The architecture of our information filtering system is shown on figure 1. This model associates a behavior modeling method based on the Chan formula [5] and a new version of the hierarchical clustering algorithm [6]. This new version – called FRAC in the rest of this article – has the advantages to be distributed, to be optimized in computation time and to converge systematically.

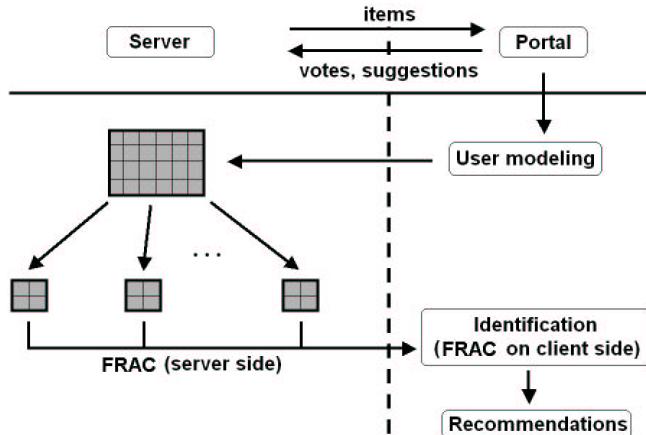

Figure 1. Architecture of the information filtering module.

In order to distribute the system, the server side part is separated from the client side. The function of user modeling determines numerical votes for items according to user actions. Then, numerical votes are sent to the server, like the non-numerical ones⁴. Thus, the server uses, as input parameters, the matrix of user votes and the database including sites and descriptors. In this way, the server has no information about the population, except anonymous votes. User preferences are stored in the profile on clients. Thus, the confidentiality criterion is duly fulfilled.

The FRAC algorithm aims at reducing quantity of data that must be processed. The offline computations of FRAC allow to build typical user profiles. It is no longer necessary to consider the whole vote matrix, but only votes of persons belonging to the group of the active user. This reduces the number of considered people, but also

³ The recommendations system won't be able to provide relevant documents as soon as it receives the first queries.

⁴ The list of favorites are given explicitly by users, while numerical votes are estimated in a transparent way. This is the reason why we use the non-numerical votes to determine the content of the bouquet.

the number of items: it is pointless to keep documents that none of the group members has read. In this way, we avoid the problem of bottleneck of collaborative filtering on client side: the active user is identified to one of the typical users groups in a very short time.

3.1 Behavior modeling

In the Casablanca interface, users have the possibility to define a list of favorites, that is to say some sites they are interested in among those contained in the bouquet. However, we can't describe these non-numerical votes as boolean. We can't differentiate items in which the active user is not interested (negative votes) from those he/she doesn't know or has omitted. This kind of votes is not sufficient to do relevant predictions with collaborative filtering methods.

In an ideal recommender system, users can explicitly rate each item. Ratings are integers in accordance with an arbitrary graduation. Nevertheless, in an industrial context, there can be marketing reasons which require to proceed differently. The ASTRA satellite bouquet is partially fulfilled with websites paid by advertisers. In this case, the risk that most users negatively and explicitly rate an advertisement can't be taken. For this reason, we have chosen to determine numerical marks in a transparent way for users.

Another advantage of this method is to deal with the problem of sparsity by increasing the number of votes in the matrix. Users generally rate the websites with whom they are familiar. It only represents a small part of the available items. The behavior modeling process is based on implicit criteria. A function estimates ratings that the active user is likely to give to different websites. It relies on several parameters, such as the percentage of visited links, the time or the reading frequency. In this way, the system can collect much more information than when using explicit ratings of users.

Casablanca generates log files on client side. These files are very similar to those of an Apache server. Each time a page is loaded in the portal, pieces of data are stored including time, path of the page and information about the website it belongs to. We consequently deduce the user preferences from an analysis of usage.

To do so, we developed a user modeling function based on the formula of Philip CHAN [5]. We adapted this formula in such a way that it is applicable to items (cf. infra, formula 1, p. 3), while the original formula was designed for web pages. But, in the ASTRA context, items correspond to websites, that is to say indivisible sets of pages. The time spent on an item is, for example, calculated as the cumulative times spent on each of its pages. A consultation is the set of consecutive lines relating to a same website in the log files. The log files only stored the uploading time of a page. We consequently have to limit the duration beyond the last upload in a consultation, if there is no other consultation just after. We also modified coefficients in the original Chan formula, in order to optimize the results in accordance with log files of ASTRA.

