final time period in negotiations in which only humans were involved. The average final time period with two human negotiators was 11.36, while the average final time period against our agent playing the role of Zimbabwe and the role of England was 6.36 and 6.27 respectively.

We used the 2-sample Wilcoxon test to compare between the final time periods of our agent and the human agent when playing against the same opponent (for England role $p < 0.001$ and for Zimbabwe role $p < 0.002$). In addition, we used the Wilcoxon signed rank test, to examine the final time period achieved by the same human player in the two simulations in which he participated - once involving another human player, and another involving an automated agent (for England role $p < 0.0004$, for Zimbabwe role $p < 0.001$).

We also examined the total number of offers made and received in each negotiation. The average number of offers made and received in negotiations involving our agent was 10.86 and 10.59, while in negotiation involving only human players the average number was 18.09. Using 2-sample Wilcoxon test we show that significantly fewer offers were made when our agent was involved ($p < 0.007$ and $p < 0.004$).

6 Conclusions

This paper outlines an automated agent design for bilateral negotiation with bounded rational agents where there is incomplete information regarding the opponent's utility preferences. The automated agent incorporated a qualitative decision making mechanism. The results showed that our agent is indeed capable of negotiating successfully with human counterparts and reaching efficient agreements. In addition, the results demonstrated that the agent played at least as well as, and in the case of one of the two roles, gained significantly higher utility values, than the human player. Though the experiments were conducted on a specific domain, it is quite straightforward to adapt the simulation environment to any other scenario.

Although much time was spent on designing the mechanism for generating an offer, the results showed that most of the agreements reached were offered by the human counterpart. Our agent accepted the offers based on a probabilistic heuristic. A future research direction would be to improve this mechanism and the probabilistic heuristic and then test it by conducting the same sets of experiments.

Self-Organizing Multiagent Approach to Optimization in Positioning Problems

Sana Moujahed and Olivier Simonin and Abderrafia Koukam¹ and Khaled Ghédira²

Abstract. The facility positioning³ problem concerns the location of facilities such as bus-stops, fire stations, schools, so as to optimize one or several objectives. This paper contributes to research on location problems by proposing a reactive multiagent approach. Particularly, we deal with the p-median problem, where the objective is to minimize the weighted distance between the demand points and the facilities. The proposed model relies on a set of agents (the facilities) situated in a common environment which interact and attempt to reach a global optimization goal: the distance minimization. The interactions between agents and their environment, which is based on the artificial potential fields approach, allow us to locally optimize the agent's location. The optimization of the whole system is then obtained from a self-organization of the agents. The efficiency of the proposed approach is confirmed by computational results based on a set of comparisons with the k-means clustering technique.

1 INTRODUCTION

The facility positioning problems have witnessed an explosive growth in the last four decades. As Krarup and Pruzan [8] point out, this is not at all surprising since location policy is one of the most profitable areas of applied systems analysis. This is due to the importance of location decisions which are often made at all levels of human organization. Then, such decisions are frequently strategic since they have consequential economic effects.

The term facility is used in its broadest sense. It refers to entities such as bus-stops, schools, hospitals, fire stations, etc. The general problem is, then, the location of new facilities to optimize some objectives such as distance, travel time or cost and demand satisfaction.

However, positioning problems are often extremely difficult to solve, at least optimally (often classified as NP-Hard). There have been works based on genetic algorithms, branch and bound, greedy heuristics, etc. These approaches are not easily adapted for dynamic systems where the system constraints or data change. This is a real limitation since most of real problems are subject to change and dynamics. To deal with this lack of flexibility and robustness, we adopt a multiagent approach which is known to be well suited for dynamical problems [5].

This paper proposes a multiagent approach for the facility location problem, which is based on the self-organization of reactive agents. To our knowledge, no reactive agent-based approaches have been already used to deal with this problem. The choice of a multiagent

approach provides several advantages. First, multiagent systems are well suited to model distributed problems. In such systems, several entities evolving/moving in a common environment have to cooperate to perform collective and local goals. Second, even if the multiagent approach does not guarantee to find optimal solution, it is, often, able to find satisfying ones without too much computational cost [19]. Through this paper we show that the reactive multiagent approach can be an interesting new way for optimization in positioning problems. Then, it provides satisfying solutions in addition to other assets as flexibility, modularity and adaptability to open systems. In our approach, agent behavior is based on the combination of attractive and repulsive forces. The idea is that the behavior of agents at the microscopic level leads to emergence of solutions at the macroscopic level [12].

This paper is structured as follows: section 2 presents the facility location problems. Then, section 3 details the proposed multiagent approach. Section 4 presents experimental evaluations through comparisons with the k-means approach. In section 5, some aspects of the model are discussed. Then, the last section gives some conclusions and perspectives.

2 THE POSITIONING PROBLEM

2.1 Overview

In the literature, the general facility positioning problem consists in locating new facilities to optimize some objectives such as distance, demand covering, travel time, cost.

There are four components that characterize location problems [14]: (1) a space in which demands and facilities are located, (2) a metric that indicates distance (or other measures as time) between demands and facilities, (3) demands, which must be assigned to facilities, and (4) facilities that have to be located. There exists two types of location problems: continuous and discrete ones. The problem is continuous when the facilities to be sited can generally be placed anywhere on the plane or on the network. In discrete location problems the facilities can be placed only at a limited number of eligible points.

A non-exhaustive list of facilities problems includes: p-center, p-median, set covering, maximal covering, dynamic location, stochastic location and multiobjective location problems. This paper focuses, particularly, on the p-median problem. The mathematical formulations of the previous variants are well known. However, formulating is only one step of analyzing a location problem. The other step and the most challenging one is to find optimal solutions.

Typically, the possible approaches to such a problem and especially to the p-median problem, consist in exact methods which allow to find optimal solutions. A well-known example of methods is

¹ Laboratory S.e.T, University of Technology Belfort Montbéliard 90010 Belfort, France, email: (sana.moujahed, olivier.simonin, abder.koukam)@utbm.fr

² Laboratory S.O.I.E, National School of computer science of Tunis 2010 La Manouba, Tunisia, email: khaled.ghedira@isg.rnu.tn

³ Deployment, location and siting are used as synonyms

branch and bound [18]. However, these solutions are quickly inefficient for very complex problems, i.e. with hundreds of constraints and variables. Then obtaining optimal solutions for these problems requires colossal computational resources.

Another category of methods are proposed for the p-median problem. These methods, known as heuristics, allow to find good solutions, but do not guarantee finding the optimal one(s): greedy heuristics [2], genetic algorithms [6], lagrangean relaxation [3], etc. However, these approaches have several drawbacks such as the rigidity, the lack of robustness and flexibility, the computational cost (huge population size and long convergence time, for example in genetic algorithms). Particularly, these approaches are limited in their ability to cope with dynamic problems characterized by the change of problem constraints and optimization criteria.

This paper explores another possible heuristic which is based on multiagent systems. The remainder of the paper will focus on this approach. The next section presents formally the continuous p-median problem.

2.2 Continuous p-median problem statement

In the rest of the paper, the continuous p-median problem is considered. It consists to locate a fixed number of facilities such that the whole environment can be used. The objective is to minimize the distance between demands and facilities.

The problem is expressed as follow [13]:

E = the set of demand points in the plane \mathbb{R}^2 (or more generally \mathbb{R}^n) indexed by e

W_e = a positive weight assigned to each demand

p = the maximum number of facility to locate

$d(x, e)$ = the distance between the facility x and the demand e

The problem is to find a subset X of p facility locations within a feasible region $S \subset \mathbb{R}^2$, such that:

$$\min_{X \subset S, |X|=p} F_E(X) \quad (1)$$

$$F_E(X) = \sum_{e \in E} W_e \cdot \min_{x \in X} d(x, e)$$

The objective function (1) minimizes the weighted sum of distances of the demand points to their closest facility.

3 A SELF-ORGANIZATION APPROACH FOR THE CONTINUOUS P-MEDIAN PROBLEM

Our model relies on the Artificial Potential Fields (APF) approach which is a possible manner to build self-organized systems. This approach is presented in the next section, the proposed model is detailed in section 3.2.

3.1 The artificial potential fields approach

Self-organization exists in many natural systems and especially in insect societies. Such systems are composed of simple entities, for instance ants, which can build tri-dimensional structures or solve complex problems without any global control [11]. Their organization results from the numerous interactions between agents and their environment. It is the environment that guides the agent behaviors and the whole system organization (called stigmergy principle) [12].

Such an approach has been used to define decentralized algorithm to deal with path finding problems (ant algorithm [4]), collective tasks (such as boxpushing [1], navigation [15], foraging with robots),

etc. Most of these works are based either on digital pheromones (as inspired by ants) or on artificial potential fields (APF). We adopt this second one because it is well suited to deal with spatial constraints, as it is the case in the p-median problem.

This APF approach has several inspirations (physical, biological, etc). The concept was introduced in Lewin's topological psychology [9]. The basic idea is that human behavior is controlled by a force field generated by objects or situations with positive or negative values or valences. During the past decade, potential field theory has gained popularity among researchers in the field of autonomous robots [7] and especially in robot motion planning thanks to their capability to act in continuous domains in real-time. By assigning repulsive force fields to obstacles and an attractive force field to the desired destination, a robot can follow a collision-free path via the computation of a motion vector from the superposed force fields [1]. In [16], artificial potential fields are used to tackle cooperation and conflict resolution between situated reactive agents.

However, the APF technique is limited by a well known drawback: local minima. Indeed, adding attractive and repulsive fields can produce areas where forces are equilibrated. Then, an agent that uses potential fields to move can be trapped in such places. The originality of our approach relies on the fact that we do not try to avoid such local minima. At the opposite, we exploit them as interesting places where facilities are located at the balance of different influences.

3.2 A self-organizing multiagent model

As facilities are elements to be placed in the environment, we model them as reactive agents. The environment is defined by a finite and continuous space. Demands, which are static data of the problem, are defined as an environment characteristic.

As in the reactive multiagent methodology proposed in [17], our approach consists to, first, define the behavior of a single agent (facility) so as to optimize its position considering the perceived demand. Second, we consider interactions between agents, to obtain the collective problem solving.

3.2.1 Local demand satisfaction

We first define the behavior of an agent which must minimize its distance to the perceived demand. The key idea is that demand induces attraction forces which are applied on the agent. Considering one demand point, an attractive force is defined from the agent towards the demand. It is expressed as a vector the intensity of which is proportional to the demand weight and to the distance between the agent and the demand. Formally, for an agent A perceiving a demand D with weight W_D

$$\vec{F}_{D/A} = W_D \cdot \overrightarrow{AD} \quad (2)$$

The influence of the attraction decreases when the agent moves towards the demand. Thus, if the agent attains the demand the attraction behavior is inhibited.

For the set of perceived demands, the influence on an agent is defined as the sum of all induced forces. Formally, the local attraction force undergone by an agent A is computed as follows:

$$\vec{F}_{demands/A} = \frac{\sum_{i=1}^n \vec{F}_{i/A}}{n} \quad (3)$$

n is the number of demands perceived by the agent A through its attraction radius r_a ($n = 5$ in Fig.1). The demand is indexed by i .

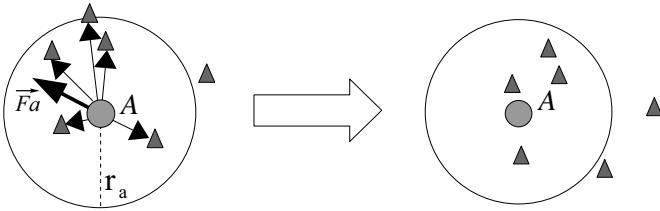

Figure 1. Attractions lead the agent to the weighted barycenter of demands

As a consequence the agent moves to the weighted barycenter of the demands, which is known to approach the minimum average distance to several close weighted points [10, 13]. For example, if an agent is subject to two attractive forces (from two different demands), it will be more attracted towards the biggest demand. Then, it will move towards a balance point. This point is defined as the place where the two attraction forces are equilibrated.

Now, we have to consider several agents applying such a behavior. Then, some of them could move to the same locations. In such a case the process is sub-optimal since several agents cover the same demand. To prevent such a process repulsive forces are introduced to the model.

3.2.2 Local coordination

In order to avoid that agents have the same locations, we introduce repulsive forces between them. It concerns close agents, i.e. situated under a particular distance, defined as the repulsion radius (r_r in Fig.2).

The force intensity is defined as inversely proportional to the inter-agent distance (see Fig.2).

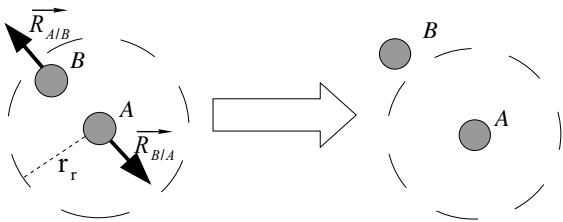

Figure 2. Repulsions between agents A and B lead them to keep away

Formally the repulsive force induced by an agent B on an agent A is expressed as follow:

$$\vec{R}_{B/A} = \frac{\vec{BA}}{\|\vec{AB}\|^2} \quad (4)$$

Then, the local repulsive force undergone by an agent A is computed as follows:

$$\vec{R}_{agents/A} = \frac{\sum_{j=1}^m \vec{R}_{j/A}}{m} \quad (5)$$

m is the number of agents perceived by the agent A. These agents are indexed by j . Fig.2 illustrates this repulsive process between two agents.

This repulsion process allows the coordination of agents while moving to the demand (see next section). Moreover, such repulsive forces can allow to respect constraints on minimal distances separating facilities (constraint present in many facility location applications).

3.2.3 Collective solving

The agent behavior is defined as the weighted sum of both local attraction and repulsion forces. Formally, for an agent A, it is expressed as follows:

$$\vec{Move} = \alpha \vec{F}_{demands/A} + (1 - \alpha) \vec{R}_{agents/A} \quad (6)$$

The coefficient α allows us to favour either the attraction or the repulsion.

We now consider the whole system, where several facilities must optimize their positioning to cover numerous demands. In the self-organizing approach, no global control is used. Agents are created and distributed in the environment and act following the defined individual behavior.

To implement the proposed multiagent model, we can (i) assign a thread to each agent or (ii) define a scheduler that simulates the parallel agents computation. We adopt the second solution which is generally used for reactive agents implementation. Finally, the collective solving process is presented in Algorithm 1. The initialization (step 1) and the fitness computation (step 9) are detailed in the next section.

4 EXPERIMENTATIONS

After exposing the principle of the approach, the model is evaluated on a case study. It consists in positioning facilities (bus-stops, restaurants, etc) on a continuous environment corresponding to the map of France presented in Fig.3 (400x400 size). It contains the demand weights which are values between 0 and 255 (randomly generated). These weights are represented as a gradation from black color (255) to white color (0).

The initial positioning of facilities is performed with a random computation (Fig.3 (a)). Parameters values are: $\alpha = 0.5$, $r_a = 25$, $r_r = 20$.

When the algorithm starts, facility agents (the white points in Fig.3) move towards demands while avoiding other agents (Fig.3 (b)). In the first iterations we can observe important moves to the highest demands while the repulsive forces globally stabilize this tendency. The system iterates until it attains a global equilibrium state (convergence to a stable state).

Fig.3 (c) shows the final state to which the system converges. The facilities repartition is characterized by an intensification of the

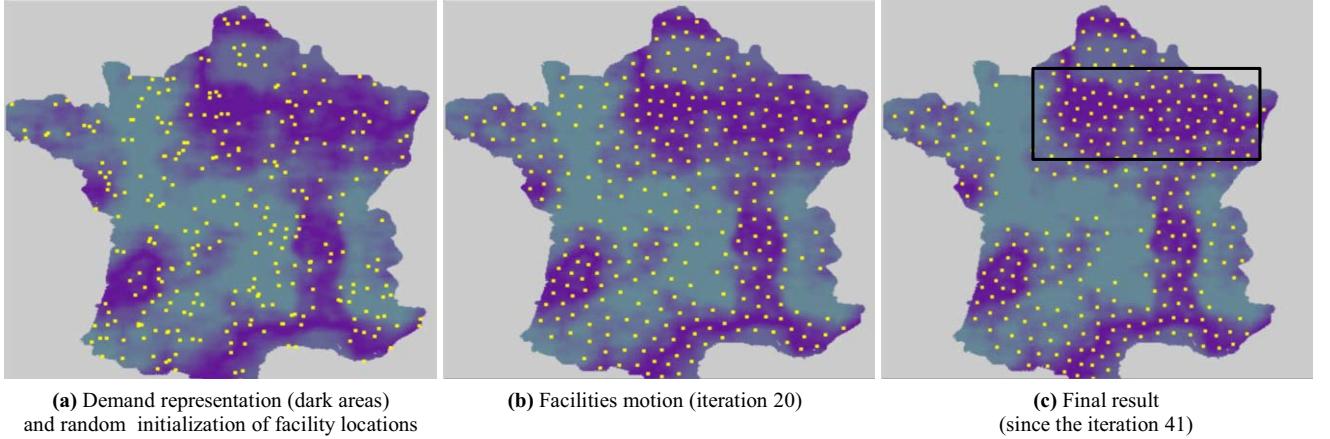

Figure 3. The evolution of facilities positioning for the case study with 400 agents

agents in areas where demands is high. This result is visible inside the rectangular area. It is also clear that all facilities respect a minimal distance between them.

The performance of the multiagent model has been compared with the k-means clustering technique. The k-means algorithm is a well known technique that computes very good solutions to the facility location problem [10]. It allows us to classify or to group objects based on attributes/features into K number of groups. The grouping is done by minimizing the sum of distances between data and the corresponding cluster centroid (Algorithm 2).

Algorithm 2 The k-means clustering

-
- 1: **repeat**
 - 2: Place k points into the space represented by the objects that are being clustered.
 - 3: Assign each object to the group that has the closest centroid. When all objects have been assigned, recalculate the positions of the k centroids as weighted barycenters.
 - 4: **until** The centroids no longer move.
-

Comparisons are made according to a global fitness index expressed by the formula (7) and corresponding to the mean distance between each demand and the nearest facility:

$$Fitness = \frac{\sum_{ij} D_{ij} * d(C_{ij}, x_{ij})}{\sum_{ij} D_{ij}} \quad (7)$$

D_{ij} = the demand at point x_{ij}

$d(C_{ij}, x_{ij})$ = the distance between the point x_{ij} and the nearest facility C_{ij}

Comparisons are carried out on different number of facilities, as shown in Table 1. For each facility number, 50 tests have been executed. The fitness values obtained by applying the multiagent approach are very close to the k-means ones. The difference is small and it is inversely proportional to the number of facilities.

A second comparison has been performed considering another criterion: the time required to converge to a solution. Results are presented in Table 2, they show that the multiagent model converges to a solution more rapidly than the k-mean, e.g. for 400 facilities the multiagent approach is 3 times faster than the k-means. It is particularly

Table 1. Comparison with k-means clustering

Fitness: minimal values					
Facilities	50	100	150	200	400
Multiagent	16,592	11,187	9,164	7,945	5,696
k-means	15,556	10,965	9,010	7,820	5,593
Difference	1,036	0,222	0,154	0,125	0,095

interesting to note that the multiagent approach is more efficient than the k-means while the number of agents increases.

Table 2. Comparison of computation time

Computation time (in second)			
Facilities	100	150	400
Multiagent	34.289	24.925	33.019
k-means	37.678	73.306	118.251

Fig.4 plots the evolution of the fitness values for 400 facilities. We can show that the fitness decreases until the convergence to a constant value. Here, the convergence is attained rapidly: since the 41 th iteration.

All the experimentations have shown that the agents systematically converge to a stable location. It corresponds to a global balance between attraction to demands and inter-agents repulsive forces.

5 DISCUSSION

The previous experimentations allow to point up some observations on the proposed model. The obtained solutions are globally satisfying considering the fitness values. We have shown that these solutions are quickly obtained.

For each specific application, the multiagent approach needs a parameter setting stage. However, the proposed model depends only on three parameters: attraction and repulsion radius, and the weight combination of influences (α in formula (6)). Attraction and repulsion radius depend on the considered application. Generally, the attraction radius is defined by the coverage distance (for a demand, the next facility must be within a specified distance, the covering radius).

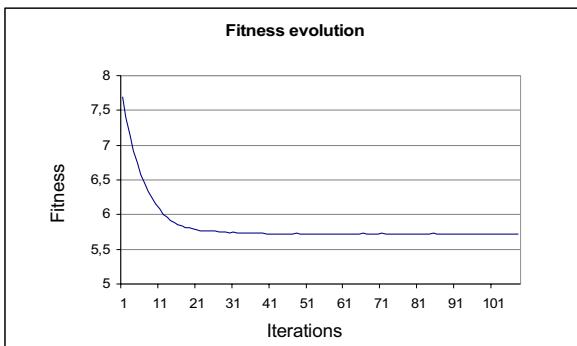

Figure 4. The fitness evolution for the case study with 400 agents

The repulsion radius is defined by the minimal distance allowed between two facilities. α is defined following the designer objectives.

Generally, the existing solutions for facility positioning [2, 18, 6] are not easily adaptable when the problem constraints change, particularly, for dynamic perturbations. It can concern the environment structure (e.g. demands), the facilities number, etc. For instance, when facilities have been located, any change in the demand will generally needs a new execution of the employed algorithm (it is the case with genetic algorithms, branch and bound, etc). At the opposite, our self-organizing approach will immediately adapt the locations to the perturbation. The algorithm can compute this adaptation from its last state. Moreover, it is interesting to not stop the algorithm in order to observe new solutions which are dynamically obtained while perturbing the system.

The proposed model can be also adapted to variations in the problem statement. For instance, we have applied our model to bus-stops positioning in a real bus-line network. The considered network serves a 60000 inhabitants city. Demands correspond to real values of inhabitants density per quarter. In this problem the positioning of facilities is limited to the lines. The model has been adapted to this new constraint without changing the agent behaviors. We have just constrained the agents to stay on lines (the move vector is transformed so as the agents move along lines). Experiments have shown that the fitness value decreases until its convergence to a constant value, which corresponds to an optimization of the bus-stops location.

6 CONCLUSIONS

This paper has presented a self-organizing multiagent approach for the continuous p-median problem. Facilities, which are modeled as reactive agents, move according to their local perception. Demands induce attractive forces and the proximity between agents generates repulsive ones. The agent behavior is defined as a combination of these two kind of opposite influences.

Local minima, which must be avoided in the artificial potential fields approach are exploited in our model as balance points between demands.

At a collective level, we have shown that the system, i.e. the whole set of agents, interact to minimize distances to demands. Then, the system converges to a global stable state.

The relevance of our approach has been shown through its application to location of facilities on a continuous environment. In particular, it has been compared to the k-means clustering algorithm. A first

evaluation criterion concerns the variation of the final fitness value. The multiagent results tend to the k-means values when the number of agents increases. The second evaluation concerns the computation time to obtain a stable solution. In this case, the multiagent approach is clearly faster and this advantage grows with the number of agents. These different evaluations show that a self-organizing multiagent approach can be an interesting perspective to optimization in positioning problems.

Future works deal, first, with a more formal evaluation of the global system convergence. Then, we seek to apply our approach to another problematic in location problems: the dimensioning problem. It consists to optimize the number of facilities to locate, since each new facility increases the location cost. We obtain a multicriteria problem. We then propose to add two behaviors allowing the creation and the removing of agents in order to optimize facilities location and number.

Arguing with Confidential Information

Nir Oren and **Timothy J. Norman** and **Alun Preece¹**

Abstract. While researchers have looked at many aspects of argumentation, an area often neglected is that of argumentation strategies. That is, given multiple possible arguments that an agent can put forth, which should be selected in what circumstances. In this paper, we propose a heuristic that implements one such strategy. The heuristic assigns a utility cost to revealing information, as well as a utility to winning, drawing and losing an argument. An agent participating in a dialogue then attempts to maximise its utility. We present a formal argumentation framework in which this heuristic may operate, and show how it functions within the framework. Finally, we discuss how this heuristic may be extended in future work, and its relevance to argumentation theory in general.

1 Introduction

Argumentation has emerged as a powerful reasoning mechanism in many domains. One common dialogue goal is to persuade, where one or more participants attempt to convince the others of their point of view. This type of dialogue can be found in many areas including distributed planning and conflict resolution, education and in models of legal argument. At the same time that the breadth of applications of argumentation has expanded, so has the sophistication of formal models designed to capture the characteristics of the domain. Prakken [11] for example, has focused on legal argumentation, and has identified four layers with which such an argumentation framework must concern itself. These are:

- The logical layer, which allows one to represent basic concepts such as facts about the world. Most commonly, this layer consists of some form of non-monotonic logic.
- The dialectic layer, in which argument specific concepts such as the ability of an argument to defeat another are represented.
- The procedural layer governs the way in which argument takes place. Commonly, a dialogue game [17] is used to allow agents to interact with each other.
- The heuristic layer contains the remaining parts of the system. Depending on the form of the underlying layers, these may include methods for deciding which arguments to put forth and techniques for adjudicating arguments.

While many researchers have focused on the lowest two levels (excellent surveys can be found in [3, 11, 12]), and investigation into various aspects of the procedural layer is ongoing (for example, [16, 6]), many open questions remain at the heuristic level.

In this paper, we propose a decision heuristic for an agent allowing it to decide which argument to put forth. The basis for our idea is simple; the agent treats some parts of its knowledge as more confidential than other parts, and, while attempting to win the argument, attempts

to reveal as little of the more secret information to others as possible. This concept often appears in adversarial argumentation under the guise of not mentioning information that might help an opponent's case, but also appears in many other settings. For example, revealing trade secrets, even to win an argument, may damage an agent in the long term. The heuristic often emerges in negotiation dialogues, as well as persuasion dialogues in hostile setting (such as takeover talks or in some legal cases). Utilising this heuristic in arguments between computer agents can also be useful; revealing confidential information in an ongoing dialogue may damage an agent's chances of winning a future argument.

In the next section, we examine a few existing approaches to strategy selection, after which we discuss the theoretical foundations of our approach. We then present the heuristic, after which we see how it operates by means of an example. We conclude the paper by looking at possible directions in which this work can be extended.

2 Background and related research

Argumentation researchers have recognised the need for argument selection strategies for a long time. However, the field has only recently started receiving more attention. Moore, in his work with the DC dialectical system [7], suggested that an agent's argumentation strategy should take three things into account:

- Maintaining the focus of the dispute.
- Building its point of view or attacking the opponent's one.
- Selecting an argument that fulfils the previous two objectives.

The first two items correspond to the military concept of a strategy, i.e. a high level direction and goals for the argumentation process. The third item corresponds to an agent's tactics. Tactics allow an agent to select a concrete action that fulfils its higher level goals. While Moore's work focused on natural language argument, these requirements formed the basis of most other research into agent argumentation strategies.

In 2002, Amgoud and Maudet [1] proposed a computational system which would capture some of the heuristics for argumentation suggested by Moore. Their system requires very little from the argumentation framework. A preference ordering is needed over all possible arguments, and a level of prudence is assigned to each agent. An argument is assigned a strength based on how convoluted a chain of arguments is required to defend it. An agent can then have a "build" or "destroy" strategy. When using the build strategy, an agent asserts arguments with a strength below its prudence level. If it cannot build, it switches to a destroy strategy. In this mode, it attacks an opponent's arguments when it can. While the authors note other strategies are reasonable, they make no mention of them. Shortcomings of their approach include its basis on classical propositional logic and the assumption of unbounded rationality; computational limits may affect

¹ Department of Computing Science, University of Aberdeen, AB24 3UE, Scotland, email: noren,tnorman,apreece@csd.abdn.ac.uk

the arguments agents decide to put forth. Finally, no attempt is made to capture the intuition that a fact defended by multiple arguments is more acceptable than one defended by fewer (the so called “accrual of evidence” argument scheme [9]).

Using some ideas from Amgoud’s work, Kakas et al. [5] proposed a three layer system for agent strategies in argumentation. The first layer contains “default” rules, of the form $\text{utterance} \leftarrow \text{condition}$, while the two higher layers provide preference orderings over the rules. Assuming certain restrictions on the rules, they show that only one utterance will be selected using their system, a trait they refer to as determinism. While their approach is able to represent strategies proposed by a number of other techniques, it does require hand crafting of the rules. No suggestions are made regarding what a “good” set of rules would be.

In [2], Bench-Capon describes a dialogue game based on Toulmin’s work. He identifies a number of stages in the dialogue in which an agent might be faced with a choice, and provides some heuristics as to what argument should be advanced in each of these cases. Only an informal justification for his heuristics is provided.

3 Confidentiality Based Argumentation

In many realms of argument, auxiliary considerations (apart from simply winning or losing the argument) come into play. In many scenarios, one such consideration involves hiding certain information from an opponent. In this section, we describe a utility based heuristic to guide an agent taking part in a dialogue while being careful about what information it reveals. When faced with a number of possible arguments that it can advance, we claim it should put forth the one that minimises the exposure of information that it would like to keep private. The limitations of our current approach, as well as extensions and refinements to it are discussed in Section 5.

Our formalism is based on many ideas from other formal argument systems (e.g. [4, 10, 8, 15]). We use our own formal argumentation system which introduces features not seen in others, and which allows us to study our proposed heuristic in isolation. Our argumentation framework is very simple, and does not contain features such as a preference ordering on arguments which allows one to overrule another. Our system is formalised in two parts. After specifying the argumentation framework, our heuristic is described, in terms of the framework.

3.1 The Argumentation Framework

Argumentation takes place over the language Σ , which contains propositional literals and their negation.

Definition 1 Argument An argument is a pair (P, c) , where $P \subseteq \Sigma \cup \{\top\}$ and $c \in \Sigma$ such that if $x \in P$ then $\neg x \notin P$. We define $\text{Args}(\Sigma)$ to be the set of all possible arguments derivable from our language.

P represents the premises of an argument (also referred to as an argument’s support), while c stands for an argument’s conclusion. Informally, we can read an argument as stating “if the conjunction of its premises holds, the conclusion holds”. Facts can be represented using the form (\top, a) .

Arguments interact by supporting and attacking each other. Informally, when an argument attacks another, it renders the latter’s conclusions invalid.

Definition 2 Attack An argument $A = (P_a, c_a)$ attacks $B = (P_b, c_b)$ if $\exists f \in P_b$ such that $f = \neg c_a$ or $c_a = \neg c_b$. For convenience, we write this as $\text{attacks}(A, B)$.

An argument is only relevant to an instance of argumentation if its premises are true. We call such an argument *justified*. However, a simple definition of this concept can cause problems when it comes to self attacking (or self defending) arguments, as well as circular reasoning, and care must thus be taken when describing this concept. Before doing so, we must (informally) describe the proof theory used to determine which literals and arguments are in effect at any time.

The idea behind determining what arguments and literals are admissible at any time is as follows. We start by looking at the facts, and determining what knowledge can be derived from them by following chains of argument. Whenever a conflict occurs (i.e. we are able to derive both x and $\neg x$), we remove these literals from our derived set. Care must be taken to also get rid of any arguments (and further facts) derived from any conflicting literals. To do this, we keep track of the conflicting literals in a separate set, whenever a new conflict arises, we begin the knowledge determination process afresh, never adding any arguments whose conclusions are in the conflicting set to the knowledge set. The philosophical and practical ramifications of this approach are examined in Section 5.

More formally, an instance of the framework creates two sets $J \subseteq \text{Args}(\Sigma)$ and $C \subseteq \Sigma$ representing justified arguments and conflicts respectively.

Definition 3 Derivation An argument $A = (P_a, c_a)$ is derivable from a set S given a conflict set C (written $S, C \vdash A$) iff $c_a \notin C$ and $(\forall p \in P_a : (\exists s \in S \text{ such that } s = (P_s, p) \text{ and } p \notin C) \text{ or } P_a = \{\top\})$.

Clearly, we need to know what elements are in C . Given a knowledge base of arguments $\kappa \subseteq \text{Args}(\Sigma)$, this can be done with the following reasoning procedure:

$$\begin{aligned} J_0 &= \{A | A \in \kappa \text{ such that } \{\}, \{\} \vdash A\} \\ C_0 &= \{\} \end{aligned}$$

Then, for $i > 0, j = 1 \dots i$, we have:

$$C_i = C_{i-1} \cup \{c_A, \neg c_A | \exists A = (P_A, c_A), B = (P_B, \neg c_A) \in J_{i-1} \text{ such that } \text{attacks}(A, B)\}$$

$$\begin{aligned} X_{i0} &= \{A | A \in \kappa \text{ and } \{\}, C_i \vdash A\} \\ X_{ij} &= \{A | A \in \kappa \text{ and } X_{i(j-1)}, C_i \vdash A\} \end{aligned}$$

$$J_i = X_{ii}$$

The set X allows us to recompute all derivable arguments from scratch after every increment of i^2 . Since i represents the length of a chain of arguments, when $i = j$ our set will be consistent to the depth of our reasoning, and we may assign all of these arguments to J . Eventually, $J_i = J_{i-1}$ (and $C_i = C_{i-1}$) which means there are no further arguments to find. We can thus define the conclusions asserted by κ as $K = \{c | A = (P, c) \in J_i\}$, for the smallest i such that $J_i = J_{i+1}$. We will use the shorthand $K(\kappa)$ and $C(\kappa)$

² This allows us to get rid of long invalid chains of arguments, as well as detect and eliminate arbitrary loops

to represent those literals which are respectively asserted by, or in conflict with the knowledge base κ .

We provide an example which illustrates the approach (note that not all steps are shown):

Example 1 $\kappa = \{(\top, s), (s, t), (t, \neg s)\}$

$$J_0 = \{(\top, s)\}, C_1 = \{\}$$

$$J_1 = X_{11} = \{(\top, s), (s, t)\}$$

...

$$J_2 = (\top, s), (s, t), (t, \neg s), C_3 = \{s, \neg s\}$$

$$X_{30} = \{\} \dots J_4 = J_3 = \{\}$$

3.2 The Heuristic

Agents engage in a dialogue using the argumentation framework described above in an attempt to persuade each other of certain facts. An agent has a private knowledge base (KB) as well as a goal literal g and a preference ranking ρ which specifies an agent's reluctance to reveal certain literals. The environment, apart from containing agents, contains a public knowledge base which takes on a role similar to a global commitment store, and we thus refer to it as CS below.

Definition 4 Environment An environment is a pair $(Agents, CS)$ where $Agents$ is the set of agents participating in the dialogue and $CS \subseteq \text{Args}(\Sigma)$

Definition 5 Agent An Agent $\alpha \in Agents$ is a tuple $(Name, KB, \rho, g, U_{win}, U_{draw}, U_{lose})$ where $KB \subseteq \text{Args}(\Sigma)$, $g \in \Sigma$. ρ is a preference ranking function and $U_{win}, U_{draw}, U_{lose} \in \mathbb{R}$ are the utilities gained for winning, drawing or losing an argument.

The preference ranking expresses the “cost” to an agent of revealing certain information in a specific context. It maps a set of literals L to a real number. The cost of being in a certain environmental state is the result of applying the preference ranking function ρ to the literals present in that state.

Definition 6 Preference Ranking A preference ranking ρ is a function $\rho : L \rightarrow \mathbb{R}$ where $L \subseteq 2^\Sigma$.

Agents take turns to put forward a line of argument consisting of a number of individual arguments. For example, an agent could make the utterance $\{(\top, a), (a, b)\}$. Alternatively, an agent may pass (by uttering an empty argument $\{\}$). The dialogue ends when CS has remained unchanged for n turns i.e. after all players have had a chance to modify it, but didn't (this is normally caused by all agents having passed consecutively). Once this has happened, the acceptable set of arguments is computed over the CS , and the status of each agent's goal can be determined, allowing one to compute the winners of the game.

Definition 7 Turns and utterances The function

$$\text{turn} : \text{Environment} \times \text{Name} \rightarrow \text{Environment}$$

takes an environment (of the form $\text{Environment} = (Agents, CS)$) and an agent label, and returns a new environment containing the result of the utterance ($\text{utterance} : \text{Environment} \times \text{Name} \rightarrow 2^{\text{Args}(\Sigma)}$) made by the labelled agent during its turn.

$$\text{turn}(\text{Environment}, \alpha) = (\text{Agents}, \{CS \cup \text{utterance}(\text{Environment}, \alpha)\})$$

At turn i , we set $\alpha = \text{Agent}_i \bmod n$, where n is the number of agents taking part in the dialogue. The *utterance* function is dependent on the agent's strategy, and we will describe one such strategy below. Before doing so, we define the dialogue game itself. Each turn in the dialogue game results in a new public commitment store, which is used by agents in later turns.

Definition 8 Dialogue game The dialogue game is defined as
 $turn_0 = \text{turn}((\text{Agents}, CS_0), \text{Agent}_0)$
 $turn_{i+1} = \text{turn}(turn_i, \text{Agent}_i \bmod n)$

The game ends when $turn_i \dots turn_{i-n+1} = turn_{i-n}$.

CS_0 is dependent on the system, and contains any arguments that are deemed to be common knowledge (though these arguments may be attacked like any other argument during later turns in the game). Also, note that the null utterance $\{\}$ is defined to be a pass.

By using the procedure described earlier, agents can

- Determine, by looking at CS , what literals are in force (i.e. in $K(CS)$) and in conflict.
- Determine, by combining CS with parts of their own knowledge base, what literals they can prove (or cause to conflict).

By doing the latter, together with examining which literals are introduced into K and C , as well as their cost as computed from ρ , an agent will narrow down the range of arguments it will consider submitting, though it may still have multiple arguments to choose from. It should be noted that an agent might be willing to draw or even lose an argument rather than reveal too much information. Winning (or drawing) an argument earns the agent a certain amount of utility. Thus, the final choice about which argument to put forth is based on the effect of the argument in combination with its utility cost. We begin by defining the set of winning and drawing arguments paying no attention to the argument cost.

Definition 9 Winning arguments An agent's set of winning arguments is defined as
 $Win = \{A \in 2^{KB} \mid g \in K(A \cup KB) \text{ and if } A \neq \{\}, \{\} \notin A\}$.

Definition 10 Drawing arguments An agent's set of drawing arguments is defined as

$$Draw = \{A \in 2^{KB} \mid (g \in C(A \cup KB) \text{ or } \{g, \neg g\} \not\subseteq K(A \cup KB)) \text{ and if } A \neq \{\}, \{\} \notin A\}$$

While many possibilities exist as to how to weigh the cost of information, for reasons discussed in Section 5, we compute the information cost based on the literals present in CS after an argument has been advanced. Currently we make no distinction between whether information is revealed due to an utterance we make, or whether another agent revealed it.

Definition 11 Argument utility Given an agent with a preference ranking ρ , we define an agent's net utility U for advancing an argument A as

$$U(A) = \begin{cases} U_{win} - \rho(L) & \text{if } A \in Win \\ U_{draw} - \rho(L) & \text{if } A \in Draw \\ U_{lose} - \rho(L) & \text{otherwise} \end{cases}$$

such that $L = K(CS \cup A) \cup C(CS \cup A)$

The utterance an agent makes is chosen from the set of arguments that maximise its utility:

$$\text{utterance} \in \{a \subseteq A \mid \forall a, b \ U(a) \geq U(b)\}$$

At the end of the game, the literals in $K(CS)$ will be those for which undefeated arguments exist.

4 Example

To increase readability, we present our example in a somewhat informal manner. The argument consists of a hypothetical dialogue between a government and some other agent regarding the case for, or against, weapons of mass destruction (WMDs) existing at some location.

Assume that our agent ($Agent_0$) would like to show the existence of WMDs, i.e. $g = WMD$. Assume further that $U_{win} = 100$, $U_{draw} = 50$, $U_{lose} = 0$ and that the following arguments exist in the agent's private KB (where the context is clear, we omit brackets):

$(\top, spysat), (\top, chemicals), (\top, news), (\top, factories)$

$(\top, smuggling), (smuggling, \neg medicine), (news, WMD)$

$(\{factories, chemicals\}, WMD), (spysat, WMD)$

$(\{sanctions, smuggling, factories, chemicals\}, \neg medicine)$

While we will not fully describe the agents preference rating function ρ , we set the costs for tuples including literals as follows:

$(spysat, 100)$	$(chemicals, 30)$
$(news, 0)$	$(\{medicine, chemicals\}, 50)$
$(smuggling, 30)$	$(factories, 0)$

Note that if both medicine and chemicals are present, the agent's utility cost is 50, not 80.

As an example, ρ of an environment state containing both *spysat* and *chemicals* will be assigned a cost of 130.

The dialogue might thus proceed as follows:

- (1) $Agent_0 : (\top, news), (news, WMD)$
- (2) $Agent_1 : (\top, \neg news)$
- (3) $Agent_0 : (\top, factories), (\top, chemicals), (\{factories, chemicals\}, WMD)$
- (4) $Agent_1 : (\top, sanctions), (\{sanctions, factories, chemicals\}, medicine), (medicine, \neg WMD)$
- (5) $Agent_0 : (\top, smuggling), (\{sanctions, smuggling, factories, chemicals\}, \neg medicine)$
- (6) $Agent_1 : \{\}$
- (7) $Agent_0 : \{\}$

Informally, the dialogue proceeds as follows: $Agent_0$ claims that WMDs exist since the news says they do. $Agent_1$ retorts that he has not seen those news reports. $Agent_0$ then points out that factories and chemicals exist, and that these were used to produce WMDs. In response, $Agent_1$ says that due to sanctions, these were actually used to produce medicine. $Agent_0$ attacks this argument by pointing out that smuggling exists, which means that the factories were not used to produce medicines, reinstating the WMD argument. Both agents have nothing more to say, and thus pass. $Agent_0$ thus wins the game.

It should be noted that while $Agent_0$ is aware that spy satellites have photographed the WMDs, it does not want to advance this argument due to the cost of revealing this information. The final utility gained by $Agent_0$ for winning the argument is 20: 100 for winning the argument, less 30 for revealing *smuggling*, and 50 for the presence of the *chemicals* and *medicine* literals. Also, note that the fact

that $Agent_1$ revealed the existence of medicines cost $Agent_0$ an additional 20 utility. This is somewhat counterintuitive, and extensions to overcome this behaviour are examined in the next section.

5 Discussion

This section examines the argumentation framework and the heuristic, tying it back to the concept of an argumentation strategy as proposed by Moore. We also examine some of the novel features of argument that emerge when dialogue takes place in the framework using the heuristic, and propose avenues for future research.

It should be noted that nothing in our framework forces literals to cost utility. Many scenarios can be imagined wherein revealing a literal causes a utility gain. For example, if an agent would like to steer a conversation towards a certain direction, it might gain utility for revealing literals relating to that topic, even though those might, in the long run, weaken its argument.