All pieces of information retrieved in the log files remain on client side, in order to preserve privacy. Only numerical votes which have been deduced from this process are sent anonymously to the server⁵. We call them "user profiles". They are required for the use of FRAC clustering algorithm. These profiles are not persistent, that is to say stored for a limited duration. Moreover, the sending on server side is initiated by the active user.

⁵ There is no way to retrieve the user from a profile on the server [4].

Adapted Chan formula:

$$\text{Interest}(\text{item}) = 1 + 2 \cdot \text{IsFavorite}(\text{item}) + \text{Recent}(\text{item}) + 2 \cdot \text{Frequency}(\text{item}) \cdot \text{Duration}(\text{item}) + \text{PercentVisitedLinks}(\text{item})$$

$$\text{With: } \text{Recent}(\text{item}) = \frac{\text{date(last visit)} - \text{date(log beginning)}}{\text{date(present)} - \text{date(log beginning)}}$$

$$\text{And: } \text{Duration}(\text{item}) = \max_{\text{consultations}} \left(\frac{\text{time spent on pages of item}}{\text{size of the item}} \right) \quad (1)$$

$\text{Interest}(\text{item})$ must be rounded up to the nearest integer.

$\text{IsFavorite}(\text{item})$ equals 1 if the item has been voted by the user (non-numerical vote) and 0 otherwise.

$\text{Frequency}(\text{item}) \cdot \text{Duration}(\text{item})$ must be normalized so that the maximum is 1.

$\text{PercentVisitedLinks}(\text{item})$ corresponds to the number of visited pages divided by the number of pages on the item.

3.2 Clustering algorithm

Once the profiles of users have been sent to the server, the system has to build virtual communities of interests. In our model, this step is carried out by a hierarchical clustering algorithm, called FRAC. This is an improved and decentralized version of the RecTree algorithm [6]. It attempts to split the set of users into cliques by recursively calling the nearest neighbors method [7] (K-Means), as illustrated on figure 2.

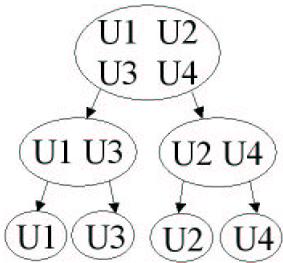

Figure 2. Hierarchical organization of users.

In this section, we explain how to build typical user profiles on server side and how to identify the active user to a group. This second step takes place on client side. We made sure that the identification phase is done in a very short response time. In this way, the client part provides real-time predictions. Offline computation time on server side has also been improved to fit in with the update frequency of the ASTRA satellite bouquet.

The FRAC algorithm is a model-based approach, described as a clustering method. However, it is managed as a memory-based approach because all the pieces of information are required for similarity computation. It allows, within the scope of our architecture, to limit the number of persons considered in the prediction computations. Thus, the results will be potentially more relevant, since observations will be based on a group closer to the active user [12].

In order to compute these groups of interests, the server extracts data from the profiles of users and aggregates the numerical votes in a global matrix. This matrix constitutes the root of the tree (cf. supra, fig. 2). The set of users is then divided into two sub-groups using the K-means method. In our case, the number k equals 2, since our overall strategy is to recursively divide the population into binary sub-sets. Once this first subdivision has been completed, it is repeatedly applied to the new subgroups, and this until the selected depth of the tree has been reached. This means, the more one goes down in the structure of the tree, the more the clusters become specific to a certain group of similar users. Consequently, people belonging to a

leaf of the tree share the same opinion concerning the assignment of a rating for a given item.

The K-Means algorithm is very sensitive to initial starting conditions and may converge more or less quickly to different local minima⁶. The usual way to proceed consists in choosing randomly k centers in the users/items representation space. Numerous studies have been made to improve K-Means by refining the selection of these initial points [2]. But it remains a difficult problem and some of these approaches don't obtain better results than the method with a random initialization. In our case, the problem is much simpler since we only have two centers. Thus, we propose a new way to select the starting points, shown on figure 3.

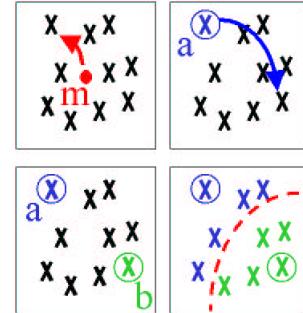

Figure 3. Initialization of 2-Means algorithm.