Our approach seems to share much in common with the "sceptical" approach to argumentation. When arguments conflict, we refuse to decide between them, instead ruling them both invalid. This means that our reasoning procedure is not complete, given the (rather convoluted) set of arguments $(\top, A), (\top, B), (A, \neg B), (B, \neg A), (A, C), (B, C), (\neg A, C), (\neg B, C)$ we can intuitively see that C should hold, but doesn't. Other argumentation systems (namely those utilising the unique-status-assignment approach [12]) are similarly incomplete, leaving this an open area for future research. Our sceptical approach does yield a sound system, as no conflicting arguments will remain in the final set of arguments.

The simplicity of our approach means that only specific types of arguments can be represented (namely, those whose premises are a conjunction of literals, and whose conclusion is a single literal). However, as seen in the example, even with this limitation, useful arguments can still emerge.

We developed our own argumentation framework rather than using an existing one for a number of reasons, including:

- The abstract nature of many frameworks (e.g. [4]) makes arguments atomic concepts. We needed a finer level of granularity so as to be able to talk about which facts are exposed (allowing us to measure the amount of information revealed during the dialogue process). Less abstract frameworks (e.g. [13, 10]), while looking at concepts such as derivability of arguments, still have as their main focus, the interactions between arguments.
- Almost all other frameworks define higher level concepts in terms of arguments attacking, defeating and defending one another. For us, the concept of one argument justifying another is critical, together with the concept of attack.
- Other argumentation systems contain concepts which we do not require, such as a preference ordering over arguments.

Another significant difference between our argumentation framework and most existing approaches is the scope of arguments. In our approach, agents can be aware of and utter arguments of which other agents are unaware. For example, even if no other agent knew of the literals X and Y , an agent could make the utterance $(\{X, Y\}, Z)$. An agent arguing for $\neg Z$ would then have no choice but to try obtain a draw result.

While representing the heuristic using one of the other approaches is (probably) not impossible, it appears to be more difficult than by using our own system.

Looking at Moore's three criteria for an agent argumentation strategy, we see that our heuristic fulfils its requirements. If the focus of

the argument were not maintained, more information would be given than is strictly necessary to win, thus fulfilling the first requirement. Both the second and third requirements are clearly met by the decision procedure for which argument to advance described in Definition 11.

The way in which we represent the information ‘leaked’ during the dialogue, as well as calculate the agent’s net utility, while simple, allows us to start studying dialogues in which agents attempt to hide information. Until now, most work involving utility and argumentation has focused on negotiation dialogues (e.g. [14]). We propose a number of possible extensions to the work presented in this paper.

One simple extension involves the addition of a context to the agent’s cost. In other words, given that fact A , B and C are known, we would like to be able to capture the notion that it is cheaper to reveal D and E together than as speech acts at different stages of the dialogue. Another form of context, which often appears in real world dialogues, occurs when two different pieces of information help derive a third, at different costs. In this case, the agent might be happy to reveal one without revealing the other, but currently, we are unable to perform complex reasoning about which to reveal. Without some form of lookahead to allow the agent to plan later moves, this extension is difficult to utilise. Once some form of lookahead exists, the addition of opponent modelling can further enhance the framework. Experimentally, evaluating the effects of various levels of lookahead, as well as different forms of opponent modelling might yield some interesting results.

Currently, we do not differentiate between information which the agent has explicitly committed to, and information that the agent has not yet disagreed with. More concretely, assume that the CS contains the argument (\top, A) . If an agent makes use of this argument, perhaps by submitting the argument (A, B) , then it is committed to the fact that A is true. If however, it never puts forth arguments making use of the fact, then an opponent cannot know if the agent is actually committed to A or not. We plan to extend our formalism and heuristic to capture this interaction in the near future.

Another extension that emerges from this line of reasoning is the concept of lying. An agent might commit to A to win an argument, even if its knowledge base contains only $\neg A$. How best to deal with this situation is an open question.

The way in which we handle conflicts is also open to debate. At the argumentation framework level, enhancements are required that allow one to present further evidence in support of a literal. By increasing the complexity of the model, methods for retracting literals can be introduced, opening up a whole host of questions at the heuristic level. For example, how does retracting support for a literal influence the information an opponent has of the retracting agent’s knowledge base?

6 Conclusions

In this paper, we proposed a heuristic for argumentation based on minimising the cost of information revealed to other dialogue participants. While such an argumentation strategy arises in many real world situations, we are not familiar with any application that explicitly makes use of this technique. To study the heuristic, we proposed an argumentation framework that allowed us to focus on it in detail. Several novel features emerged from the interplay between the heuristic and the framework, including the ability of an agent to win an argument that it should not have been able to win (if all information were available to all dialogue participants). While we have only examined a very abstract model utilising the heuristic, we believe

that many interesting extensions are possible.

Auction Mechanisms for Efficient Advertisement Selection on Public Displays

Terry Payne and Ester David and Nicholas R. Jennings and Matthew Sharifi¹

Abstract. Public electronic displays can be used as an advertising medium when space is a scarce resource, and it is desirable to expose many adverts to as wide an audience as possible. Although the efficiency of such advertising systems can be improved if the display is aware of the identity and interests of the audience, this knowledge is difficult to acquire when users are not actively interacting with the display. To this end, we present *BluScreen*, an intelligent public display, which selects and displays adverts in response to users detected in the audience. Here, users are identified and their advert viewing history tracked, by detecting any Bluetooth-enabled devices they are carrying (e.g. phones, PDAs, etc.). Within *BluScreen* we have implemented an agent system that utilises an auction-based marketplace to efficiently select adverts for the display, and deployed this within an installation in our Department. We demonstrate, by means of an empirical evaluation, that the performance of this auction-based mechanism when used with our proposed bidding strategy, efficiently selects the best adverts in response to the audience presence. We benchmarked our advertising method with two other commonly applied selection methods for displaying adverts on public displays; specifically the *Round-Robin* and the *Random* approaches. The results show that our auction-based approach, that utilised the novel use of Bluetooth detection, outperforms these two methods by up to 64%.

1 Introduction

Public electronic displays² are increasingly being used to provide information to users, to entertain (e.g. showing news bulletins), or to advertise products within public environments such as airports, city centres, and retail stores. Within these displays, advertisers typically utilise a variety of delivery methods to maximise the number of different adverts displayed, and thus increase their overall exposure to target audiences [8]. However, these methods are typically naïve and do not take into account the current audience.

On the other hand, a number of *interactive* public displays have been proposed that support communication with a user through active use of handheld devices such as PDAs or phones, or to a closed set of known users with pre-defined interests and requirements [3, 7]. Such systems assume prior knowledge about the target audience, and require either that a single user has exclusive access to the display, or that users carry specific *tracking* devices [4, 10] so that their presence can be identified. These approaches fail to work in public spaces, where no prior knowledge exists regarding users who may view the display, and where such displays need to react to the presence of several users simultaneously.

In contrast, we have developed an intelligent public display that utilises a novel approach to detect nearby users, in order to improve the selection of adverts for display. The goal of the selection is to maximise the exposure of as many adverts as possible to as wide an audience as possible (i.e. to maximise the number of distinct adverts seen by the population of users). In doing so, the main advantage of our system design is that it achieves this goal without: (i) any prior knowledge on the audience, (ii) the need for any specific action by the user, or (iii) the need for any client-based software. Moreover, unlike interactive public displays, our detection technology facilitates an awareness of several devices simultaneously.

As no direct feedback is received from the audience and the only knowledge available is based on the past observations of user presence, one of the key challenges of our system is to predict which advert is likely to gain the highest exposure during the next advertising cycle. To approximate this prediction, our system utilizes history information of past users' exposure to certain sets of adverts (so that we don't repeat material they have already seen), along with the information about what users are currently viewing on the display. In particular, we developed a multi-agent auction-based mechanism to efficiently select an advert for each advertising time slot. In this system, each agent represents a stakeholder that wishes to advertise, and it is provided with a bidding strategy that utilises a heuristic to predict future advert exposure, based on the expected audience composition.

In order to evaluate our design, we deployed a prototype of the system in our department (where it advertises information about research projects, press releases and announcements), and developed a simulator which models user behaviour. Here we report empirical results that show that the auction is more efficient in selecting adverts to maximise exposure of this advertising material to a set of users in the shortest time possible. Specifically, the auction requires, on average, 36% fewer advertising cycles to display all the adverts to each user, when compared to the *Round-Robin* approach (or 64% fewer adverts when compared to the *Random* selection approach).

In more detail, this paper advances the state of the art by:

1. Deploying the *BluScreen* prototype which synergistically combines a public screen with the novel detection of nearby handheld devices using Bluetooth wireless technology.
2. Developing a multi-agent auction-based marketplace for effectively marketing adverts on the *BluScreen* prototype.
3. Devising a novel heuristic-based bidding strategy that can be used by the agents in the auction mechanism.
4. Benchmarking our method against two commonly used selection strategies, *Round-Robin* and *Random*, to demonstrate that our method can efficiently display the best set of adverts given the current audience.

² An electronic display can change the advert presented over time.

The remainder of this paper is organised as follows: Section 2 discusses related work and motivates the use of agents and auction-based marketplaces within *BluScreen*. The deployed system and use of Bluetooth-devices is discussed in Section 3 and the underlying architecture and auction mechanism are described in Sections 4 and 5. In Section 6, we describe the device simulation and our experimental testbed, and present empirical results. Section 7 concludes.

2 Related Work

Targeted advertising has become prevalent through personal advertising systems, such as recommendation systems or web-based banner adverts [1]. These select content based upon prior knowledge of the individual viewing the material, and such systems work well on personal devices (where the owner's preferences and interests can be gathered and cached locally) or within interactive environments which utilise some form of credential to identify the user (e.g. e-commerce sites such as Amazon.com). Such approaches work well when advertising to an individual user, where a rich user profile exists a priori; in contrast, *BluScreen* selects adverts based on the presence of several users, where no profile data is available.

CASy [2] extends this targeted advertising metaphor by using a Vickrey auction mechanism to sell advertising space within a *modelled* electronic shopping mall. The auction was used to rank a set of possible advertisements provided by different retail outlets, and select the top ranking advertisements for presentation on public displays. Feedback is provided through subsequent sales information, allowing the model to build up a profile of a user's preferences. Although a number of different consumer models were evaluated, both with static and adaptive bidding strategies, the system has not been deployed, and is not suitable for advertising to many individuals simultaneously, as it requires explicit interaction with a single user to initially acquire the user's interest and preferences.

The Hermes Photo Display [3] is an example of a community-based display that interacts with users via Bluetooth-enabled phones. Although not used for advertising, users can share photos with each other by either uploading them from a phone to the display, or downloading shared photos to their phone. No specific client software is required on the phone, as the system utilises the fact that many modern mobile phones can share multimedia via Bluetooth. Although this display can be used to share photos; unlike *BluScreen*, the presented content is static, and requires direct user interaction (i.e. via a touch-screen) to browse the photos.

Groupcast [7] was a project that responded to the local audience within a corporate environment to display bespoke media. It had the advantage of knowing a priori the profiles of several members of the audience, and thus could exploit this pre-defined knowledge. User identification was based on an infrared badge system and embedded sensors within an office environment. When several users passed by the display, Groupcast compared the user's profiles to identify common areas of interest. Whereas *BluScreen* selects the best content to maximise exposure to the current audience, Groupcast would try to present content that matched this common interest. However, acquiring such content a priori, and determining high fidelity user profiles were found to be major stumbling blocks, and the mutual content selection was finally abandoned.

3 The BluScreen Prototype

The notion that user presence in front of the intelligent display can be identified remotely, has been explored using several methods within

different pervasive projects. However, most require the deployment of specialised hardware, such as *Active Badges*, [4, 10]. The Bluetooth wireless protocol, characterised by its relative maturity, market penetration³, and emphasis on short-range communication (e.g. 2-3 meters), has emerged as an alternative, generic mechanism for identifying or interacting with users through small, handheld devices.

BluScreen utilises Bluetooth-enabled devices as proxies for identifying users. Bluetooth sensors attached to an intelligent screen can be used to identify these devices⁴ in the local environment, and can record the encounters as a collocation event in terms of location and duration. The duration of this collocation event is assumed to relate to a possible level of interest in the displayed material; e.g. a user who is interested in the current advertising material will linger at the display during the advert.

A *BluScreen* prototype has been developed and deployed to evaluate the feasibility of the auction-based approach. A 23 inch flat-screen display and Bluetooth sensor were deployed outside an office adjacent to the corner of two corridors and an exit (thus maximising visibility to individuals moving within both corridors). The environment was scanned for Bluetooth devices every 20 seconds⁵, and these scans were logged over six months to determine whether or not Bluetooth devices could be used as a proxy for human presence. Twelve adverts were generated, describing a range of topics including research projects, upcoming events, and general information.

Device Type	Unique Samples	Devices
<i>Occasional</i>	< 10	135
<i>Frequent</i>	10-1000	70
<i>Persistent</i>	> 1000	6

Table 1. Number of Bluetooth devices observed at different frequencies over a six month sample period.

Table 1 summarises the number of devices detected, split into three clusters: *occasional*, whereby devices are observed for only a short time (such as visitors, etc.); *frequent* representing devices that regularly pass by the display; and *persistent* which represents devices that are regularly found in proximity to the sensor (such as laptops, etc.) that do not represent individuals passing the screen. Of the 212 unique Bluetooth devices detected, approximately 70 were detected with some degree of regularity, suggesting that Bluetooth detection could be used as a proxy for individuals passing in front of a screen.

4 The Agent Architecture

Several types of agents have been designed within the *BluScreen* architecture that we developed (illustrated in Figure 1):

Bluetooth Device-Detection Agent This agent monitors the environment by periodically sampling it to determine if there are any Bluetooth devices detectable. Current samples are then compared to previous samples to determine if new devices are present or existing devices have left the environment, and to update the exposure rate of existing devices.

Advertising Agent Each Advertising Agent represents a single *Advertisement* and is responsible for effectively purchasing advertising space by generating bids based on their predicted valuation of the upcoming advertising cycle. This predicted valuation may be

³ In October, 2005, ElectronicsWeekly.com reported that "...Bluetooth is expected to ship around 270 million units during 2005..."

⁴ Only Bluetooth devices in discovery mode are detectable.

⁵ The choice of a 20 second scanning cycle was determined by evaluating different scanning cycle lengths with varying numbers of nearby devices.

based on the expected exposure to an arbitrary audience (i.e. being seen by as many users as possible) or could be more selective (e.g. by identifying whether or not users have a preference for the type of material contained in the agent's advertisement). However, our deployed prototype described here currently implements the former method. Thus, each advertising agent maintains a history of successful advertising cycles (i.e. for which cycles an agent won an auction, and thus displayed its advert on the *BluScreen* display), and also the time (and duration) of each Bluetooth-device that was detected by that display during each advertising cycle.

Marketplace Agent The marketplace agent facilitates the sale of advertising time slots. A repetitive second-price sealed-bid auction [9] is used as a selection mechanism (this choice is justified below) to determine which advertising agent (if any) will display its advert on the next time slot, and its corresponding payment.

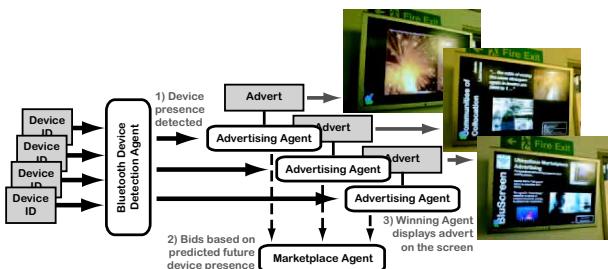

Figure 1. The *BluScreen* Agent Architecture for a single intelligent display

5 Auction Mechanism

BluScreen is designed to support a scaleable and a dynamic advertising framework, while maximising the exposure of as many adverts as possible to as wide an audience as possible, within a knowledge-poor environment. The main principle of our design is to distribute the control of the content displayed, in a way that no single entity can dictate who will advertise next. In contrast, the system, as a whole, will decide who will be the most profitable agent (i.e., expected to gain the highest exposure by displaying its advert in the next advertising cycle) and therefore will be awarded the facility of advertising in that cycle. Note that although the advertising agents are self interested (i.e. aim to maximise their own exposure to as large an audience as possible using their fixed budget), this does not contradict our desired overall design goal, since in our context, we assume that each agent will bid a value that reflects its expected exposure from displaying on the next cycle. Specifically, we have implemented a repetitive, second-price sealed-bid auction that takes place before each of the advertising cycles⁶. The winner of each auction is the advertising agent who placed the highest bid, and it is charged for the second highest bid. As truth-revealing has been shown to be a

⁶ We chose this mechanism for several reasons. As one of the critical requirements of this system is to operate in a timely manner, only *one-shot* auctions were considered. Now, *first-price* and *second-price* sealed-bid auctions are the most popular forms of such auctions. Here we chose the second-price for its superiority in terms of its economically desired properties. In particular, it has a dominant strategy of truth revealing. Such a property is highly desired as it frees the agents from requiring expensive and costly strategies in terms of time and computation. In our context, this is even more significant as the system should react in a timely manner. Moreover, the second-price sealed-bid auction is efficient in the sense that the auctioned item, in our case the right to advertise on the next advertising cycle, is awarded to the bidder that values it the most. Our choice can also be supported by the fact that the continuously repeated second-price sealed-bid auction is also being used for web advertising using search engines like Google and Overture [5].

dominant strategy in this case, the effective local decisions of each individual agent contribute towards effective overall system.

In this section we start by describing the *BluScreen* model and the mechanism we developed, including the strategies of the advertising agents given their valuation for the next advertising cycle's auction. However, as our system is a knowledge-poor environment where no direct feedback is collected from the users (instead only a limited history and the current status of the detected devices is available), in the final part of this section we provide the agent with a heuristic method to generate this value.

5.1 The Auction Model

In our model we assume that there is a single *BluScreen* instance available for advertising which is managed by the marketplace agent⁷. The advertising time is divided into discrete intervals which we term the *advertising cycle*, C^i . During each such cycle, only one agent can display its corresponding advert, and during this time only this agent has the ability to collect information about devices which were detected by the *BluScreen*. However, at the end of each advertising cycle, the marketplace agent informs all the advertising agents about any devices detected in front of the screen at that time.

Each advertising agent, a_j , is assumed to be self interested, and to be managed by a different stake-holder which credits it with a fixed budget for advertising. For each advertising cycle, each advertising agent generates its private value (discussed in detail below) and places a corresponding bid in terms of some currency. Once an agent has fully spent its budget, it is deleted from the system. On the other hand, at any point in time, new agents may be added to the system. The goal of each advertising agent is to utilise its budget in a way that maximises its exposure.

The marketplace agent acts as the auctioneer and runs an auction before each of the advertising cycles. As part of the auctioneer duties, it sets a reservation price that represents the minimum acceptable bid⁸. In the case that none of the agents place bids that meet this price, a default advert is displayed. The marketplace agent is also assumed to be trusted by the advertising agents. This feature is necessary for the proper behaviour of the system, as in a second-price sealed-bid auction no one observes the whole set of bids except the auctioneer.

5.2 Bidding Strategy for the Advertising Agents

In our model, agents participate in a *repetitive*, second-price sealed bid auction whilst facing budget constraints. For non-repetitive variants of this auction, it has been shown that the bidding strategy:

$$\beta(a_j) = \min \{ \text{budget}(a_j), v \} \quad (1)$$

is a **dominant strategy** [6], where $\text{budget}(a_j)$ is the current balance of agent a_j and v is its private valuation. Now, it is easy to see that this holds for the repetitive case as well, as in each round of the second-price sealed-bid auction, a new advertising cycle is auctioned. However, there exists a dependence with previous rounds in terms of the devices that were exposed in the past, and those that are currently in front of the screen. However, this dependence is concealed in the valuation of the bidder for the next advertising cycle.

⁷ This assumption is made to simplify our task of validating the correctness and the efficiency of the proposed mechanism and strategy. This assumption will be relaxed in future work.

⁸ The reservation price is used to avoid selling the advertising space for free, and to ensure that when competition is low, there is a minimum income.

But, once the agent has generated its valuation for the next advertising cycle, its dominant strategy is truth telling.

Although the agents utilise truth telling as a dominant strategy, they still face a very challenging problem of being able to estimate their *expected exposure*, as they are provided only with information about past and current audience composition (in terms of detectable Bluetooth devices), and from that alone they need to estimate their future exposure. In the next subsection we describe a heuristic method we developed for the bidder valuation estimation task.

5.3 Heuristics for Estimating Private Values

Here we provide an advertising agent, a_j , with a heuristic strategy for generating its valuation (expected utility) for the next advertising cycle, C^{i+1} . Recall that the main target of an agent a_j is to maximise its exposure to as large an audience as possible, given its financial constraints. The core principle of this heuristic is to utilise the information an agent has about past devices' exposure, to predict the future expected exposure. Specifically, each time an advertising agent a_j has to make a decision about its valuation for the next cycle C^{i+1} , it has two types of information on which to base its decision:

- (i) history observation, $H(a_j)$, of exposed devices which were collected during the advertising cycles it won, $WonCycles(a_j)$, in the past, $H(a_j) = \{(C^t, d, x)\}$ where $C^t \in WonCycles(a_j)$, d is the device id, and x is the exposure duration; and
- (ii) the current set of detected devices which were in front of the screen at the end of C^i , termed $end(C^i)$.