We work in a N-dimensional space, since the coordinates correspond to the votes of users for the N items. However, the example on the diagram 3 is in dimension 2 for more legibility. We start from the principle that the two most distant users are inevitably in different clusters. Consequently, they constitute the ideal candidates for the initial points. To identify them, we first search the most distant point from the middle M of the users/items representation space. This point is called A on figure 3. Then, we compute the point B, which is the most distant from A. A and B are subsequently the starting points of the 2-Means algorithm. This initialization phase is in $O(2n)$, where n is the number of users. Metrics used to determine distances is the Pearson correlation coefficient [9].

Once groups of persons have been formed as previously mentioned, the position of the center is recalculated for each cluster (either by computing the isobarycenter, either by using the equation 2 according to the precision we want) and this operation is repeated from the beginning until we have obtained a stable state (where the

⁶ We want to minimize the distances between users of a same group and maximize them between users of different clusters.

centers no longer move after recalculation of their position). Our initialization allows to reach this state much more quickly.

$$r_{c_{t+1},l} = \alpha \cdot \sum_{Y_{c_t,u}} (r_{u,l} \cdot |w(c_t, u)|) \quad (2)$$

With: $r_{c_{t+1},l}$ the coordinate of the new center c_{t+1} for the item l;
 $r_{u,l}$ the vote of the user u for the item l;
 $w(c_t, u)$ the distance between the previous center and u;
 $Y_{c_t,u} = \{u | w(c_t, u) \neq 0\}$;
 $\alpha = \frac{1}{\sum_{Y_{c_t,u}} |w(c_t, u)|}$.

The nearest neighbors algorithm complexity is in $o(k^2n)$ for k clusters and n users. Moreover, the whole complexity of the construction of the tree yields $o(n \log_2 n)$. The final center of each leaf of the FRAC tree corresponds to a profile of typical users. It means that we consider these centers as virtual users synthesizing the preferences of each subset of users.

The profiles of typical users are then sent on client side, using IP multicast addresses. Subsequently, the system uses the Pearson correlation coefficient to compute distances between the active user and the typical users. We consider that the active user belongs to the community whose center is the closest to him/her. At last, we can predict the interest of the active user for a resource r_l with the equation 3.

$$p_{u_a,r_l} = \max(r_{min}, \min(r_{u_t,l} + (\bar{r}_{u_a} - \bar{r}_{u_t}), r_{max}) \quad (3)$$

With: u_a the active user;
 u_t the nearest typical user;
 p_{u_a,r_l} the prediction of u_a for r_l ;
 \bar{r}_u the average of votes of u ;
 r_{min} and r_{max} respectively the min and max bounds of the vote scale.

The identification phase of the active user to one of cliques is in $o(2p)$ on client side, where p corresponds to depth of the tree. Even when the active user didn't want to share his/her preferences, it is possible to do predictions since they are made on client side.

The clusterization can be performed so that cliques hold about the same number of persons for a given depth of the tree. In this way, we introduce novelty in recommendations.

4 PERFORMANCE ANALYSIS

In this section, we compare our clustering algorithm with Item-item [10] and the Correlation-based Collaborative Filter CorrCF [9]. We have implemented all these methods in Java. The different tests have been done on a laptop computer equipped with a CPU 1.8 GHz and 1 Go of RAM. We evaluate these techniques in terms of computation time and relevancy of predictions.

4.1 Computation time

In order to compare the computation times of the aforementioned algorithms, we have generated matrices with different sizes. In this simulation, the votes of each user follow a Gaussian distribution centered on the middle of the representation space. We argue that this situation increases the number of iterations needed in the clustering algorithm, since the users are close to each other. Moreover, there is only 1% of missing data in the generated matrices. Consequently, we almost work in worse case for the computation time tests.

The results of these tests are shown in the table 1. The announced times include the writing of results in text files. The FRAC algorithm provides results in a quite short time. It is thus possible to apply it to large databases. For example, the system only needs about 6 or 7 minutes to compute typical behavior profiles with 10.000 users and 100 items. In the same case, the CorrCF algorithm requires several hours of computation (one of which is spent to compute the similarity matrix). The response time of CorrCF increases besides exponentially with the size of the database and is not in accordance with industrial constraints.

We note that Item-Item gets results much more quickly than FRAC when there is a lot of users and only few items. Nevertheless, the tendency may be reversed when the number of items grows, even if the number of users is still much more important (cf. table 1 for 10.000 users and 1000 items). Moreover, the corpus we used is not the most appropriate for our algorithm, since the number of items is almost twice as big as the number of users.

At last, we have tried to cluster huge populations. The FRAC algorithm was able to supply results in about 11 hours for 120.000 users and 150 items. This computation time is much smaller than the bouquet update period⁷. Consequently, it is completely suitable for the Casablanca software.

4.2 Recommendations relevancy

In order to compute the prediction relevancy in our system, we used the GroupLens database⁸. The latter is composed of 100.000 ratings of real users. Thus, we considered a matrix of 943 users and 1682 items. Moreover, each user has rated at least 20 items. The database has been divided into a training set (including 80% of all ratings) and a test set (20% of votes). We compare our algorithm with the three others by using the Mean Absolute Error (MAE).

MAE is a widely used metric which shows the deviation between predictions and real user-specified values. Consequently, we computed the average error between the predictions and the N ratings of the test set as shown in formula 4.

$$MAE = \frac{\sum_{i=1}^N |p_i - q_i|}{N} \quad (4)$$

The results are shown in the figure 4. The FRAC algorithm does predictions as good as the CorrCF – which is memory-based – and not so far from the Item-Item.

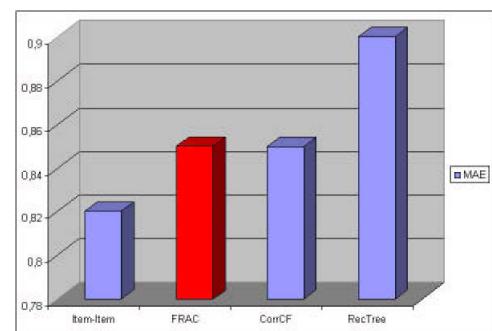

Figure 4. Comparison of prediction quality.

⁷ The bouquet is updated once a week. It means that the list of websites change. But the content of websites is updated every two hours.

5 CONCLUSION

The novelty of our model relies on the fact that we have mixed a distributed collaborative filtering method with a behaviour modeling technique. The main advantage of this combination is to take into account in an overall way the strong constraints due to an industrial context such as the time constraints, the privacy, the data sparsity and the scalability to real commercial applications. Our recommender system has been implemented in a satellite broadcasting software with about 120.000 users. We also dealt with the ASTRA business plan by getting individual preferences – only stored on client side – in a transparent way.

Before our collaboration with ASTRA, Casablanca wasn't able to classify websites in order of preference. Thus, the filtering module was accepting the voted packages which were broadcasted until the cache was full. Most of the time, the content of the cache wasn't optimum and was even almost random. From now on, the system is able to anticipate the arrival of the packages and to decide if it is interesting to add them in the cache. The filtering module sorts out the websites and optimizes the suggestions according to the cache size defined by the active user. We are now evaluating the satisfaction of users as regards recommendations. ASTRA has recruited voluntary beta-testers to experiment the system in real conditions. We searched in the literature the different existing methodologies to measure the user satisfaction. We finally choose the approach in [1] because it is relying on an analysis of usage.

While waiting for the results of this long-term study, the off-line performance analysis highlights the fact that our algorithm gets rather quickly results on server side, even when the corpus is not very adequate. Moreover, the identification phase on client side is in $o(2p)$. This part of computations has been optimized in order to supply users with recommendations in a very short response time.

Another advantage of our algorithm is the stability of the model. Thanks to the new initialization phase, the results are reproducible when we launch the clustering process several times. Furthermore, contrary to some algorithms such as K-Means, the computations systematically end.

ACKNOWLEDGEMENTS

We want to thank ASTRA and the CRPHT which have encouraged this work.

The MEXAR2 Support to Space Mission Planners

Amedeo Cesta and Gabriella Cortellessa and Simone Fratini and Angelo Oddi and Nicola Policella¹

Abstract. This paper describes a fielded AI system in daily use at the European Space Agency (ESA-ESOC) since February 2005. The tool, named MEXAR2, provides continuous support to human mission planners in synthesizing plans for downlinking on-board memory data from the MARS EXPRESS spacecraft to Earth.