Using this information, an advertising agent, a_j , assumes that the devices that will be in front of the screen in C^{i+1} are $end(C^i)$. Therefore, we propose that a_j will search through its history to check if these devices were exposed to its advert in the past, and, if so, for how long⁹. If a device was exposed to the same advert during several different advertising cycles, then we propose to consider only the one in which it was exposed to the most. Formally, a_j 's valuation for C^{i+1} is:

$$v(a_j, C^{i+1}) = \sum_{d \in end(C^i)} 1 - \max \{x \mid \{C^t, d, x\} \in H(a_j)\}^{10} \quad (2)$$

Now, we believe this is the best heuristic an agent can use, given its limited information it faces currently. We intend to incorporate more sophisticated mechanisms for generating statistics within future versions of *BluScreen*, that can provide the agents with more relevant information, such as the rate of detected devices as a function of the time in the day. Given that information, agents will be able to apply learning methods to improve their predictions.

6 Empirical Evaluation

To evaluate the bidding strategy described in the previous Section within a controlled environment, a simulation was developed. This is based on the same architecture as the deployed *BluScreen* instance,

⁹ If a device only observes part of an advert, a_j still has an incentive to expose its advert to this device, as we make the assumption that the advert may be dynamic (e.g. contain video). Therefore a device is only exposed to all the information contained in the advert if it observes the advert for the whole advertising cycle. However, having observed a partial advert will diminish the devices' contribution towards bids in future cycles.

¹⁰ In the case where a device is not exposed to any of the previous displays, we assume the default value of x is zero.

but it additionally supports the modelling of users in the audience, in terms of Bluetooth devices present¹¹.

The *BluScreen* simulation modelled devices' behaviour (i.e. as a proxy for a user) in terms of their likelihood of arriving at, and subsequently remaining at, a *BluScreen* display given the currently displayed advertisement. The *device model* was defined with the following assumptions:

- Device presence is measured in discrete sample-intervals, to simulate observations made by the Bluetooth sensor;
- The duration of an advert is assumed to be equal to a whole number of sample-intervals;
- An advert is considered as *fully seen* only when a device has been present for the whole duration of the advert;
- Devices can arrive at any point during an advertising cycle, whereby the probability that a device will arrive is P_{arrive} ;
- The probability a device may leave without observing the subsequent advert is P_{depart} . A device will automatically leave if it has *fully seen* the subsequent advert;
- Both P_{depart} and P_{arrive} assume a uniform distribution.

Two alternate selection methods were compared with the auction: **Round-Robin** selection and **Random** selection. The former is a familiar mechanism used to repeatedly cycle through a number of adverts (in order). Given our device model, this approach represents the optimal selection mechanism when $P_{depart} = 0$ and $P_{arrive} = 1$. The latter mechanism randomly selects a new advert to display at the beginning of each new advertising cycle, independently of what has been previously selected. This method was selected as a baseline against which the other worst-case methods can be compared.

To simplify this analysis, each experiment consisted of ten adverts of equal duration (i.e. six samples which is equivalent to a 2 minute advert), represented by ten advertising agents. In each experiment, adverts are selected and presented until every device has *fully seen* all ten adverts. To ensure statistical stability, the results of each experiment are averaged over 10,000 test runs, and the mean results are reported. Where necessary, a Student's t-test is used to confirm statistical significance at the 95% confidence level.

6.1 Experimental Results

In our first experiment, we examine the behaviour of each selection mechanism as the number of devices present increases (Figure 2). The number of devices, N_d , was varied between 1 and 100, and the device behaviour was defined using $P_{depart} = 0.05$ and $P_{arrive} = 0.5$. The graph supports the hypothesis that advert selection using the *BluScreen auction* is statistically more significant than either *Round-Robin* or *Random* (assuming the modelling parameters defined above). Specifically, as N_d increases, there is a corresponding exponential rise in the number of required adverts. The mean number of adverts required by the *BluScreen auction* is lower than the *Round-Robin* selection mechanism or the *Random* selection mechanism for all numbers of devices tested; e.g. for $N_d = 50$, the auction method required a mean of 40.24 ± 0.06 advertising cycles to display all 10 adverts to all the devices, compared to *Round-Robin* (64.16 ± 0.18) or *Random* (108.50 ± 0.28). This suggests that although each selection method can scale, a single device will be exposed to all the adverts in typically 36% fewer advertising cycles than

¹¹ Although the deployed prototype could be used to test the auction mechanism based on observed real-world events, factors such as the location of the screen, variances in the advertised material, and the number of detectable devices can affect the resulting performance.

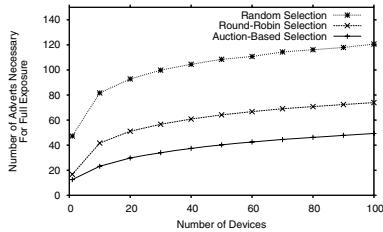

Figure 2. The effect of varying the number of observed devices; $P_{depart} = 0.05$, $P_{arrive} = 0.5$.

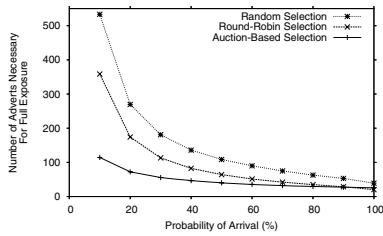

Figure 3. The effect of varying the probability of a device arriving during an advertising cycle. $P_{depart} = 0.05$, $N_d = 50$.

the *Round-Robin* approach, or 64% fewer advertising cycles than the *Random* approach when using the *BluScreen auction*.

The second two experiments therefore explore how the efficiency of the different selection mechanisms change as the device model is varied. In each of these experiments, $N_d = 50$. In particular, Figure 3 plots the results for $0 < P_{arrival} \leq 1$. These results show that for low values of $P_{arrival}$, the number of adverts required is significantly lower for *BluScreen auction* than for either of the other methods considered. However, as the probability increases towards 100%, the efficiency of both *BluScreen auction* and *Round-Robin* converge. This result is expected, as when all devices are guaranteed to be present, *BluScreen auction* will select each advert in turn (depending on the tie-breaking strategy (e.g. random) used by the auctioneer), and thus exhibit the same behaviour as *Round-Robin*.

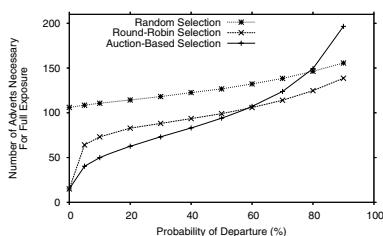

Figure 4. The effect of varying the probability of a device leaving the audience during an advertising cycle. $P_{arrive} = 0.5$, $N_d = 50$.

One artefact of assuming low departure probabilities is that once a device has arrived, it is unlikely to depart, and hence is more likely to remain through a complete cycle of adverts (in the case of *Round-Robin*), or its presence be accurately predicted (when using *BluScreen auction*). Therefore, as P_{depart} increases, the efficiency of both approaches should degrade. Figure 4 illustrates this. As one would expect, the performance of both *BluScreen auction* and *Round-Robin* are statistically equivalent when $P_{depart} = 0$. However, the number of adverts required increases sharply in the range $P_{depart} = [0.01 \dots 0.1]$; and then rises almost linearly until $P_{depart} = 0.5$. Beyond this value, the rise becomes logarithmic. This rise is more significant for the auction approach, and may be due to poor estimates in future device presence, leading to erroneous pri-

vate value predictions. In contrast, the rise in the number of adverts required for *Random* is almost linear; this result is not surprising as the selection of each advert is independent of the audience composition, and hence is unaffected by the departure of a device.

7 Conclusions

In this paper, we addressed the problem of unobtrusively providing audience composition data to an intelligent public display, to select the optimal advert that maximises exposure of a set of adverts. To this end, we proposed the novel use of Bluetooth wireless technology to detect nearby handheld devices, and designed an auction-based marketplace and bidding heuristic which predicted the level of expected exposure of an advert given the detected audience and knowledge of previous exposure the audience members had to different adverts. A prototype public display that utilises this marketplace was implemented and deployed in our Department. The logs generated by this system indicated that a large number of Bluetooth-enabled devices could be detected, and that a significant subset was detected on a regular basis. Moreover, we implemented a simulation environment to facilitate controlled evaluation of the auction mechanism, when compared with other commonly used advert selection mechanisms, and showed that in most cases the auction-based approach outperforms the other commonly used approaches. This approach has particular relevance for advertising in environments where users only linger for short periods, but often return (such as railway platforms etc.).

In future work, we plan to extend our approach to work with multiple displays, to increase the exposure of adverts to a larger community, and to build user preferences based on the duration users spend viewing different adverts that are categorised (thus taking into account inferred interest, as well as exposure).

Verifying Interlevel Relations within Multi-Agent Systems

Alexei Sharpanskykh and Jan Treur¹

Abstract. An approach to handle the complex dynamics of a multi-agent system is based on distinguishing aggregation levels by structuring the system into parts or components. The behavior of every aggregation level is specified by a set of dynamic properties for components and interactions at that level, expressed in some (temporal) language. The dynamic properties of higher aggregation levels in principle can be logically related to dynamic properties of lower levels. This asks for identification and verification of such interlevel relations. In this article it is shown how this problem can be addressed using model checking techniques.

1 INTRODUCTION

Often dynamics of a multi-agent system is described by a behavioral specification, which consists of dynamic properties of elements of the multi-agent system (i.e., agents, interaction relations, and an environment). Usually, these properties are expressed as formulae in some (temporal) language. Even if the behavioral description of a single element is simple, the general dynamics of the whole multi-agent system is often difficult to analyze. In particular, with increase of the number of elements within the multi-agent system, the complexity of the dynamics of the system grows considerably. In order to analyze the behavior of a complex multi-agent system (e.g., for critical domains such as air traffic control and health care), appropriate approaches for handling the dynamics of the multi-agent system are important.

One of the approaches to manage complex dynamics is by distinguishing different *aggregation levels*, based on a clustering of a multi-agent system into parts or components with further specification of their dynamics and relations between them; e.g., [4]. At the lowest aggregation level a component is an agent or an environmental object (e.g., a database), with which agents interact. Further, at higher aggregation levels a component has the form of either a group of agents or a multi-agent system as a whole. In the simplest case two levels can be distinguished: the lower level at which agents interact and the higher level, where the whole multi-agent system is considered as one component. In the general case the number of aggregation levels is not restricted. At every aggregation level the behavior of a component is described by a set of dynamic properties. The dynamic properties of a component of a higher aggregation level can be logically related by an *interlevel relation* to dynamic properties of components of an adjacent lower

aggregation level. This interlevel relation takes the form that a number of properties of the lower level logically entail the properties of the higher level component.

Identifying interlevel relations is usually achieved by applying informal or semi-formal early requirements engineering techniques; e.g., *i** [8] and SADT [7]. To formally prove that the identified interlevel relations are indeed correct, model checking techniques [1, 9] may be of use. The idea is that the lower level properties in an interlevel relation are used as a system specification, whereas the higher level properties are checked for this system specification. However, model checking techniques are only suitable for systems specified as finite-state concurrent systems. In the general case, at any aggregation level a behavioral specification for a multi-agent system component consists of dynamic properties expressed by possibly complex temporal relations, which do not allow direct application of automatic model checking procedures. In order to apply model checking techniques it is needed to transform an original behavioral specification of the lower aggregation level into a model based on a finite state transition system. In order to obtain this, as a first step a behavioral description for the lower aggregation level is replaced by one in executable temporal format. After that, using an automated procedure an executable temporal specification is translated into a general finite state transition system format that consists of standard transition rules. Such a representation can be easily translated into an input format of one of the existing model checkers. Then, using model checking techniques it is possible to prove (or refute) automatically that the interlevel relations between dynamic properties of adjacent aggregation levels expressed as specification in some temporal language hold.

The proposed approach has similarities with compositional reasoning and verification techniques [3, 4] in the way how it handles complex dynamics of a system. However, it differs from the latter in distinguishing multiple aggregation levels in a system specification and representing verification of system dynamics as a problem of checking logic entailment relations between dynamic properties of adjacent aggregation levels. Other approaches for verifying multi-agent system dynamics are based on modal temporal logics, automatically translated into executable format by techniques from [2], and verified by clausal resolution methods.

In the next section the concepts for formal specification of a multi-agent system's dynamics and the temporal language used are briefly introduced. After that, in Section 3 the transformation procedure from a behavioral specification into a finite state transition system description is described and illustrated by means of an example. The paper ends with a discussion in Section 4.

2 MODELING OF DYNAMIC PROPERTIES

Components can be active (e.g., an agent) or passive (e.g., database). An active component represents an autonomous entity that interacts with an environment and with other components. Active components interact with each other by communicating messages to each other (at the mental level) and performing actions (at the physical level). An environment can be considered as a set of passive components with certain properties and states. Components interact with each other via *input* and *output* (interface) states. At its input an active component receives observations from an environment or communications from other components whereas at its output it generates communications to other components or actions in an environment.

From the external perspective behavior of a component is characterized by a set of dynamic properties, which represent relations over time between its input and output states. Dynamic properties are specified in the Temporal Trace Language (TTL) [4, 11]. TTL is a variant of order-sorted predicate logic [6] and has some similarities with Situation Calculus [10] and Event Calculus [5]. Whereas the standard multi-sorted predicate logic is a language to reason about static properties only, TTL is an extension of such language with facilities for reasoning about the dynamic properties of arbitrary systems.

The state properties are expressed using a standard multi-sorted first-order predicate language with a signature, which consists of a number of sorts, sorted constants, variables, functions and predicates. Every component A has assigned an interaction state ontology $\text{InteractionOnt}(A)$ for its input and output states. Specifically, using an ontology InteractionOnt one can define observations of state properties, communications, and actions.

For enabling dynamic reasoning TTL includes special sorts: TIME (a set of linearly ordered time points), STATE (a set of all state names of a system), TRACE (a set of all trace names; a trace or a trajectory can be thought of as a timeline with a state for each time point), STATPROP (a set of all state property names), and VALUE (an ordered set of numbers). Furthermore, for every sort S from the state language the following TTL sorts exist: the sort S^{VARS} , which contains all variable names of sort S ; the sort S^{TERMS} , which contains names of all ground terms, constructed using sort S ; sorts S^{GTERMS} and S^{VARS} are subsorts of sort S^{TERMS} .

In TTL, formulae of the state language are used as objects. To provide names of object language formulae ϕ in TTL the operator $(*)$ is used (written as ϕ^*), which maps variable sets, term sets and formula sets of the state language to the elements of TTL sorts S^{GTERMS} , S^{TERMS} , S^{VARS} and STATPROP . The state language and TTL define disjoint sets of expressions. Therefore, in TTL formulae we shall use the same notations for the elements of the object language (i.e., constants, variables, functions, predicates) and for their names in TTL without introducing any ambiguity. Further we shall use t with subscripts and superscripts for variables of the sort TIME ; and γ with subscripts and superscripts for variables of the sort TRACE .

For the explicit indication of an aspect of a state for a component, to which a state property is related, sorts ASPECT_COMPONENT (a set of the component aspects of a system; i.e., input, output, internal); COMPONENT (a set of all component names of a system); $\text{COMPONENT_STATE_ASPECT}$ (a set of all names of aspects of all component states) and a function symbol

$\text{comp_aspect: ASPECT_COMPONENT} \times \text{COMPONENT} \rightarrow \text{COMPONENT_STATE_ASPECT}$

are used.

A state for a component is described by a function symbol state of type $\text{TRACE} \times \text{TIME} \times \text{COMPONENT_STATE_ASPECT} \rightarrow \text{STATE}$.

The set of function symbols of TTL includes $\wedge, \vee, \rightarrow, \leftrightarrow: \text{STATPROP} \times \text{STATPROP} \rightarrow \text{STATPROP}$; not: $\text{STATPROP} \rightarrow \text{STATPROP}$, $\forall, \exists: S^{\text{VARS}} \times \text{STATPROP} \rightarrow \text{STATPROP}$, which counterparts in the state language are boolean propositional connectives and quantifiers. Further we shall use $\wedge, \vee, \rightarrow, \leftrightarrow$ in infix notation and \forall, \exists in prefix notation for better readability.

Notice that also within states statements about time can be made (e.g., in state properties representing memory). To relate time within a state property (sort LTIME) to time external to states (sort TIME) a function $\text{present_time}: \text{LTIME}^{\text{TERMS}} \rightarrow \text{STATPROP}$ is used. Furthermore, for the purposes of this paper it is assumed that $\text{LTIME}^{\text{GTERMS}} = \text{TIME}$ and $\text{LVALUE}^{\text{GTERMS}} = \text{VALUE}$ (LVALUE is a sort of the state language, which is a set of numbers). We shall use u with subscripts and superscripts to denote constants of sort $\text{LTIME}^{\text{VARS}}$. For formalising relations between sorts VALUE and TIME function symbols $-, +, /, \cdot: \text{TIME} \times \text{VALUE} \rightarrow \text{TIME}$ are introduced. And for sorts $\text{LVALUE}^{\text{TERMS}}$ and $\text{LTIME}^{\text{TERMS}}$ the function symbols $-, +, /, \cdot$ are overloaded: $\text{LTIME}^{\text{TERMS}} \times \text{LVALUE}^{\text{TERMS}} \rightarrow \text{STATPROP}$.

The states of a component are related to names of state properties via the formally defined satisfaction relation denoted by the infix predicate \models (or denoted by the prefix predicate holds): $\text{state}(\gamma, t, \text{output}(A)) \models p$ (or $\text{holds}(\text{state}(\gamma, t, \text{output}(A)))$), which denotes that the state property with a name p holds in trace γ at time point t at the output state of component A. Sometimes, when the indication of a component aspect is not necessary, this relation will be used without the third argument: $\text{state}(\gamma, t) \models p$. Both $\text{state}(\gamma, t, \text{output}(A))$ and p are terms of TTL. In general, TTL terms are constructed by induction in a standard way from variables, constants and function symbols typed with all before mentioned TTL sorts.

Transition relations between states are described by dynamic properties, which are expressed by TTL-formulae. The set of *atomic TTL-formulae* is defined as:

- (1) If v_1 is a term of sort STATE , and u_1 is a term of the sort STATPROP , then $\text{holds}(v_1, u_1)$ is an atomic TTL formula.
- (2) If t_1, t_2 are terms of any TTL sort, then $t_1=t_2$ is an atomic TTL formula.
- (3) If t_1, t_2 are terms of sort TIME , then $t_1 < t_2$ is an atomic TTL formula.

The set of *well-formed TTL-formulae* is defined inductively in a standard way using boolean propositional connectives and quantifiers. TTL has semantics of the order-sorted predicate logic. A more detailed specification of the syntax and the semantics for the TTL (including the axiomatic basis) is given in [11].

Dynamic properties to model a behavioral specification are assumed to be specified in the form of a logical implication from a temporal input pattern to a temporal output pattern. The consequent parts of dynamic properties do not contain any disjunctions in order to prevent non-determinism in behavior. It is a necessary assumption for enabling verification of a system using existing model checking techniques and tools. Past, interval and future statements are defined as follows:

- a) A *past statement* for a trace γ and a time point t over state ontology Ont is a temporal statement $\phi_p(\gamma, t)$ in TTL, such that each time variable s different from t is restricted to the time interval before t : for every time quantifier for a time variable s a restriction of the form $s \leq t$, or $s < t$ is required within the statement.
- b) A *future statement* for a trace γ and a time point t over state ontology Ont is a temporal statement $\phi_f(\gamma, t)$ in TTL, such that for every quantified time variable s , different from t a restriction of the form $s \geq t$, or $s > t$ is required within the statement.

c) An *interval statement* for a trace γ and time points t_1 and t_2 over state ontology Ont is a temporal statement $\phi(\gamma, t_1, t_2)$ in TTL, that is a past statement for t_2 and a future statement for t_1 .

An executable specification of the dynamics of a component consists of a set of dynamic properties in an executable temporal language, representing temporal relations between a number of postulated internal states. Internal states of a component A are described using a postulated internal state ontology $\text{InternalOnt}(A)$. In cognitive sciences, which have been used as a source of inspiration, it is often assumed that an agent maintains a memory in the form of some internal model of the history. Furthermore, we assume that internal states are formed on the basis of (input) observations (sensory representations) or communications. For this the function symbol $\text{memory} : \text{LTIME}^{\text{TERMS}} \times \text{STATPROP} \rightarrow \text{STATPROP}$ is used. For example, $\text{memory}(t, \text{observed}(a))$ expresses that the component has memory that it observed a state property a at time point t . Before performing an action or communication it is postulated that a component creates an internal preparation state. For example, $\text{preparation_for}(b)$ represents a preparation of a component to perform an action or a communication b . Each dynamic property in the internal behavioral specification is specified in one of the following *executable* forms:

- (1) $\forall t \text{state}(\gamma, t) \models X \Rightarrow \text{state}(\gamma, t+c) \models Y$ (states relation property)
- (2) $\forall t \text{state}(\gamma, t) \models X \Rightarrow \text{state}(\gamma, t+1) \models X$ (consistency property)
- (3) $\forall t \text{state}(\gamma, t) \models X \Rightarrow \text{state}(\gamma, t) \models Y$ (state relation property),

where c is some integer constant, X and Y are (conjunctions of) names of state properties and $X \neq Y$.

3 TRANSFORMATION PROCEDURE

The procedure described in this section achieves the transformation of a behavioral specification for multi-agent system components into the executable format and subsequently into the representation of a finite state transition system. An external behavioral specification of a component is defined as follows.

Definition (External behavioral specification)

An *external behavioral specification* for a multi-agent system component consists of dynamic properties $\phi(\gamma, t)$ expressed in TTL of the form $[\phi_p(\gamma, t) \Rightarrow \phi_f(\gamma, t)]$, where $\phi_p(\gamma, t)$ is a past statement over the interaction ontology and $\phi_f(\gamma, t)$ is a future statement. The future statement is represented in the form of a conditional behavior: $\phi_f(\gamma, t) \Leftrightarrow \forall t_i > t [\phi_{\text{cond}}(\gamma, t, t_i) \Rightarrow \phi_{\text{bh}}(\gamma, t_i)]$, where $\phi_{\text{cond}}(\gamma, t, t_i)$ is an interval statement over the interaction ontology, which describes a condition for some specified action(s) and/or communication(s), and $\phi_{\text{bh}}(\gamma, t_i)$ is a (conjunction of) future statement(s) for t_i over the output ontology of the form $\text{state}(\gamma, t_i+c) \models \text{output}(a)$, for some integer constant c and action or communication a .

When a past formula $\phi_p(\gamma, t)$ is true for γ at time t , a potential to perform one or more action(s) and/or communication(s) exists. This potential is realized at time t_i when the condition formula $\phi_{\text{cond}}(\gamma, t, t_i)$ becomes true, which leads to the action(s) and/or communication(s) being performed at the time point(s) t_i+c indicated in $\phi_{\text{bh}}(\gamma, t_i)$.

The procedure is applied to the multi-agent system considered at any two adjacent aggregation levels. The behavioral specification of the lower aggregation level is constructed from the dynamic properties of the lower level components. By interlevel relations these properties can be logically related to the properties of higher level components. In order to enable automatic verification of such interlevel relations, the non-executable lower level behavioral specification is automatically replaced by an

executable one. Further, for performing model checking, the executable specification is automatically transformed into a finite state transition system description.

Let $\phi(\gamma, t)$ be a non-executable dynamic property from an external behavioral specification for the component A, for which an executable representation should be found.

The Transformation Procedure

- (1) Identify executable temporal properties, which describe transitions from interaction states to memory states.
- (2) Identify executable temporal properties, which describe transitions from memory states to preparation states for output.
- (3) Specify executable properties, which describe the transition from preparation states to the corresponding output states.
- (4) From the executable properties, identified during steps 1-3, construct a part of the specification $\pi(\gamma, t)$, which describes the internal dynamics of component A, corresponding to property $\phi(\gamma, t)$.
- (5) Apply steps 1-4 to all properties in the behavioral specification of lower level components A. In the end add to the executable specification the dynamic properties, which were initially specified in executable form using an ontology, different than $\text{InteractOnt}(A)$.
- (6) Translate the identified during the steps 1-5 executable rules into the transition system representation.

The details of the described procedure are described by means of an example, in which a multi-agent system for co-operative information gathering is considered at two aggregation levels. At the higher level the multi-agent system as a whole is considered. At the lower level four components and their interactions are considered: two information gathering agents A and B, agent C, and environment component E representing the external world. Each of the agents is able to acquire partial information from an external source (component E) by initiated observations. Each agent can be reactive or proactive with respect to the information acquisition process. An agent is proactive if it is able to start information acquisition independently of requests of any other agents, and an agent is reactive if it requires a request from some other agent to perform information acquisition.

Observations of any agent taken separately are insufficient to draw conclusions of a desired type; however, the combined information of both agents is sufficient. Therefore, the agents need to co-operate to be able to draw conclusions. Each agent can be proactive with respect to the conclusion generation, i.e., after receiving both observation results an agent is capable to generate and communicate a conclusion to agent C. Moreover, an agent can be request pro-active to ask information from another agent, and an agent can be pro-active or reactive in provision of (already acquired) information to the other agent.

For the lower-level components of this example multi-agent system, a number of dynamic properties were identified and formalized in TTL. For the purposes of illustration of the proposed transformation procedure the dynamic property that describes an information provision reactivity of the agent B has been chosen. Informally this property expresses that the agent B generates an information chunk (the constant IC of sort $\text{INFORMATION_CHUNK}^{\text{TERMS}}$) for the agent A if the agent B observes the IC at its input from the environment and at some point in the past B received a request for the IC from the agent A. According to the definition of an external behavioral specification the considered property can be represented in the form $[\phi_p(\gamma, t) \Rightarrow \phi_f(\gamma, t)]$, where $\phi_p(\gamma, t)$ is a formula

$\exists t_2 \leq t \text{state}(\gamma, t_2, \text{input}(B)) \models \text{communicated}(\text{request_from_to_for}(A, B, \text{IC}))$ and $\phi_f(\gamma, t)$ is a formula

$\forall t_1 > t [state(\gamma, t_1, input(B)) \models observed(provided_result_from_to(E, B, IC)) \Rightarrow state(\gamma, t_1 + c, output(B)) \models output(communicated(send_from_to(B, A, IC)))]$
with $\varphi_{cond}(\gamma, t, t_1)$ is

$state(\gamma, t_1, input(B)) \models observed(provided_result_from_to(E, B, IC))$
and $\varphi_{bh}(\gamma, t_1)$ is

$state(\gamma, t_1 + c, output(B)) \models output(communicated(send_from_to(B, A, IC)))$,
where t is the present time point with respect to which the formulae are evaluated and c is some natural number.

Step 1. From interaction states to memory states

The formula $\varphi_{mem}(\gamma, t)$ obtained by replacing all occurrences in $\varphi_p(\gamma, t)$ of subformulae of the form $state(\gamma, t') \models p$ by $state(\gamma, t) \models memory(t', p)$ is called the *memory formula for* $\varphi_p(\gamma, t)$. Thus, a memory formula defines a sequence of past events (i.e., a history; e.g., observations of an external world, actions) for the present time point t . According to Lemma 1 (given in [11]) $\varphi_{mem}(\gamma, t)$ is equivalent to some formula $\delta^*(\gamma, t)$ of the form $state(\gamma, t) \models q_{mem}(t)$, where $q_{mem}(t)$ is called the *normalized memory state formula for* $\varphi_{mem}(\gamma, t)$, which uniquely describes the present state at the time point t by a certain history of events. Moreover, q_{mem} is the state formula $\forall u' [present_time(u') \rightarrow q_{mem}(u')]$. For the considered example $q_{mem}(t)$ for $\varphi_{mem}(\gamma, t)$ is specified as:

$$\exists u_2 \leq t \text{ memory}(u_2, \text{communicated(request_from_to_for(A, B, IC)))}$$

Additionally, memory state persistency properties are composed for all memory atoms. Rules that describe creation and persistence of memory atoms are given in the executable theory from observation states to memory states $Th_{o \rightarrow m}$ (a general description of this and the following theories is given in [11]). For the example:

$$\begin{aligned} \forall t' \text{ state}(\gamma, t', input(B)) \models \text{communicated(request_from_to_for(A, B, IC)))} \Rightarrow \\ \text{state}(\gamma, t', internal(B)) \models \\ \text{memory}(t', \text{communicated(request_from_to_for(A, B, IC)))}) \\ \forall t'' \text{ state}(\gamma, t'', internal(B)) \models \\ \text{memory}(t', \text{communicated(request_from_to_for(A, B, IC)))}) \Rightarrow \\ \text{state}(\gamma, t'' + 1, internal(B)) \models \\ \text{memory}(t', \text{communicated(request_from_to_for(A, B, IC)))}) \end{aligned}$$

Step 2. From memory states to preparation states

Obtain $\varphi_{cmem}(\gamma, t, t_1)$ by replacing all occurrences in $\varphi_{cond}(\gamma, t, t_1)$ of $state(\gamma, t') \models p$ by $state(\gamma, t_1) \models memory(t', p)$. The condition memory formula $\varphi_{cmem}(\gamma, t, t_1)$ contains a history of events, between the time point t , when $\varphi_p(\gamma, t)$ is true and the time point t_1 , when the formula $\varphi_{cond}(\gamma, t, t_1)$ becomes true. Again by Lemma 1 $\varphi_{cmem}(\gamma, t, t_1)$ is equivalent to the formula $state(\gamma, t_1) \models q_{cond}(t, t_1)$, where $q_{cond}(t, t_1)$ is called the *normalized condition state formula for* $\varphi_{cmem}(\gamma, t, t_1)$, and $q_{cond}(t)$ is the state formula $\forall u' [present_time(u') \rightarrow q_{cond}(t, u')]$.

For the considered example $q_{cond}(t, t_1)$ for $\varphi_{cmem}(\gamma, t)$ is obtained as: $memory(t_1, \text{observed(provided_result_from_to}(E, B, IC)))$ and $q_{cond}(t): \forall u' [present_time(u') \rightarrow memory(u', \text{observed(provided_result_from_to}(E, B, IC)))]$.

Obtain $\varphi_{prep}(\gamma, t_1)$ by replacing in $\varphi_{bh}(\gamma, t_1)$ any occurrence of $state(\gamma, t_1 + c) \models output(a)$ by $state(\gamma, t_1) \models preparation_for(output(t_1 + c, a))$, for some number c and action or communication a . The preparation state is created at the same time point t_1 , when the condition for an output $\varphi_{cond}(\gamma, t, t_1)$ is true. By Lemma 1 $\varphi_{prep}(\gamma, t_1)$ is equivalent to the state formula $state(\gamma, t_1) \models q_{prep}(t_1)$, where $q_{prep}(t_1)$ is called the *normalized preparation state formula for* $\varphi_{cond}(\gamma, t_1)$. Moreover, q_{prep} is the state formula $\forall u' [present_time(u')] \rightarrow q_{prep}(u')]$. For the considered example $q_{prep}(t_1)$ is composed as $preparation_for(output(t_1 + c, \text{communicated(send_from_to}(B, A, IC))))$.

Rules, which describe generation and persistence of condition memory states, a transition from the condition to the preparation state, and the preparation state generation and persistence, are given in the executable theory from memory states to preparation states $Th_{m \rightarrow p}$. For the considered example:

$$\begin{aligned} \forall t' [state(\gamma, t', input(B)) \models observed(provided_result_from_to(E, B, IC)) \Rightarrow \\ state(\gamma, t', internal(B)) \models \\ [memory(t', \text{observed(provided_result_from_to}(E, B, IC))) \wedge \\ stimulus_reaction(observed(provided_result_from_to}(E, B, IC)))]] \\ \forall t'' \text{ state}(\gamma, t'', internal(B)) \models \\ memory(t', \text{observed(provided_result_from_to}(E, B, IC))) \Rightarrow \\ state(\gamma, t'' + 1, internal(B)) \models \\ memory(t', \text{observed(provided_result_from_to}(E, B, IC))) \\ \forall t' \text{ state}(\gamma, t') \models \forall u'' [present_time(u'') \rightarrow \\ \exists u_2 [memory(u_2, \text{communicated(request_from_to_for}(A, B, IC)))]] \Rightarrow \\ state(\gamma, t') \models \forall u'' [present_time(u'') \rightarrow [\forall u_1 > u'' \\ [memory(u_1, \text{observed(provided_result_from_to}(E, B, IC))) \rightarrow \\ preparation_for(output(u_1 + c, \text{communicated(send_from_to}(B, A, IC))))]]] \\ \forall t', t \text{ state}(\gamma, t') \models \forall u'' [present_time(u'') \rightarrow [\forall u_1 > u'' \\ [memory(u_1, \text{observed(provided_result_from_to}(E, B, IC))) \rightarrow \\ preparation_for(output(u_1 + c, \text{communicated(send_from_to}(B, A, IC))))] \wedge \\ \wedge \forall u'' [present_time(u'') \rightarrow \\ memory(u'', \text{observed(provided_result_from_to}(E, B, IC)))] \wedge \\ stimulus_reaction(observed(provided_result_from_to}(E, B, IC)))]] \Rightarrow \\ state(\gamma, t', internal(B)) \models \forall u_1 [present_time(u_1) \rightarrow \\ preparation_for(output(u_1 + c, \text{communicated(send_from_to}(B, A, IC))))]] \\ \forall t' \text{ state}(\gamma, t') \models \\ [stimulus_reaction(observed(provided_result_from_to}(E, B, IC))) \wedge \\ not(preparation_for(output(t' + c, \text{communicated(send_from_to}(B, A, IC)))))] \Rightarrow \\ state(\gamma, t' + 1) \models \\ stimulus_reaction(observed(provided_result_from_to}(E, B, IC))) \\ \forall t' \text{ state}(\gamma, t', internal(B)) \models \\ [preparation_for(output(t' + c, \text{communicated(send_from_to}(B, A, IC)))) \wedge \\ not(output(\text{communicated(send_from_to}(B, A, IC))))] \Rightarrow \\ state(\gamma, t' + 1, internal(B)) \models \\ preparation_for(output(t' + c, \text{communicated(send_from_to}(B, A, IC)))) \end{aligned}$$

The auxiliary functions $stimulus_reaction(a)$ are used for reactivation of agent preparation states for generating recurring actions or communications.

Step 3. From preparation states to output states

The preparation state $preparation_for(output(t' + c, a))$ is followed by the output state, created at the time point $t_1 + c$. Rules that describe a transition from preparation to output state(s) are given in the executable theory from the preparation to the output state(s) $Th_{p \rightarrow o}$. For the considered example the following rule holds:

$$\begin{aligned} \forall t' \text{ state}(\gamma, t', internal(B)) \models \\ preparation_for(output(t' + c, \text{communicated(send_from_to}(B, A, IC)))) \Rightarrow \\ state(\gamma, t' + c, output(B)) \models output(\text{communicated(send_from_to}(B, A, IC))) \end{aligned}$$

Step 4. Constructing an executable specification

An executable specification $\pi(\gamma, t)$ for the component A is defined by a union of the dynamic properties from the executable theories $Th_{o \rightarrow m}$, $Th_{m \rightarrow p}$ and $Th_{p \rightarrow o}$, identified during the steps 1-3. For the purposes of analysis of component dynamics the non-executable external behavioral specification is replaced by the executable behavioral specification. The justification of such substitution is based on the theorem in [11].

At Step 5 an executable specification is constructed for the whole external behavioral specification of an agent.

Step 6. Translation of an executable specification into a description of a transition system

For the purpose of practical verification a behavioral specification based on executable temporal logical properties generated at Step 5 is translated into a finite state transition system model (a general procedure is described in [11]).

To translate the executable specification of agent behavior into the transition system representation the atom *present_time* is used. This atom is evaluated to *true* only in a state for the current time point. The executable properties from the executable specification, translated into the transition rules for the considered example are given below:

```

present_time(t) ∧ communicated(request_from_to_for(A,B,IC)) →
    memory(t,communicated(request_from_to_for(A,B,IC)))
present_time(t) ∧ observed(provided_result_from_to(E,B,IC)) →
    memory(t,observed(provided_result_from_to(E,B,IC)) ∧
        stimulus_reaction(observed(provided_result_from_to(E,B,IC))))
memory(t,communicated(request_from_to_for(A,B,IC))) →
    memory(t,communicated(request_from_to_for(A,B,IC)))
memory(t,observed(provided_result_from_to(E,B,IC)) →
    memory(t,observed(provided_result_from_to(E,B,IC)))
present_time(t) ∧
    ∃u2≤t memory(u2,communicated(request_from_to_for(A, B,IC))) →
        conditional_preparation_for(output(communicated(send_from_to(B,A,IC))))
present_time(t) ∧
    conditional_preparation_for(output(communicated(send_from_to(B,A,IC)))) ∧
    memory(t,observed(provided_result_from_to(E,B,IC))) ∧
    stimulus_reaction(observed(provided_result_from_to(E,B,IC))) →
        preparation_for(output(t+c,communicated(send_from_to(B,A,IC))))
present_time(t) ∧
    stimulus_reaction(observed(provided_result_from_to(E,B,IC))) ∧
    not(preparation_for(output(t+c,communicated(send_from_to(B,A,IC))))) →
        stimulus_reaction(observed(provided_result_from_to(E,B,IC)))
    preparation_for(output(t+c,communicated(send_from_to(B,A,IC)))) ∧
    not(output(communicated(send_from_to(B,A,IC)))) →
        preparation_for(output(t+c,communicated(send_from_to(B,A,IC)))) ∧
    present_time(t+c-1) →
        output(communicated(send_from_to(B,A,IC))).

```

For automatic verification of relationships between dynamic properties of different aggregation levels by means of the model checking tool SMV, the obtained finite state transition system is translated into the input format of the SMV model checker. For the description of the translation procedure and the complete SMV specification for the considered example we refer to [11].

One of the possible dynamic properties of the higher aggregation level that can be verified against the generated SMV specification is formulated and formalized in CTL as follows:

GP (Concluding effectiveness): If at some point in time environmental component E generates all the correct relevant information, then later agent C will receive a correct conclusion.

AG (E_output_observed_provide_result_from_to_E_A_info & E_output_observed_provide_result_from_to_E_B_info → **AF** input_C_communicated_send_from_to_A_C_info),

where **A** is a path quantifier defined in CTL, meaning “for all computational paths”, **G** and **F** are temporal quantifiers that correspond to “globally” and “eventually” respectively.

The automatic verification by the SMV model checker confirmed that this property holds with respect to the considered model of the multi-agent system as specified at the lower level.

4 DISCUSSION

The approach to analyzing behavior of a multi-agent system proposed in this paper is based on distinguishing dynamic properties of different aggregation levels and verifying interlevel relations between them using model checking techniques. To enable model checking an automated procedure has been developed, which allows transformation of a behavioral specification of a certain aggregation level first into an executable temporal specification, and subsequently into a description of a finite state transition system. Using this, model checking is performed in the environment SMV. The proposed approach has been evaluated by several case studies, in which verification of agent-based systems from natural domains has been performed.

Notice that an SMV-specification comprises constants, variables and state transition rules with limited expressiveness

(e.g., no quantifiers). Furthermore, for expressing one complex temporal relation a large quantity (including auxiliary) of transition rules is needed. Specification of multi-agent system behavior in the more expressive predicate-logic-based language TTL is much easier. TTL proposes an intuitive way of creating a specification of system dynamics, which still can be automatically translated into a state transition system description, as shown here.

The complexity of the representation of the obtained executable model is linear in size of the non-executable behavioral specification. More specifically, the non-executable specification is related to the SMV specification in the following linear way: (1) for every quantified variable from a non-executable specification a variable and an appropriate rule for its update are introduced; (2) for every nested quantifier an additional variable and an auxiliary executable rule are introduced, which establishes a relation between the quantified variables; (3) for every communicated and observed function from a past and a conditional formulae from dynamic properties, a corresponding memory state creation and a memory state persistence rule are introduced using the variables described in (1) and (2), and variables that correspond to external events; (4) for every non-executable dynamic property auxiliary variables φ_{mem} and φ_{prep} (i.e., the variables that indicate truth values of $\varphi_{mem}(\gamma, t)$ and $\varphi_{prep}(\gamma, t)$ respectively) and corresponding update rules are introduced; (5) for every action and communication specified in $\varphi_{bh}(\gamma, t)$ a variable and an appropriate update rule are introduced; (6) for reactivation of agent preparation states the auxiliary variables and the update rules corresponding to communicated and observed functions from $\varphi_{prep}(\gamma, t)$ are introduced. For verifying an executable model in the SMV OBDD-based symbolic model checking algorithms are used; the study of complexity of such algorithms is given in [9].

Flexible Provisioning of Service Workflows

Sebastian Stein and Nicholas R. Jennings and Terry R. Payne¹

Abstract. Service-oriented computing is a promising paradigm for highly distributed and complex computer systems. In such systems, services are offered by provider agents over a computer network and automatically discovered and provisioned by consumer agents that need particular resources or behaviours for their workflows. However, in open systems where there are significant degrees of uncertainty and dynamism, and where the agents are self-interested, the provisioning of these services needs to be performed in a more flexible way than has hitherto been considered. To this end, we devise a number of heuristics that vary provisioning according to the predicted performance of provider agents. We then empirically benchmark our algorithms and show that they lead to a 350% improvement in average utility, while successfully completing 5–6 times as many workflows as current approaches.

1 INTRODUCTION

Computer systems are becoming increasingly complex, distributed and open in nature. In so doing, they pose new challenges to contemporary software engineering techniques, as applications need to deal with many widely distributed and dynamic resources. In this context, service-oriented computing has gained popularity as an appropriate paradigm to build such systems [3]. In this approach, resources are offered as services, which are advertised to consumer applications using computer-readable descriptions and then provisioned dynamically when needed, often as part of complex workflows [2].

A defining feature of these distributed systems is that participants are usually heterogeneous, self-interested agents that act autonomously in accordance with their own private goals [4]. As such, agents choose actions that maximise their own welfare, and so they cannot be assumed to honour every request, to be available whenever they are needed or even to report their capabilities and status truthfully. Additionally, network problems, competition for resources or even software bugs exacerbate the potential for service failures. Thus, when interacting with service providing agents and making real investments that depend on their performance (whether in terms of money, time or other resources), dealing with service failures becomes a vital issue to consider.

Against this background, we believe that flexible service provisioning (i.e., selecting and allocating service providers to specific tasks) is the key to handling and controlling service failures. It allows the consumer to dynamically select service providers based on their performance characteristics and provision replacement providers when services fail. Specifically, provisioning services in the context of a workflow enables a consumer agent to identify particularly failure-prone tasks and invest additional resources in them. To date, however, this provisioning process has received comparatively little

attention. In particular, the fact that a type of service might be offered by multiple providers is seldom explored, and most research is concerned with finding and invoking the first matching service that helps fulfil a given goal [6]. Such a naïve approach means that a single service failure will result in the failure of the whole workflow, which is highly undesirable, especially when success is critical to the interests of the consumer agent.

When it has been considered, this problem is usually addressed reactively by dynamic replanning in case of failure [5], but this method is computationally expensive and can lead to long delays when there are particularly unreliable services. In [1], the authors take a more proactive approach by provisioning services that maximise an expected utility function. However, they again provision only single providers, which makes workflows vulnerable to service failures.