The introduction of the tool in the mission planning workflow significantly decreased the time spent in producing plans. Moreover MEXAR2 improves the quality of the produced plans thus guaranteeing a strong reliability in data return enabling a more intensive science activity on board. The introduction of MEXAR2 has modified the role of the human mission planners who can now evaluate and compare different solutions rather than dedicating their time exclusively to computing single solutions (a tedious and repetitive task which does not capitalize on the mission planners' decision-making expertise). These characteristics have effectively made MEXAR2 a fundamental work companion for the human mission planners.

1 CONTEXT

A critical problem for interplanetary space missions is maximizing science while guaranteeing data return to Earth. Additionally, the reduction of investments in the field, requires space programs to perform ambitious tasks with more limited budgets with respect to the past. Europe's MARS EXPRESS is seen, quoting the mission web description, "as a pilot project for new methods of funding and working". Specifically, an innovative working relationship between ESA, industry, national agencies and the scientific community, as well as the reuse of equipment developed for the ESA Rosetta mission, were important factors that have contributed to the development of MARS EXPRESS as a relatively low cost mission².

Notwithstanding the low budget, the mission exposes ambitious goals for the scientific experiments on board. The seven payloads the orbiter is equipped with, are expected to maximize their data return to take advantage of the opportunity offered by the proximity to the Red Planet. Indeed an amount of novel information from Mars is arriving to the space science community and, through the media, to citizens. We may remember either the accurate pictures taken by the High Resolution Stereo Camera (HRSC) which image the entire planet in full colour 3D and with a resolution of about 10 meters, or the information about the distribution of water, both liquid and solid, in the upper portion of the crust of Mars, distributed by MARSIS, the Mars Advanced Radar for Subsurface and Ionosphere Sounding.

Obviously, in a deep-space mission like MARS EXPRESS, data transmission to Earth represents the fundamental aspect. The space-probe continuously produces a large amount of data resulting from the activities of its payloads and from on-board device monitoring and verification tasks (the so-called *housekeeping* data). All these data are to be transferred to Earth during bounded downlink sessions.

Moreover, in the case of MARS EXPRESS, a single pointing system is present. This implies that, during regular operations, the space-probe either points to Mars, to performs payload operations, or points to Earth, to download the produced data. As a consequence, on-board data generally require to be first stored in a Solid State Mass Memory (SSMM) and then transferred to Earth.

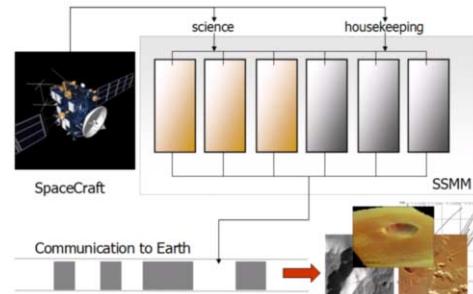

Figure 1. Bringing data from Mars to Earth

In Fig. 1 the main data flow is shown: the spacecraft instruments produce data that are stored in the SSMM on-board memory. The main problem to be solved consists in synthesizing sequences of spacecraft operations (*dump plans*) that are necessary to deliver the content of the on-board memory during the available downlink windows. The average data production on a single day can be around 2-3 Gbit while the transmission rate of the communication channel, which varies between 45Kbs and 182Kbs, may not be sufficient. The on-board memory is subdivided into different banks, called *packet stores*, in which both scientific (*science* from payloads) and spacecraft management data (*housekeeping*) can be stored. In particular housekeeping has to be guaranteed to arrive to Earth daily so as to allow checking for the safety of the different operations on board. Notice that each packet store assigned to science data is managed cyclically, so in case new data are produced before the previous are dumped to Earth, older data are overwritten and the related observation experiments have to be re-scheduled. Even if the on-board memory is about 9.4 Gbit the irregular distribution of transmission windows, the different transmission rates of such windows and the different data rates for data production (e.g., the stereo camera can produce files close to 1Gbit) may often create usage peaks close to the packet store capacities.

To complicate matters there is an additional uncertainty factor in data production for some instruments due to different compression algorithms. Usually dump plans for the on-board memory are computed for a nominal expected production of a certain payload activity, a POR (Payload Operation Request), but mission planners may discover from housekeeping check that data on-board are more than expected so they have to recompute the *dump plan*, i.e., the sequence of dump commands that implements the memory download policy.