To address these shortcomings, we investigate the process of provisioning service workflows in environments where service success is not generally guaranteed. We show that the current approach of provisioning single providers is insufficient in such environments, and then advance the state of the art by developing several strategies that deal proactively with unreliable providers. This is achieved by provisioning several redundant service providers for a single task in order to reduce the associated failure probability, and by provisioning new providers to those tasks that appear to have failed. We also develop a novel heuristic that provisions workflows in a flexible manner depending on the characteristics of the service providers. Specifically, our heuristic provisions more providers to tasks that are particularly likely to fail, while relying on fewer providers when success is more certain. In order to verify our approach, we report our empirical results that show the value of flexible service provisioning over the naïve approach. In particular, we show that our heuristic successfully completes over 90% of its workflows in most environments where current approaches complete none. Furthermore, the results indicate that our heuristic achieves a 350% improvement in average utility over the naïve strategy.

The remainder of this paper is organised as follows. In the next section we present two simple provisioning strategies, followed by an extended strategy that provisions services in a flexible manner. In Section 3 we describe our experimental testbed and present empirical results for our strategies. Section 4 concludes.

2 PROVISIONING STRATEGIES

In this section, we outline the type of dynamism and uncertainty that service providers display in the complex systems we consider. This is followed by an overview of the kinds of workflows and associated rewards that service consumers typically face. We then present two strategies (*parallel* and *serial*) that provision providers redundantly, but in an inflexible manner, in order to increase their chance of success. Finally, we outline a flexible strategy that provisions providers depending on the agent's assessment of its situation.

¹ School of Electronics and Computer Science, University of Southampton, United Kingdom, {ss04r,nrj,trp}@ecs.soton.ac.uk

2.1 Modelling Service-Oriented Systems

As discussed in Section 1, the inherently uncertain behaviour of autonomous service providers can pose serious threats to the goals of a service consumer. Providers are generally not guaranteed to execute services successfully, and even when they do, the time of completion may be influenced by network traffic, other commitments the provider has made and the hardware a service is executed on. Hence, we model services probabilistically and we assume that some information has already been learnt about the performance characteristics of the service providers for a given task, including their average failure probability and a distribution function for the duration of a successful service execution.

In service-oriented systems, service consumers often face large workflows of inter-dependent tasks. For the purpose of this paper, we represent such workflows as directed, acyclic graphs with the nodes N being tasks and the edges E defining the dependencies between tasks (i.e., an edge $(t_1 \mapsto t_2)$ means that task t_1 has to complete successfully before t_2 can be started). A workflow is only considered complete when all its constituent tasks have been completed.

Furthermore, to evaluate our strategies, we define a utility function $u(t)$ to capture the value of finishing a workflow at time t . We chose to represent this by a maximum utility u_{\max} , awarded for completion, a deadline d , and a penalty charge p , to be deducted from the final utility for every time step a workflow is late. Formally, we write:

$$u(t) = \begin{cases} u_{\max} & \text{if } t \leq d \\ u_{\max} - p(t - d) & \text{if } t > d \text{ and } t < d + u_{\max}/p \\ 0 & \text{if } t \geq d + u_{\max}/p \end{cases} \quad (1)$$

As is common in contemporary frameworks [3], services in our model are invoked *on demand*. Specifically, a consumer requests the execution of a provisioned service when the associated task becomes available. At that time, the consumer incurs a cost (e.g., financial remuneration or communication cost), which is assumed uniform among the providers of a certain task. Thus, the overall profit of a workflow execution is the difference of the utility of finishing the workflow (or 0 if unsuccessful) and its total cost.

Having outlined our environment and basic assumptions, we now continue to develop several provisioning strategies. As discussed, the aim of these is to improve upon the currently predominant strategy of provisioning a single, randomly chosen service provider for each task in a workflow — a strategy that we refer to as the *naïve* strategy.

2.2 Parallel Service Provisioning

Recognising the ease of discovering substitute services in service-oriented systems, our first strategy uses redundant service provisioning to control the effect of unreliable providers. In general, if the success probability of a randomly chosen provider is S_1 , then provisioning n providers for a task results in a success probability S_n :

$$S_n = 1 - (1 - S_1)^n \quad (2)$$

When $S_1 > 0$, then $\lim_{n \rightarrow \infty} S_n = 1$, which implies that it is possible to increase the probability of success to an arbitrarily high amount as long as there are sufficient providers in the system. However, as more providers are provisioned, the total cost incurred rises linearly with n .

This result leads us to our first strategy, *parallel(n)*, which always provisions exactly n randomly chosen members of the set of available providers for a given task. The strategy *parallel(1)*, here, is a special case that is equivalent to the naïve strategy.

2.3 Serial Service Provisioning

An alternative approach to relying on parallel provisioning of providers to increase the probability of success, is to re-provision services when it becomes apparent that a particular provider has failed. In this case, the consumer first provisions a single provider and, after invocation, waits for some time. If the provider has not been successful, the consumer tries a different provider and so on. However, as providers cannot generally be assumed to notify the consumer of failure and because they have non-deterministic duration times, the consumer has to choose an appropriate waiting period. This period should give the provider a reasonable time to finish, but should not waste unnecessary time when the service has already failed².

With this in mind, let $T(w)$ be the probability that a randomly chosen service provider successfully completes within the waiting time w (note that $T(w) \leq S_1$). Then the success probability of serial provisioning with n available providers is:

$$T_n(w) = 1 - (1 - T(w))^n \quad (3)$$

This is usually less than the success probability of provisioning the same number of providers in parallel and the average time taken will also be higher for serial provisioning because of the additional waiting time that is introduced. On the other hand, the average cost drops, because costs are only incurred at the time of invocation.

This leads us to our second strategy, *serial(w)*, which always provisions exactly one randomly chosen member of the set of available providers. After a waiting period of w time units, if no success has been registered yet and if there are still more providers, the agent re-provisions a new, randomly chosen provider. A special case of this strategy, *serial(∞)*, is equivalent to the naïve strategy.

2.4 Flexible Service Provisioning

The strategies discussed so far provision services in an inflexible manner, as they always select the same number of providers for each task. This approach is insufficient in most scenarios, however, because some services may benefit from being provisioned redundantly, while others have a high degree of certainty and so need not be provisioned in this manner. Furthermore, it is not clear how to choose n and w in the above strategies so as to balance the associated cost and maximise the expected utility of a workflow, and it is desirable to automate this decision.

To address these shortcomings, in this section we develop a *flexible* strategy that combines the above two strategies, *parallel(n)* and *serial(w)*, by automatically finding values for the number of parallel invocations (n_i) and waiting time (w_i) for every task t_i in a given workflow. To focus on the basic problem, we assume that this allocation is made once and then used non-adaptively for the entire execution of the workflow³. We also assume that the consumer is risk-neutral — that is, we want our algorithm to choose values n_i and w_i in order to maximise the consumer's long-term expected profit.

Now, many optimisation approaches exist in the literature, but due to the complex nature of this particular problem, which includes the

² When re-provisioning services, we assume that all previously provisioned services are subsequently ignored (even if they had succeeded at a later time). This assumption draws a clear distinction between serial and parallel provisioning techniques, but does not fundamentally alter our results.

³ This simplifies the problem and helps us verify that our algorithm makes good initial predictions even without receiving ongoing feedback during a workflow. However, in future work we will use such information to update the agent's service provisions dynamically.

summation of random variables (the service durations), integer variables and a non-linear objective function, we have decided to use a local search technique that approximates the expected profit using a heuristic function, and searches for a good allocation rather than an optimal one.

Specifically, our local search algorithm begins with a random allocation and then applies steepest ascent hill climbing [7] to gradually improve the allocation until a maximum is found. The heuristic function we use is based on the utility function u and we use it to calculate the estimated profit \tilde{u} :

$$\tilde{u} = p \cdot u(\tilde{t}) - \bar{c} \quad (4)$$

where p is the probability of finishing all tasks at some point in time, \tilde{t} is the estimated completion time for the workflow, and \bar{c} is the expected cost.

In the following, we explain how p , \tilde{t} and \bar{c} are calculated, starting with appropriate calculations for each individual task in Section 2.4.1 and then extending this to the whole workflow in Section 2.4.2.

2.4.1 Local Task Calculations

We are interested in three performance measures for each task t_i in the workflow — the overall success probability of the task (s), its expected cost (\bar{c}) and its expected duration (\bar{d}). These are calculated using the information that the consumer has about each task and the relevant providers:

- p is the number of providers provisioned in parallel for the task.
- w is the waiting time before a new set of providers is provisioned.
- a is the number of available providers.
- f is the average failure probability of a provider.
- c is the cost of a provider.
- D is the cumulative density function for a single service duration.

First, we calculate the probability of success s as in equation 3, but noting that $T = (1 - f) \cdot D(w)$ and using the total number of available providers:

$$s = 1 - (1 - (1 - f) \cdot D(w))^a \quad (5)$$

In showing how to calculate the total cost, we assume that $a \bmod p = 0$ (i.e., that we can invoke up to $m = a/p$ sets of p providers with no remaining providers at the end⁴). Each invoked set of providers then has a probability of success $\hat{s} = 1 - (1 - (1 - f) \cdot D(w))^p$ and an associated cost cp . The consumer is guaranteed to pay cp at least once, and may pay again if the previous invocation was unsuccessful with probability $\hat{f} = (1 - \hat{s})$. Using this, and assuming that $\hat{f} < 1$, we can write the expected cost \bar{c} as:

$$\bar{c} = cp \sum_{k=0}^{m-1} \hat{f}^k = cp \frac{1 - \hat{f}^m}{1 - \hat{f}} \quad (6)$$

Using the same assumptions and treating the simpler case with $a \bmod p = 0$, we now investigate how to calculate the expected duration of a task, \bar{d} . We define this to be the mean time until the first provider carries out the task successfully, conditional on an overall success (i.e., at least one provider is successful).

First, we define μ to be the mean duration of a single successful invocation of p providers (also conditional on overall success). Then we follow a similar technique for calculating \bar{d} as we did for \bar{c} . We consider all possible outcomes for the invocation by calculating the expected duration when the task is completed after exactly k failed

⁴ Due to space restrictions in this paper, we omit the general case.

invocations as well as the associated probability. Then we multiply these durations with their probabilities and sum them to get the overall expected duration.

More formally, if a task succeeds after exactly k unsuccessful invocations, the expected duration, \bar{d}_k , is the expected duration for a single invocation added to k waiting time durations w for the previously failed invocations:

$$\bar{d}_k = \mu + kw \quad (7)$$

The probability of the task completing after the k th attempt is:

$$s_k = \hat{f}^k (1 - \hat{f}) \quad (8)$$

With this, we calculate the overall expected duration, conditional on at least one provider being successful (assuming $\hat{f} < 1$):

$$\begin{aligned} \bar{d} &= \frac{1}{s} \cdot \sum_{k=0}^{m-1} \bar{d}_k s_k \\ &= \frac{1}{s} \cdot \sum_{k=0}^{m-1} ((\mu + kw) \cdot \hat{f}^k (1 - \hat{f})) \\ &= \frac{1}{s} \cdot \left(\mu (1 - \hat{f}^m) + w \frac{\hat{f} - m\hat{f}^m + (m-1)\hat{f}^{m+1}}{1 - \hat{f}} \right) \end{aligned} \quad (9)$$

We have now shown how to calculate various performance characteristics of a single task. In the following section, we explain how this is extended to calculate the overall heuristic function for an allocation over the whole workflow.

2.4.2 Global Workflow Calculations

Let s_i , \bar{c}_i and \bar{d}_i be the success probability, the expected cost and the expected duration of task t_i . With this information for each task, we are now interested in calculating the overall probability of success s , the estimated completion time of the workflow \tilde{t} and the total expected cost \bar{c} .

The overall probability of success is simply the product of all s_i :

$$s = \prod_{\{i | t_i \in N\}} s_i \quad (10)$$

The expected total cost is the sum of all task costs, each multiplied by the respective success probabilities of their predecessors in the workflow (where r_i is the probability that task t_i is ever reached):

$$\bar{c} = \sum_{\{i | t_i \in N\}} r_i c_i \quad (11)$$

$$r_i = \begin{cases} 1 & \text{if } \forall t_j \cdot ((t_j \mapsto t_i) \notin E) \\ \frac{1}{\prod_{\{j | (t_j \mapsto t_i) \in E\}} s_j} & \text{otherwise} \end{cases} \quad (12)$$

Finally, we approximate the overall time \tilde{t} using the length of the critical path in the workflow. This is the length of the longest path from any node with no predecessors to any node with no successors, using the expected durations \bar{d}_i as weights attached to the nodes. Such an approach will normally underestimate the true expected duration, because it focusses only on one path, ignoring the possibility that other services outside this path may take longer. However, it provides a fast approximation and has been used widely in project management and operations research [8]. Formally, we let $P = \{t_i \mid t_i \text{ is on the critical path}\}$. This gives us:

$$\tilde{t} = \sum_{\{i | t_i \in P\}} \bar{d}_i \quad (13)$$

Using these values and the heuristic function given in equation 4, it is now possible to use steepest ascent hill-climbing to find a good allocation of providers. In practice, we found it useful to perform this in two iterations — once using a modified utility function \tilde{u} , which is a linear version of u , giving a higher reward than usual for finishing early and a larger loss for finishing late, and then again using the normal utility function u . This approach allows the algorithm to escape from a common local maximum where the agent decides to concede, allocate minimal resources to the tasks and hence incur a low net loss, but also a very low probability of success. Furthermore, we could generally increase performance by adding a constant amount of extra time to \tilde{t} to account for the error in the prediction. In all our experiments we set this to 20% of the workflow deadline, as this produces good results in a variety of experimental settings.

3 EMPIRICAL EVALUATION

As stated in Section 1, the aim of our work is to deal effectively with unreliable service providers when provisioning workflows. To this end, in this section we empirically compare our proposed strategies to the currently predominant naïve approach. In particular, we investigate the average utility gained by all strategies, as well as the average proportion of successfully completed workflows. In the remainder of this section, we describe our experimental testbed and methodology, followed by the results.

3.1 Experimental Testbed

In order to analyse our strategies empirically, we developed a simulation of a simple service-oriented system. In this simulation, we generate large numbers of random workflows and measure the performance of our strategies by recording the percentage of workflows that failed (where t time steps had elapsed, so that $u(t) \leq 0$) and succeeded (where all tasks were completed within t time steps, so that $u(t) > 0$). We also measure the average profit of a single service consuming agent.

Our simulation is discrete, notifying the consumer of any successful service execution once every integer time step, at which point new services are also invoked according to the consumer's provisioning strategy. While the consumer is notified in case of service failure, no information is given when a provider fails.

To simplify the analysis and because our approach does not deal directly with differentiating between individual providers at this time, we examined environments with homogeneous service providers (i.e., all providers share the same success probability and duration distributions).

For the data presented in this section, we used workflows consisting of 10 tasks in a strict series (i.e., without parallel tasks, because this allowed us to verify some results analytically), we assumed that there were 1,000 providers for every task with each provider having a cost of 10 and a gamma distribution with shape $k = 2$ and scale $\theta = 10$ as the probability distribution of the service duration. We set a deadline of 400 time units for the workflow, an associated maximum utility of 1,000 and a penalty of 10 per time unit. We also performed similar experiments in a variety of environments, including heterogeneous and parallel tasks, and observed the same broad trends that are presented in the following section.

To prove the statistical significance of our results, we averaged data over 1,000 test runs and performed an analysis of variance

(ANOVA) where appropriate to test whether the strategies we tested produced significantly different results. When this was the case, we carried out pairwise comparisons using the least significant difference (LSD) test. Thus all results reported in this paper are statistically significant ($p = 0.001$).

3.2 Experimental Results

In our first experiment, we compared the performance of strategy $\text{parallel}(n)$ ⁵ with the naïve approach in environments where service providers have a varying probability of failure (see Figure 1). From this, it is clear that there is a considerable difference in performance between the different strategies — the average profit gained by the naïve strategy falls dramatically as soon as failures are introduced into the system. In this case, the average utility of provisioning single providers falls to below 0 when the failure probability of providers is only 0.3. A statistical analysis reveals that the naïve strategy dominates the other two when there is no uncertainty in the system. However, as soon as the failure probability is raised to 0.1, $\text{parallel}(2)$ begins to dominate the other strategies. Between 0.3 and 0.6 $\text{parallel}(6)$ then becomes the dominant strategy as increased service redundancy leads to a higher probability of success. Above this, the parallel strategies do not yield better results than the naïve strategy as they also begin to fail in most cases.

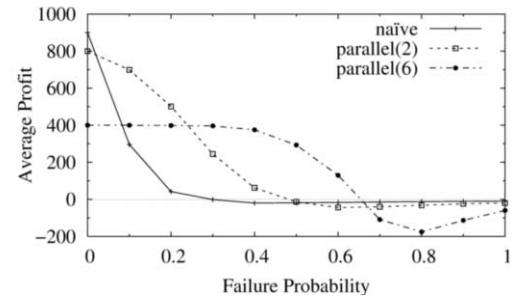

Figure 1. Effect of provisioning different numbers of providers in parallel

Summarising these trends, it is obvious that redundant provisioning yields a considerable improvement over the naïve approach in a range of environments. For example, when the failure probability is 0.2, provisioning two providers results in an almost 1,100% improvement in average profit over the naïve strategy. However, no redundant strategy dominates the other and both eventually make losses when the probability of failure increases to such an extent that the chosen redundancy levels do not suffice to ensure success.

We carried out a similar experiment to verify the advantage of serial provisioning over the naïve strategy (see Figure 2). Here, again, there is a marked improvement over the naïve strategy for failure probabilities up to and including 0.5. This improvement is due to the fact that serial provisioning responds to failures as they occur, while only paying for additional services when necessary. However, as the failure probability rises, this strategy begins to miss its deadlines and hence incurs increasingly large losses.

Finally, to show how the *flexible* strategy compares against the naïve provisioning approach and inflexible redundancy, Figure 3 shows our experimental data (again, using the same experimental variables). The top graph shows the percentage of workflows that

⁵ Here, we arbitrarily chose $n = 2$ and $n = 6$ as representative of the general trends displayed by the strategy as more providers are provisioned.

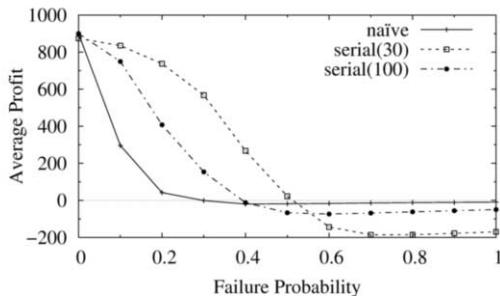

Figure 2. Effect of different amounts of waiting times for re-provisioning

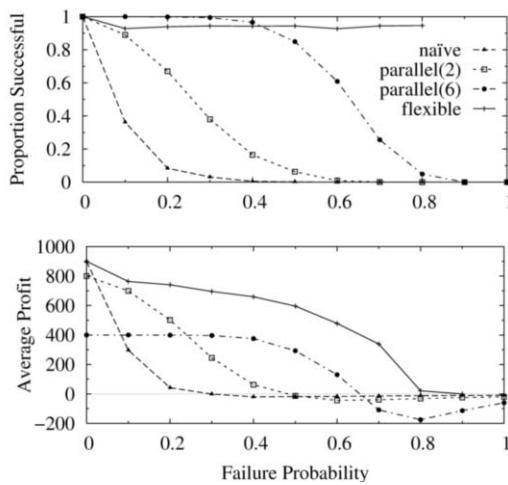

Figure 3. Performance of flexible strategy

succeeded out of all the ones generated. Here, we see that our heuristic approach initially performs slightly worse than *parallel(6)* (but always significantly better than the naïve approach). This is due to our technique of using the critical path of the workflow as an estimate for the total time taken. This technique is usually too optimistic and might result in under-provisioned tasks. However, the graph clearly shows that the flexible technique still achieves a success-rate of over 90% and, more importantly, maintains this up to a failure probability of 0.8, by which all other approaches have large failure rates. When 0.9 is reached, the strategy begins to ignore all workflows, because it cannot find a feasible allocation to offer a positive return. On the lower graph, we show the average utility that is gained by the same strategies. Here, it is clear that the flexible approach performs better than any of the other strategies. This is due to its utility prediction mechanism and the fact that it can make choices separately for the various tasks in the workflow. This flexibility allows the strategy to provision more providers for latter parts of the workflow, where success becomes more critical as a higher investment has already been made. The flexible approach also combines the benefits of the other strategies, allowing the agent to choose between parallel (e.g., when there is little time) and serial provisioning (e.g., when the agent can afford the extra waiting time) or a mixture of the two. Although performance degrades as providers become more failure-prone, flexible provisioning retains a relatively high average utility when all other strategies start to make a loss. Furthermore, the strategy avoids making a loss due to its prediction mechanism, which ignores a workflow when it seems infeasible.

To conclude, Table 1 summarises the performance of some rep-

Table 1. Summary of results with 95% confidence intervals

Strategy	Mean profit	Profit vs naïve	Success rate
naïve	103.09 ± 5.30	1	0.13 ± 0.01
parallel(6)	175.87 ± 5.79	1.71 ± 0.20	0.61 ± 0.01
serial(30)	221.91 ± 7.92	2.15 ± 0.26	0.44 ± 0.01
flexible	471.99 ± 8.71	4.58 ± 0.49	0.77 ± 0.01

resentative strategies, averaged over all environments that we tested (using the same data as in Figures 1–3). These results highlight the benefits of our strategies, and show that our flexible strategy by far outperforms the naïve approach. In particular, we achieve an improvement of approximately 350% in mean profit and successfully complete 76–78% of all workflows.

4 CONCLUSIONS

In this paper, we addressed the problem of dealing with unreliable service providers in complex systems. To this end, we developed a novel algorithm for provisioning workflows in a flexible manner and showed that this algorithm achieves a high success probability in uncertain environments and that it outperforms the current, naïve strategy of provisioning single providers. This work is particularly relevant for distributed applications where several services are composed by a consumer agent, and where these services are offered by autonomous agents whose success cannot be guaranteed. Important application domains for our approach include scientific data processing workflows and distributed business applications, where services are sourced from across departments or organisations.

In future work, we plan to extend our approach to cover more heterogeneous environments, where service providers differ significantly in terms of cost and reliability within the same service type and where such qualities are affected dynamically by system-wide competition and resource availability. Furthermore, we plan to examine in more detail the computational cost of provisioning and how this can be balanced in a flexible manner with the need to make quick decisions in dynamic environments.

Heuristic Bidding Strategies for Multiple Heterogeneous Auctions

David C. K. Yuen,¹ Andrew Byde,² Nicholas R. Jennings¹

Abstract. This paper investigates utility maximising bidding heuristics for agents that participate in multiple heterogeneous auctions, in which the auction format and the starting and closing times can be different. Our strategy allows an agent to procure one or more items and to participate in any number of auctions. For this case, forming an optimal bidding strategy by global utility maximisation is computationally intractable, and so we develop two-stage heuristics that first provide reasonable bidding thresholds with simple strategies before deciding which auctions to participate in. The proposed approach leads to an average gain of at least 24% in agent utility over commonly used benchmarks.

1 Introduction

The growing number of online auction sites liberates individual shoppers from searching only within their surrounding community. Moreover, if the item is popular, it is not uncommon to find hundreds of auctions offering the same good³. However, it can be difficult for a human to keep track of more than a few auctions. But, *global bidders* that can accept information and participate in a large number of auctions are likely to receive extra benefit when compared with bidders that only operate locally in one auction [8]. When all of these factors are taken together, it is apparent that there is a growing need to develop autonomous agent bidding strategies that can operate over multiple auctions.

To this end, we seek to devise a best response bidding strategy for global bidders participating in multiple auctions. Each such bidder may have a demand for one or more units of identical private-value goods. Our primary interest is in multiple heterogeneous auctions, because it is the most prevalent case in practice, in which the auction format and the starting and closing times can be different. We assume each seller auctions one item and these items are perfect substitutes. Due to its complex nature, most analytical studies of heterogeneous multiple auctions are based on the simplified case of homogeneous auction types that either operate sequentially [9] or completely in parallel [8]. For our more general setting, heuristic approaches are the norm [1, 2, 3, 4, 5] and are the approach we adopt here.

Now, to develop a bidding strategy that maximises the expected utility, it is theoretically possible to model the multiple auctions as a Markov Decision Process (MDP) and calculate the expected utility by backward induction [2, 3]. The utility evaluation can be simplified by adopting pessimistic estimation [4], in which an agent sets its bids using no information on the ordering of the future auctions. However, issues associated with computational intractability limit these approaches to only a low number of auctions. In contrast, Anthony *et al.* [1] devised a heuristic bidding strategy that combines the effects of the desire to obtain a bargain, the deadline and the desperation for obtaining an item into a single formula. However, their bidding tactic ignores the fact that some of the remaining auctions can be more favourable to the global agent (e.g. have fewer local bidders). Relatedly, the bidding strategy developed by Dumas *et al.* [5] consists of a probabilistic bid learning and planning stage. However, their algorithm considers simultaneous auctions as incompatible and would bid in only one of them.

Against this background, this paper develops a two-stage heuristic approach to approximate the best response bidding strategy for a global bidder. In the first stage, a threshold heuristic is employed to compute a maximum bid or threshold for each auction. Then in the second stage, the agent decides whether it should participate in each of the available auctions using an auction selection heuristic that exploits the bidding thresholds calculated from the first stage. A number of threshold and auction selection heuristics are developed under this flexible framework. In developing these heuristics, this work advances the state of art in a number of ways. First, we devise several two-stage heuristics that enable the agent to improve its utility further by bidding in more auctions than its demand. This tactic requires the agent to manage the excess procurement risk carefully and is an area ignored by previous bidding heuristics other than those using MDPs or exhaustive search approaches. Second, we provide a pseudo-polynomial time auction selection heuristic that closely approximates the near optimal solutions of an exponential time exhaustive search algorithm from the literature [4]. Third, we extend the use of equal bidding thresholds to maximise the agent utility from complementary goods [8] to our perfect substitute setting and verify that the agent's utility received is very close to the global maximum (at least for simultaneous second-price auctions).

The paper is structured as follows. Section 2 details the heuristics applied to set the threshold and select the auctions to participate in. Section 3 empirically evaluates the strate-

³ To illustrate the scale of this problem, within eBay alone, more than a thousand auctions were selling Apple's 4GB iPod mini at the time of writing.

gies and compares them with other heuristics proposed in the literature. Section 4 concludes.

2 The Multiple Auction Bidding Strategy

Before detailing the bidding heuristics, we formalise the multiple auction setting being studied. Here an auction a can be characterised by a tuple $(t^s(a), t^c(a), N(a), \theta(a))$ consisting of the starting time, closing time, number of local bidders and auction format for auction a . Notice that since $N(a)$ is the number of *local* bidders in an auction; the total number (including the agent itself) is $N(a) + 1$. The auction format can be one of the standard four single-sided types, English, Dutch, first-price (FPSB) or second-price sealed bid (SPSB), denoted as {ENG, DUT, FPSB, SPSB}. We introduce the degree of overlap $\lambda \in [0, 1]$:

$$\begin{aligned} \text{time with at least } 1 \text{ running auction: } T_{occ} &= |\{t \in \mathbb{N} | \exists a : t^s(a) \leq t < t^c(a)\}| \\ \text{degree of overlap: } \lambda &= \frac{\sum_a (t^c(a) - t_s(a)) - T_{occ}}{T_{occ} (M - 1)} \end{aligned}$$

to characterise a set of M auctions by the starting and closing times. Purely sequential and purely simultaneous auctions are the two extreme cases with $\lambda = 0$ and 1 respectively.

The agent's valuation V for obtaining multiple items is linear with random coefficient v per item up to a maximum of k items: the agent derives value $V(x) = v \min(k, x)$ from x items, and the utility of the agent for obtaining x items at cost Π is quasi-linear: $U(x, \Pi) = V(x) - \Pi$.

We assume that all bidders have identically distributed independent item-valuations v with distribution $F(x) = \text{Prob}(v \leq x)$, $f(x) = F'(x)$. We will use the uniform distribution in $[0, 1]$ as an example throughout the text, but the heuristics themselves are equally applicable to other distributions unless specified otherwise. For a set of M auctions, our goal is to devise a bidding strategy $b = (b_1, b_2, \dots, b_M)$ where b_a gives the threshold (i.e. the maximum bid that should be placed) for auction a . In sealed bid auctions, the threshold is the bid placed, in Dutch auctions, the agent bids when the current price falls the threshold, and in English auctions, the agent bids until the current price reaches the threshold. The threshold is set to zero if the auction selection heuristic indicates that the agent should not participate in that auction.

At any point in time, the bidding strategy considers the subset of auctions A^{av} that is *available*. An auction is *unavailable* if it is either closed or is of type ENG and the current price is already higher than the agent's threshold. We use $M^{av} = |A^{av}|$ for the number of available auctions. The agent is expected to keep track of the number of acquired items. At time T , the agent has an extra capacity of k_T items = $k - x_T$ where x_T is the number of items already acquired.

2.1 The Threshold Heuristics

The threshold set required by the auction selection stage is generated using one of the heuristics developed in this section. In all cases, the setting of the threshold is affected by the differences between individual auctions (e.g. the number of bidders and the auction format) and by the availability of the item in future auctions. Since we want to identify the most influential factors to the received utility, each of our heuristics examines only a subset of the above factors. Specifically, we

develop two heuristics. The *single auction dominant* heuristic assigns different thresholds according to the auction format and the number of bidders in each auction. The *equal threshold* heuristic assigns the same threshold to every auction and adjusts this according to the availability of the item in future auctions. Some heuristics in the literature have also examined the bidding history [5] and user preferences [1] when adjusting the bidding level. But, with our modular two-stage heuristic design, these external factors can easily be included later by extending or replacing the existing heuristics.

2.1.1 The Single Auction Dominant Heuristic

This heuristic sets a different threshold for each of the auctions according to the auction format and the number of bidders. Specifically, the threshold is assigned as if it were the only auction available and the agent had valuation v for a single item. We choose the single auction dominant bidding heuristic not only because its analytical solution is well known [7], but also because of its ability to adjust the bid for different auction types and numbers of bidders with little computational overhead. The threshold is the same as the true value for second price mechanisms (ENG, SPSB) and for the first price mechanisms (DUT, FPSB), it becomes [7]:

$$b_a = v - F^{-N(a)}(v) \int_0^v F^{N(a)}(x) dx$$

which is $v N(a)/(N(a)+1)$ if the private values of the bidders follow a uniform distribution.

2.1.2 The Equal Threshold Heuristic

This heuristic sets a single threshold, b_{eq} , for all auctions. This choice is justified because the global bidder's utility in multiple auctions selling complementary goods can be maximised with equal-bid pairs [8] and our brute-force best bidding strategy search upon simultaneous auctions with unit agent demand ($k = 1$) seems to suggest that placing equal bids is also suitable for our perfect substitute setting⁴.

Our goal is to find the equal bid threshold that approximately maximises expected utility:

$$\begin{aligned} E(U|b) &= E(V|b) - E(\Pi|b) \\ &= vE(\min(k, X)|b) - \sum_{a \in A^{av}} E(\Pi(a)|b) \end{aligned} \quad (1)$$

To do this, we adopt a procedure that estimates the likely number of units won (X) and the likely payments (Π) separately. Now, the expected payment $E(\Pi|b)$ is the sum of payments for each auction and the expected payment $\Pi(a)$ in a particular auction a from using threshold $b(a)$ is:

$$E(\Pi(a)|b(a)) = \int_0^{b(a)} y F^{N(a)-1}(y) f(y) dy \quad (2)$$

For valuations v that are uniformly distributed in $[0, 1]$ this gives an expected payment of $N(a) b^{N(a)+1}/(N(a) + 1)$. However, the valuation term is non-linear with respect to the number of units won, and so the situation is more complicated.

⁴ It should be noted that the optimality of equal bids is not universal even for simultaneous SPSB auctions with identical bidder distributions. For example, in the extreme case in which the valuation approaches the upper range, it is best to bid one's true value for k requested items and zero for the rest.

Thus to estimate the number of units the agent might win by using a particular bid threshold, we replace the available current and future auctions with simultaneous SPSB auctions. We believe this is a reasonable assumption for two reasons. First, the expected revenue of second-price auctions is only slightly lower than those of first-price ones. Second, unlike currently running English (or Dutch) auctions in which we know the closing price must be larger (or smaller for Dutch) than the current price, we do not have such information regarding future auctions. So, in terms of information availability, it resembles the situations in simultaneous sealed bid auctions.

Now, to measure the number of bidders \bar{N} in the set of available auctions A^{av} we use the harmonic mean $\frac{1}{\bar{N}} = \frac{1}{M^{av}} \sum_{a \in A^{av}} \frac{1}{N(a)}$ because the agent is less likely to win in auctions with many bidders and so should give less weight to their consideration.

In so doing, we assume that the events of winning each auction are independent and identically distributed, so that the number of items the agent will win has a binomial distribution. The probability of an agent with threshold b winning in any second-price auction with n other local bidders (who will bid their valuation) is $p(b) = F^n(b)$. The probability of winning x items out of M^{av} auctions is:

$$\text{Prob}(X = x|b) = \binom{M^{av}}{x} p(b)^x (1 - p(b))^{M^{av}-x}$$

Combining this with:

$$E(\min(k, X)|b) = \sum_{x \leq k} x \text{Prob}(X = x|b) + k \text{Prob}(X > k|b)$$

allows us to estimate the value term in (1).

Since the agent is not compensated for any extra units acquired, its utility drops rapidly if the purchase quota is exceeded accidentally. However, to identify the equal threshold b_{eq} that approximates the maximum utility, a simple one dimensional *golden section search* [10] is sufficient because the utility curve has only a single maximum.

2.2 The Auction Selection Heuristics

The auction selection heuristics determine which available auctions the agent should participate in, on the basis of the collection of bidding thresholds calculated using a threshold heuristic. With our flexible architecture, it is possible to introduce heuristics that satisfy different user preferences [1] at a later stage. But for now, we intend to develop heuristics that approximate well to the global utility maximum, which is the goal for most users. Specifically, we describe two such heuristics: an *exhaustive search* heuristic inspired by [4], and a much more computationally tractable *knapsack utility approximation* heuristic.

2.2.1 Exhaustive Search Selection

Byde et al. [4] describe an exhaustive search procedure for bid decision making. Their algorithm subsumes the selection of auctions into the choice of thresholds: ideally all tuples of thresholds would be tested, which includes the “trivial” zero thresholds that are equivalent to not participating in an auction at all. In our context, where thresholds are determined by a separate process, exhaustive search consists of testing

almost all subsets of available auctions. Nevertheless, some heuristic properties of different auction formats are exploited to prune the search space. For example, in English auctions, we assume that an agent prefers to bid in auction a_1 if its current price is lower than that of a_2 while the expected chance of winning is higher. In sealed bid auctions, the agent refrains from submitting a bid until the deadline is imminent so that it can learn from more auctions before making a decision.

The expected value $E(V|S, b)$ of bidding only in a set of auctions S is calculated using the sum over all possible sets $W \subseteq S$ of auctions that might be won:

$$E(V(X)|S, b) = \sum_{W \subseteq S} \left(V(|W|) \prod_{a \in W} p_a(b(a)) \prod_{a \notin W} (1 - p_a(b(a))) \right) \quad (3)$$

where $p_a(b(a))$ is the probability of winning auction a given threshold $b(a)$. Expected payments are given by (2) as above.

Clearly this heuristic is expensive to calculate both because of the exhaustive search over the set of auctions S in which to bid, and because of the exponential complexity of (3).

2.2.2 Knapsack Utility Approximation

The development of this heuristic is inspired by our observation that the utility is non-linear with respect to the number of wins. Specifically, each additional acquired item provides extra utility until the maximum demand k is reached. Beyond that point, each additional item incurs a large marginal loss because the agent does not receive any extra compensation for the increased payment. Now, since the number of wins is a random variable and the utility plummets if the agent acquires more than k items, it is crucial to carefully control the risk of exceeding the demand limit. Given this, the rationale for the heuristic proposed is to identify a subset of available auctions that minimises the expected payment (i.e. locally maximises the utility), while maintaining the expected number of wins within a certain safe level. The knapsack algorithm was chosen because its solution can be approximated in pseudo-polynomial time by dynamic programming [6].

In more detail, the heuristic works as follows. First, the agent (re)-evaluates its capacity for extra items. For planning purposes, the extra capacity $\hat{k}_T = k_T - H$ should be reduced by the number of holding auctions H . A holding auction is any sealed bid auction that the agent has submitted a bid to and has yet to receive the results or any English auction in which it is currently leading. The intuition here is that the agent has a chance to win once it holds a bid in an auction. Therefore, it should temporarily reduce the demand limit to prevent accidentally exceeding its purchase quota. Second, by making a similar argument to that of Section 2.1.2 when we simplified the auction setting, we model the multiple auctions as if they are all SPSB and run simultaneously. Given this, the threshold set generated by the threshold heuristics is converted into a M^{av} -tuple $b = (b(a_1), b(a_2), \dots, b(a_{M^{av}}))$ with its first element corresponding to the threshold of the auction with the least number of bidders, and so on. If the agent selects n auctions to participate in, it will submit n non-zero bids out of a choice of M^{av} assuming the agent has a preference for auctions with fewer bidders. The expected utility is calculated for $k \leq n \leq M^{av}$. The number of auctions to participate in,

n_{opt} , that gives the highest expected utility is then identified:

$$b_n = (\underbrace{b(a_1), b(a_2), \dots, b(a_n)}_n, \underbrace{0, \dots, 0}_{M^{av} - n})$$

$$n_{opt} = \arg \max_{n \geq k_T} E(U|b_n) \quad (4)$$

Now, the agent could just decide to participate in the n_{opt} auctions with the least number of bidders. However, this is not likely to be a good enough strategy because the simplified model ignores the differences between auction formats and discards a lot of useful information obtained after the auction starts (such as the current price of the English and Dutch auctions). On the other hand, with the exception of the case when M is small, it is impractical to calculate the exact utility as it requires the probability calculation to be repeated for each of the 2^M possible winning combinations. In contrast, if we assume the outcomes of the auctions are independent, the expected number of wins can easily be calculated as the sum of the winning probabilities of the individual auctions. By maintaining the expected number of wins at a sufficiently low level, we can mitigate the risk of accidentally purchasing too many items even if we place more than k_T bids.

We now turn to the issue of finding the optimal expected number of wins. Assuming the agent bids in n_{opt} auctions with threshold $b_{opt} = (b(a_1), b(a_2), \dots, b(a_{n_{opt}}), 0, \dots, 0)$, the expected number of wins that gives highest utility⁵ can be calculated as:

$$\hat{x}_{opt} = E(X|b_{opt}) = \sum_{i=1}^{n_{opt}} p_a(b(a_i)) + x_T$$

Finally, we can apply a knapsack algorithm to find the combination of auctions that minimises the payment, while keeping the predicted number of winning items less than or equal to the optimal number of winning items \hat{x}_{opt} . Generally speaking, the goal of the knapsack algorithm is to maximise the combined value of items packed into a bag, providing the size constraint has not been violated. Here the optimal winning number \hat{x}_{opt} is taken as the weight constraint and each auction in the subset A^{av} is a candidate item available for selection. For auction a , the weight is the chance of winning $p_a(b_a)$ if bidding with the threshold $b(a)$ found by the heuristics in Section 2.1. The value for participating in auction a is defined as minus the expected payment, so that maximising value minimises payment. The knapsack algorithm sets the bidding thresholds to zero to indicate the auctions that the agent should not participate in. The best selection of auctions to participate in is re-evaluated at each time step.

The expected payment is given by (2), but, for current English (or Dutch) auctions, the expected payment is set to the current price x_t plus (or minus for Dutch auction) the minimum bid increment. It is because the current price update at each round presents a prime opportunity for the agent to hunt for bargains. For example, if there is a more favourable auction later in which the agent is planning to bid up to $b(L)$ with an expected payment of $\pi(L)$, there is no harm in bidding lower than $b(L)$ for the current English or Dutch auction. It may get an even better deal by chance.

⁵ It is important to note that the expected number of wins $E(X)$ is different from the upper demand limit k . For example, the expected number of wins can be much smaller than the upper demand limit if the buyer has a low valuation.

3 Empirical Evaluation

This section evaluates the heuristics we have devised. We have introduced two threshold heuristics – single auction dominant (DOM) and equal threshold (EQT), and two auction selection heuristics – exhaustive search selection (ES) and knapsack utility approximation (KS). In particular, we are interested in evaluating how the combined heuristics (DOM-ES, DOM-KS, EQT-ES, EQT-KS) perform. As benchmark, we use a random strategy (RND) that chooses k auctions at the start then bids locally in them and a greedy strategy (GRD) that participates in the k_T auctions with the least number of bidders at time T . Both RND and GRD place bids following the dominant strategy for a single auction. In our experiment, we consider two scenarios: (1) simultaneous SPSB auctions, (2) unrestricted settings, in which the number of bidders, the auction types, and the starting and closing times are all randomised. The first scenario is considered because simultaneous SPSB auctions require only one round of decision. Thus this simplified setting allows us to search for the optimal bidding strategy using a global maximisation technique⁶ and compare that with our heuristics. The second scenario is actually our focus because it is the one that most closely represents reality.

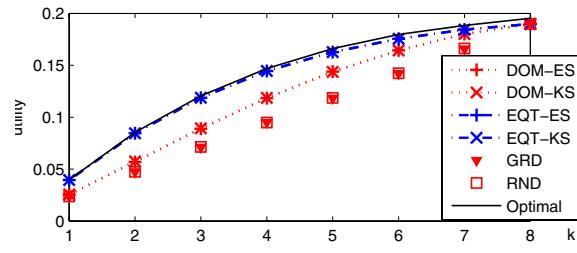

Figure 1. Agent utility for simultaneous SPSB auctions ($M = 8, N = 5$).

The first environment evaluates the agent utility for a set of 8 simultaneous SPSB auctions. Specifically, Figure 1 shows the average utility as agent demand k varies from 1 to 8. As can be seen, the combined heuristics using EQT (EQT-ES and EQT-KS) perform better than those using DOM and are within 3% of the optimal. Now, the DOM heuristic adjusts the bidding level in accordance to factors affecting each single auction (i.e. number of bidders and auction format), whereas EQT considers the future item availability from all the remaining auctions. Thus the latter effect dominates, especially for larger M , and so explains the observed improvement when using EQT. Although DOM is less successful, by using our ES or KS decision heuristics, 15-25% of the utility loss can still be recovered when compared with either GRD or RND heuristics.