Content. This paper describes how an AI-based interactive tool, called MEXAR2, has been inserted in the continuous loop of mission operation management, allowing the mission planners to gener-

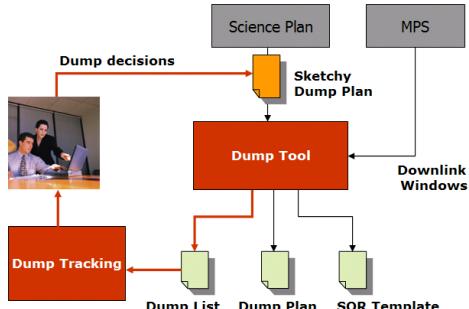

Figure 2. Dump Planning Approach before MEXAR2

ate dump plans in a shorter time, and to explore alternative solutions obtained by tuning a controlled set of parameters. MEXAR2 is in daily use at ESA-ESOC since February 2005 and has been further improved during almost a year of operational use. The key improvement introduced by MEXAR2 is the fact that an AI software tool has contributed with a new perspective to the use of supporting software for mission decision: from a common practice in which the software help is mainly for constraint checking and all the decisions are left to the human planner, to a practice in which the software has an active role in taking decision and becomes a “companion” for the human decision-maker offering a wider perspective on the problem to solve.

The paper sheds light on some key aspects that acted as enabling conditions for the MEXAR2 success story. The aim is to show how the AI background that generated MEXAR2 significantly contributed in the effectiveness of the technology infusion program.

2 THE “TRADITIONAL” MISSION PLANNING

Consolidated practice in space mission operations always involves a Scientific Control Center responsible for science activities of the various payloads (oversimplifying sketched in Fig. 2 as Science Plan), and an Operational Control Center in charge of detailed operations for the maintenance of the spacecraft and the return of scientific data. More in detail the Operational Control Centre is responsible for various activities like the uplink of set of commands, the downlink of science and housekeeping data, the monitoring of the spacecraft, the negotiation with the Science Control Center about possible adaptations and refinements of the master Science Plan. For the sake of simplicity we identify all these activities as Mission Planning System, MPS. One fundamental activity within MPS, consists of generating the Dump Plan, a sequence of Space Operation Requests (SORs) that ask the spacecraft to transmit a certain amount of data from a given packet store to Earth.

Fig. 2 depicts the work practice, within the MPS, that was established during MARS EXPRESS operation to generate dump plans, before the introduction of the MEXAR2 tool. A small team of people (mission planners), one of them being the main responsible for the task, received an initial Sketchy Dump Plan form the Scientific Control Center which, for each payload, listed the set of scheduled PORs and the relative data that were to be transferred to Earth. Starting from this initial Sketchy Dump Plan, the mission planners were in charge of refining it and producing three elaborations, namely the final Dump Plan, the Dump List and a SOR Template, a version of the dump plan formatted to be directly executed on-board.

Two simple software tools, helped the mission planners in their daily tasks, both slight enhancements of a spreadsheet file: (a) the Dump Tool that, taking as input the current Dump Plan (essentially a text file) and a specification of the downlink windows provided by MPS specialists, performed some constraint checking and generated the output formats for Dump Plan and SOR Template plus the additional file, called Dump List; (b) the Dump Tracking, a simple program that allowed easy inspection of the Dump List file. In particular the Dump List file includes information on both data storages

and data dumps distributed on the various packet stores of the SSMM, and allows to compute capacity profiles over time to check for over-production of data and, as a consequence, data loss (overwriting). The normal cycle of work consisted in the mission planners initializing the Sketchy Dump Plan with nominal data quantities extracted from the PORs in the Science Plan, using the two tools to create the current projections on the different packet stores according to the downlink windows, and analyzing the results of the Dump Tracking to refine, through updated dump decisions, the Sketchy Dump Plan. This loop was iteratively repeated until a satisfactory Dump Plan was computed.