The second scenario evaluates the unrestricted setting. We examine the received agent utility for the various heuristics with $M = 12$ and $k = 3$. For our results to generalise well to practical scenarios, M should be as large as possible. However, as we shall see later (see Figure 3), ES rapidly becomes computationally intractable as M increases; thus we set $M = 12$ as a compromise value that has a reasonable number of auctions but that is still tractable for ES. According to the ANOVA 2-factor test, all of our heuristics (DOM-KS, DOM-ES, EQT-KS,

⁶ Simulated annealing is applied as a global maximisation technique to identify the best bids. However, since it requires up to 1000 seconds to run even for this simplified setting, it is not a practical solution to our problem.

EQT-ES) are significantly better than the benchmark heuristics⁷. Amongst our heuristics, DOM-ES is significantly better than DOM-KS, whereas EQT-ES performs similarly to EQT-KS⁸. On average, our best strategies (EQT-KS, EQT-ES) improve the agent utility by 24% and 27% when compared with the GRD benchmark.

In more detail, the set of auctions can be characterised by the degree of overlap λ and the percentage that are sealed-bid (%SB). To assess how these factors affect our heuristics, the auction sets are classified into one of the four categories, C1 – C4⁹, in terms λ and %SB. The agent utility follows the order of EQT-ES \geq EQT-KS \geq DOM-KS \geq DOM-ES $>$ GRD $>$ RND and the ranking is the same for each of the four categories.

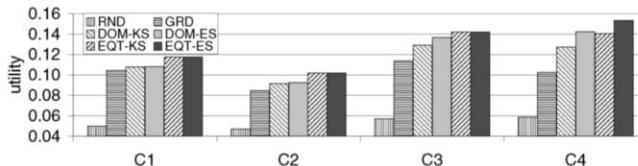

Figure 2. Agent utility for unrestricted auction setting.
($M = 12, k = 3, N = [5, 10]$ uniformly distributed)

In addition, our heuristics compare increasingly favourably¹⁰ to the GRD/RND benchmarks when $\lambda \geq 0.5$ and/or %SB < 0.5 . This is because many auctions are started or closed at about the same time if λ is large. Thus an agent can hunt for bargains by bidding in many auctions, while not taking too large a risk of accidentally purchasing too many items. When the percentage of English and Dutch auctions is high (i.e. when %SB is low), the agent receives more information in the bidding process. In short, both the careful management of excess procurement risk and improved utilisation of available information require much intelligence, and, thus, the more sophisticated heuristics are beneficial.

The DOM and EQT threshold heuristics require comparatively little computation because they adopt a simplified auction setting. However, the time taken to evaluate the more complex auction selection heuristics is an important practical consideration, especially when many decisions have to be made at the same time (which often occurs near the closing time of a set of simultaneous auctions). To this end, Figure 3 shows the average computation time for the heuristics when running on a modern PC. The ES heuristic is known to have exponential time complexity and it fails to keep up with practical requirements when M is larger than about 12. In contrast, the KS heuristic has been shown to remain acceptable for M up to at least 200 auctions with its pseudo-polynomial time complexity.

To summarise our results, the agent's utility is affected strongly by the threshold heuristic and EQT is the preferred

choice because it is better than DOM for each of the four categories of multiple auctions examined in the second scenario. For the auction selection heuristic, the computation time is an extra factor to consider in addition to the received agent utility. Here the ES heuristic can tolerate bad selection of bidding thresholds and its use should be considered if its computation time is deemed acceptable. But for a larger number of auctions ($M > 12$) the KS heuristic is more suitable because the sacrifice in performance when compared with ES is small (DOM-KS) or in some cases insignificant (EQT-KS).

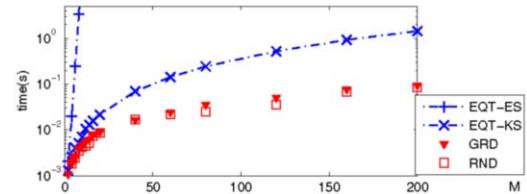

Figure 3. Average computation time for different heuristics.

4 Conclusions

This paper has developed and evaluated a novel two-stage heuristic as a bidding strategy for multiple heterogeneous auctions. In the first phase, a set of bidding thresholds is generated by the threshold heuristics, before a more sophisticated decision heuristic is applied to decide which subset of auctions to participate in. Our empirical evaluation shows that EQT is a better threshold heuristic than DOM and for the auction selection heuristic, KS is an acceptable choice especially for larger numbers of auctions. At present, the heuristics developed assume that there is only one global bidder in the market. However, as a future direction, we intend to examine the Nash equilibrium strategy and analyse the change in best response when more global agents operate in the system.

Are Parallel BDI Agents Really Better?

Huiliang Zhang and Shell Ying Huang¹

Abstract. The traditional BDI agent has 3 basic computational components that generate beliefs, generate intentions and execute intentions. They run in a sequential and cyclic manner. This may introduce several problems. Among them, the inability to watch the environment continuously in dynamic environments may be disastrous and makes an agent less rational – the agent may endanger itself. Two possible solutions are by parallelism and by controlling and managing the 3 components in suitable ways. We examine a parallel architecture with three parallel running components which are the belief manager, the intention generator and the intention executor. The agent built with this architecture will have the ability of performing several actions at once. To evaluate the parallel BDI agent, we compare the parallel agent against four versions of sequential agents where the 3 components of the BDI agent are controlled and managed in different ways and different time resources are allocated to them. Experiments are designed to simulate agents based on the sequential and parallel BDI architectures respectively and the ability of the agents to respond to the same sequences of external events of various priorities are assessed. The comparison results show that the parallel BDI agent has quicker response, react to emergencies immediately and its behaviour is more rational.

1. INTRODUCTION

As identified in the survey of agent architectures [15], three kinds of agent architectures, deliberative architecture [1, 13, 9], reactive architecture [2] and hybrid architecture [6], are proposed according to the processing mechanism of the agents. The traditional deliberative architecture has 3 basic computational components that generate beliefs, generate intentions and execute intentions. For an external event, an agent will process it by going through the belief generation, intention generation and intention execution in a sequential manner. For example, in PRS (procedural reasoning system) [9], the main control process runs in iterations. The agent will not proceed to the next step until the current step is finished. In a complicated and dynamic environment, the agent may need more time to search for proper intentions or actions need more time to be executed. Then the agent cannot perceive new information in time and the reactivity of the PRS agent cannot be assured.

A possible solution appears in the TouringMachine [6]. For each time cycle, the control framework has fixed time resource to use. This method ensures that the agent can sense the environment at fixed time intervals. The probability of overlooking emergencies

is reduced if the portions of the time spent in detection and processing are well balanced. But it is usually advised that the detection should not consume much time. So the problem of poor reactivity still exists.

In agents based on BDI logics, such as AgentSpeak(L) [12] and LORA (Logic of Rational Agents) [16], these problems may induce the slow reactivity and intention reconsideration issues. For example, in LORA, desires, intentions, and actions are generated based on belief. The original circumstance/belief may have changed during these processing. So the intentions may become impossible under new circumstance and the agent should not commit to the infeasible intentions. An improvement was made by updating belief and reconsidering intentions after executing each action. An experiments result of intention reconsideration by Kinny and Georgeff is provided in the book [16]. The result shows that the more frequently the intentions are reconsidered, the lower the effectiveness of the agent is.

Utilizing a more powerful computer is a method to lessen the problems. An alternative is to investigate what improvement can be achieved by controlling and managing the 3 basic computational components of a BDI agent in different ways. Another solution can appear in parallelizing the agents' basic actions. In [10], a multi-threaded approach is shown to have obvious advantages in lessening the impact of IO operations in the simulation of an intelligent agent like a human soccer player. From the view of a real human being, a person is always doing several things simultaneously. The brain engages many processes like planning, walking and watching for traffic continuously and at the same time. A parallel BDI agent architecture has been proposed in [17]. The architecture consists of the belief manager, the intention generator and the intention executor running in parallel. The activities of these components are coordinated by interrupts. The agent built with this architecture has the ability of reacting to urgent matters immediately and performing several actions at once.

In this paper we evaluate the parallel BDI agent by comparing it against four regular versions of sequential agents where the 3 components of the BDI agent are controlled and managed in various ways. Experiments are designed to simulate agents based on the sequential and parallel BDI architectures respectively and the way they respond to the same sequence of external events are evaluated. The comparison results show that the parallel BDI agent has quicker response and its behaviour is more rational.

The remainder of this paper is structured as follows. In section 2, we introduce the four sequential BDI agents each with their own way of controlling and managing their computational components.

¹School of Computer Engineering, Nanyang Technological University, Singapore 639798, email: {pg04043187, ASSYHUANG}@ntu.edu.sg

In section 3, the parallel BDI agent architecture proposed in [17] is summarized. The simulation experiments are described and the results are analyzed in section 4. Finally, we summarize the paper and propose possible applications of the parallel BDI architecture.

2. SEQUENTIAL BDI AGENTS

There are 3 basic computational components in a BDI agent, the belief manager to *detect* the changes in the environment to generate new beliefs, the intention generator to *deliberate* on the beliefs to generate new intentions and the intention executor to *execute* the intention plans. In a sequential agent, only one computational component is running at any time. We present several ways of controlling and managing the components in an attempt to get better performance from a sequential agent.

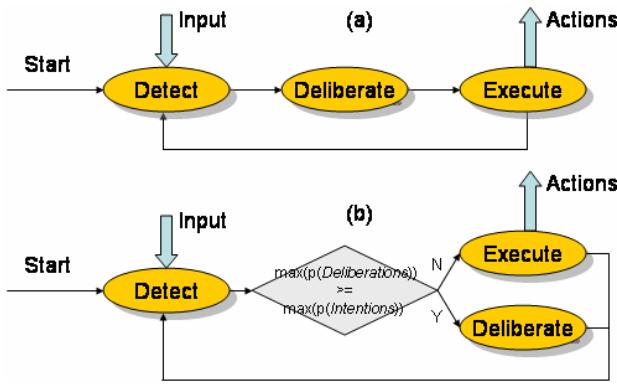

Figure 1. Sequential BDI agents.

- (1) As shown in Figure 1(a), the 3 components run in a cyclic way and each uses up the pre-allocated and fixed time resource. The deliberation/intention cannot be suspended and resumed. If the remaining time of a component (only the *deliberate* and the *execute* components) is not sufficient for a deliberation/intention to be finished, the remaining time will be wasted.
- (2) A more flexible way is to allocate time resources to the *deliberate* and *execute* components only when needed. If a component has nothing to do, it terminates and the next component starts. In order to keep the agent vigilant, the *detect* component always uses up all its allocated time. The actual time used for *deliberate/execute* should not exceed the maximum pre-allocated time to such a component. This agent has a cycle time ranging from a minimum that is the fixed time for the *detect* component to a maximum that is the sum of the allowable times of the 3 components.
- (3) This is a variant of the agent (2). It suspends a task when the time allocated to the current component is used up and resumes it when the component's turn comes in the next cycle. For example, the *execute* action can start an *intention* which costs 5 time units when there is only 1 time unit remaining.
- (4) This agent has a cycle as shown in Figure 1(b), in each cycle, after the *detect* component, the agent will choose to *deliberate* or *execute* based on the maximum priority of *deliberations* and *intentions*. After *deliberate/execute* is finished, another cycle begins. This makes the agent more watchful for emergencies.

The characteristics of the four sequential BDI agents are summarized in Table 1. In all the sequential agents, when there are

multiple deliberations/intentions to handle in the *deliberate/execute* component, the one with highest priority will be processed first. The performance of these agents will be compared with the parallel BDI agent.

Table 1. Sequential agents.

Agent no	Flexible time allocation?			suspend-resume?	Illustration
	detect	deliberate	execute		
1	N	N	N	N	Figure 1(a)
2	N	Y	Y	N	Figure 1(a)
3	N	Y	Y	Y	Figure 1(a)
4	N	Y	Y	Y	Figure 1(b)

3. PARALLEL BDI AGENT

The detailed architecture of the parallel BDI agent is proposed in [17]. Figure 2 shows an abstract representation of it. The salient features of the architecture are

- (a) The *belief manager*, the *intention generator* and the *intention executor* run continuously and in parallel. So the agent is capable of performing several actions at once. For example, the agent is able to perceive the environment, deliberate on its desire and belief to generate the next intention and execute the plan for the current intention all at the same time. This makes the agent more human-like.
- (b) The parallel running components communicate through interrupts. Interrupts have different priorities representing the importance and urgency of the desires/beliefs/intentions to be handled. After receiving an interrupt, the next action of the component will be decided by the priority of the interrupt. If the new information needs to be dealt with immediately, the component will suspend the current job and start to process the new situation. If the urgency of the new information is not higher than the current job, the new information will be kept for future processing at an appropriate time. The interrupt mechanism ensures that an emergency can be dealt with rapidly. Thus, the agent is capable of quick reaction to emergencies.

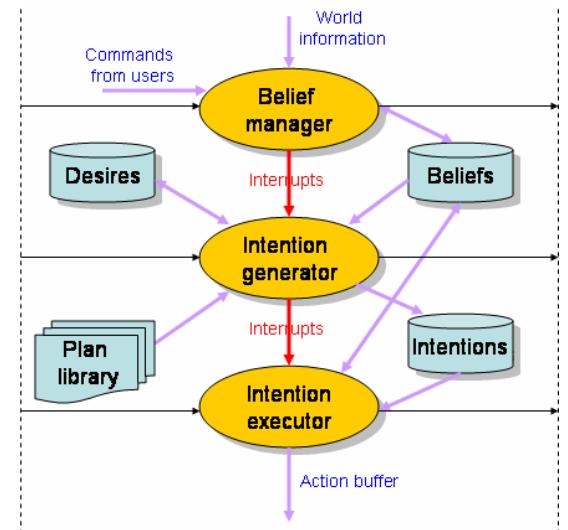

Figure 2. Parallel BDI model.

4. EXPERIMENT

4.1 Sequential BDI Agents Configuration

This is to allocate time resources to the 3 components of a sequential BDI agent. We used three time allocation schemes for sequential agents according to their emphasis on the three components. For a maximum cycle of 15 time units, three schemes showing the fixed or maximum allowable time quota for each component of the BDI agent are given in Table 2.

Table 2. Allocation schemes.

Configuration	detect	deliberate	execute
C1	1	4	10
C2	3	4	8
C3	5	3	7

The numbers in Table 2 are not completely arbitrary: (1) configuration C1 puts more emphasis on executing intentions with the risk of overlooking emergencies; (2) C3 gives more time to the *detect* component to be more vigilant, but the time for the *execute* component is cut; (3) C2 is a compromise between C1 and C3.

Each sequential agent described in Section 2 will be configured according to C1, C2 and C3 respectively in the experiments to compare them with the parallel agent.

4.2 The Input Data

The evaluation of the sequential and parallel agents is done by simulation of the processing of events by agents. All the sequential agents and the parallel agent will process some sequences of events. Each event will be processed by the 3 computational components of the BDI agent, namely, the belief manager(*detect*), the intention generator(*deliberate*) and the intention executor(*execute*).

To evaluate the agent ability to handle events of different importance or urgencies, events will have one of the four different priority levels 1 to 4, with 4 being the highest. We assume that an event can be detected and a belief generated in 1 time unit and each deliberation to generate an intention takes 2 time units. The intention execution time of events at all priority levels is uniformly distributed in the range from 1 to 7 time units. So the average intention execution time is 4 time units. This also means the average time required to handle an event is 7 (1+2+4) time units.

We use the exponential density function to represent the inter-arrival time between any two events. As shown in [14], the exponential density function is memoryless and often used to model lifetimes or waiting times. The cumulative distribution function is shown as:

$$cdf(t) = 1 - e^{-\lambda t} \quad (1)$$

where, $1/\lambda$ is the mean; t is the time units.

$cdf(t)$ shows the probability that the inter-arrival time between 2 events is less than t . So given a total number of events, *sum*, to be used in our experiments, we can decide the number of the intervals with length of n time units by:

$$G(n) = (cdf(n) - cdf(n-1)) * sum \quad (2)$$

If the *sum* of the events is provided, the numbers of the intervals with different lengths can be decided. Then the intervals are selected randomly for the events. The current time plus the interval

length is the arrival time of the next event. The event priority is selected randomly from 1 to 4.

We consider three sequences of events with different average inter-arrival times. The average inter-arrival times of the 3 sequences of events are respectively smaller than, equal to and larger than the average processing time required by an event. The events statistics used in the experiments are shown in Table 3.

Table 3. Events statistics.

Set	Expected average interval $1/\lambda$	Events count				Actual average interval	
		Priority			sum		
		1	2	3			
a	4	27	20	26	23	96	
b	7	24	22	24	25	95	
c	12	25	20	22	24	91	

When an event arrives and the agent is not doing detection, the event will be stored in an event buffer. The agent can retrieve the new events later. After receiving the event, the agent will create one *deliberation* for it. The *deliberation* will be added in a deliberation queue. The *deliberation* and *intention* plan selected later will have the same priority as the event.

4.3 Results and Analysis

We will use the *response time* to evaluate how well the agent processes the event. The *response time* is defined as the time between the arrival of the event and end of the execution of the intention plan chosen for the event. The response time is calculated as the sum of the time for detecting the event, deliberation and execution. The overhead transmit messages between the three parallel components in the parallel agent is omitted as it is felt that the delay in passing the interrupts is very small.

The results of the experiments are presented in Table 4. The ART is the Average Response Time of all events. ART_p stands for the ART of the events with priority p . ART_w is the weighted ART by the priorities of the events.

$$ART = \frac{\sum_{i=1}^{Count} T_i}{Count}, \quad ART_w = \sum_{p=1}^4 \frac{ART_p * p}{1+2+3+4} \quad (3)$$

Where, T_i is the response time for event i ; *Count* is the number of events.

Parallel agent vs sequential agents

Looking at the response times of the parallel agent (rows with agent no. 5) and the various sequential agents (rows with agent nos. 1 to 4), we can see that the parallel agent responds at least 3 times faster than the sequential agents in most the cases. This shows that the parallel agent can process events quicker than the sequential ones. The main reason for this difference comes from the fact that the parallel agent is able to use 3 CPUs while each sequential agent uses one. To give the sequential agents a single CPU which is 3 times as powerful as the CPU used in the parallel agent will enable the sequential agents respond faster but they will still not be able to guarantee immediate handling of high priority events.

One thing to note is that in a few cases the parallel agent (agent 5) responds less than 3 times faster than the sequential ones. This happens with sequential agents 2, 3, 4 with configurations C1

Table 4. ART of the events by the agents.

Con fig.	Set	Agent no	ART _p				ART	ART _w

		2	633.9	269.4	26.6	14.0	232.9	130.8
		3	508.1	87.2	34.5	21.4	162.9	87.2
		4	523.2	121.4	32.0	18.8	173.3	93.7
		5	14.1	8.9	8.2	6.5	9.4	8.2
C3	c	1	799.9	218.5	35.1	18.9	281.3	141.8
		2	219.3	26.0	13.4	11.7	72.3	35.8
		3	55.4	30.0	16.7	16.1	30.1	23.0
		4	71.9	37.8	23.6	15.9	38.0	28.2
		5	11.4	7.0	6.4	6.3	7.9	7.0

and C2 when the event sequence is set c. The ARTs and the weighted ARTs of agents 2, 3, 4 are less than 2 times those of agent 5. This means when the inter-arrival time is long enough, the parallel agent will not show its advantage. Configuration C3 is allocating too much time to the *detect* component of the agent so the sequential agents responds more than 3 times slower than the parallel agent except for the priority 4 events.

The priority 4 events are the highest priority events in the experiments. The average time needed to process one such event in the ideal case (ATN_4) is calculated by:

$$ATN_4 = \frac{\sum_{i=1}^{\text{Count}} (TDetection_i + TDeliberation_i + TExecution_i)}{\text{Count}} \quad (4)$$

where, $TDetection_i$ is the time used to detect the event i ; $TDeliberation_i$ is the time used to deliberate the event i ; $TExecution_i$ is the time used to execute the plan generated based on the event i ; $count$ is the number of events with priority 4.

In this experiment, $TDetection$ equals to 1 and $TDeliberation$ equals to 2. $TExecution$ can be obtained from the events list. Using the equation, ATN_4 equals to 6.26 for set a, 6.48 for set b, 6.3 for set c. Compared to the ART_4 (column 7 in Table 4) we can see that in the parallel agent, the events with the priority 4 from set b and c

are processed immediately. It spends just 0.24 time units more for set a. Set a is a sequence of events with an inter-arrival time smaller than the processing time required for an event. So the intention generator and the intention executor are busy handling other beliefs and intentions when a high priority belief/intention comes to them. Here the interrupt mechanism in the parallel agent is able to guarantee immediate handling of higher priority items while the sequential agents are not able to do this. It is clear that the parallel agent has a big advantage over the others on processing real emergencies.

For events with lower priority, the difference of ART between the sequential agents and the parallel agent is bigger.

With different time resources allocation in sequential agents

Looking at the ART and ART_w columns and comparing the corresponding rows for configurations C1, C2 and C3, we conclude that the performances of the sequential agents with configuration C3 are significantly worse than those with configuration C1 and C2. This shows that the sequential agents perform badly if they spend more time on detecting and less time on deliberation and intention execution. The processing of emergencies is often postponed, though the emergencies are detected earlier in configuration C3. This can be seen that in most cases (event sets a, b, c and agent number 1 to 4) the processing of the highest priority events also have longer response time. This indicates that in real life, the agent is not reacting to high priority events quickly and is taking a longer time to react to other events.

We also observe that the performances of the sequential agents with configuration C1 is significantly better than C2. This shows that the sequential agents perform much better if they spend shorter time on detecting and more time on deliberation and intention execution. Because the deliberating and executing components get more time resources, the beliefs and intention plans get cleared faster so the events experience shorter response time.

With different ways of controlling the computational components in sequential agent