Problems. This cycle is also common to different missions, but, as said before, MARS EXPRESS is strongly devoted to maximize science return, and the visibility windows are quite limited – other missions may allow time enough to regularly perform complete memory dumps. The previous procedure ended up being very time consuming because mission planners were essentially proceeding by “Trial and Error” on a textual plan, deciding to move back and forth in time the existing dump commands or splitting a current dump in multiple dumps allocated on different time windows. Two additional complicating factors were: (a) the activity of “manual” refinement was possible having a reference period of one or two days but was cognitively very difficult on a larger horizon; (c) the uncertainty factor on data production made things even worst because in certain cases, from housekeeping analysis, planners discovered that data still onboard from the previous day were more than expected and they had to restart the refinement process of the Dump Plan to take this additional data into consideration. In general this planning process too often produced dump plans not sufficiently reliable with respect to overwriting, and also entailed a significant amount of time spent on repetitive and tedious low level tasks.

Addressing problems with MEXAR2. The environment of space operation control center is the most conservative of all the work environments involved in a space program. This is to say that it is not the place where you can say “Hey! this is an AI tool for you to try”. People daily work at guaranteeing survival of the spacecraft and maximal robustness of its operations. The more tested before is a solution the more likely it will for it to be adopted. On this aspect, authors recognized they have been lucky, three years before operations, to have had the opportunity to study the memory dumping problem of MARS EXPRESS. This previous experience produced a working prototype, named MEXAR, able to solve a core problem close to the current one and allowed to start a trustful interaction with the MPS people. The prototype was not working on real data, because not available at that time, but different algorithms have been developed based on a CSP approach [5, 4]. The daily dump plan synthesis at ESA was so critic, and time consuming for humans, that in June 2004 we received a detailed description of the real data format and have been entrusted with the task of possibly improve the current practice on this work.

Thanks to the use of an AI declarative problem model we have been able to capture the data flow from real data very quickly (August 2004) and deliver a first solver able to synthesize dump plans even if several detailed constraints were still missing. Then a new solver has been developed, able to capture exactly the dump problem, and its solution have been validated by mission planners since October 2004. For six months our automated procedure have been continuously used back to back with the usual procedure in Fig. 2, and incrementally subtle bugs have been detected and solved. Since February 2005 our solver has replaced the previous procedure and ESA has asked us to design an interactive version of the tool and to further extend the capability of the solver. Since July 2005 an interactive AI tool, named MEXAR2 is entered in the daily loop of mission practice. A main advancement for the solver has been to solve multiple mission days problems while the interaction part offers to the mission planners a set of additional statistics and information on the

current solution and the possibility to obtain and compare different solutions.

3 AUTOMATING THE DUMP SYNTHESIS

The description of the details of MEXAR2 is quite synthetic due to space limit. This section and the next will show what kind of ideas has been integrated in the system.

Identifying relevant domain entities. The modeling activity to capture the basic need of the dump synthesis produces a symbolic model of the domain entities shown in Fig. 1. Our planning and scheduling background brought us to model the domain, identifying *resources* that serve *activities*. Two different types of resources are used for modeling (a) the different *packet stores*, pk_i of the SSMM. Each pk_i has its own fixed capacity, c_i , and priority, pri_i ; (b) the *communication channel*, that represents the downlink connections to Earth for transmitting data. This resource is characterized by a set of separated communication windows w_j that identify intervals of time in which downlink connections can be established. Each element w_j is a 3-tuple $\langle r_j, s_j, e_j \rangle$, where r_j is the available data rate during the time window w_j and s_j and e_j are respectively the start and the end-time of the window.

Activities a_i are characterized by a fixed duration d_i and two variables s_i and e_i which respectively represent their start- and end-time. Two types of activities are relevant, store operations st_i and memory dumps md_i . A store operation, st_i “instantaneously” stores, at its end-time e_i , an amount of data q_i in a defined packet store, pk_i . Two different types of data productions can be modeled by using store operations st_i : the *Payload Operation Request* (POR) from science, over certain intervals, and the constant rate Housekeeping Production.

Through a memory dump, $md_i = \langle pk_i, s_i, e_i, q_i \rangle$, an amount q_i of stored data is transmitted from the packet store pk_i to the ground station, during the interval $[s_i, e_i]$.

Problem constraints. A MEX-MDP (Mars Express Memory Dumping Problem) problem is composed of a set of scientific observations and a set of housekeeping productions allocated on a time horizon $\mathcal{H} = [0, H]$.

A *solution* (Dump Plan) consists of a set of dumping commands $S = \{md_1, md_2, \dots, md_{nd}\}$ such that a number of constraints are satisfied. Among such constraints there are: (a) at each instant of time $t \in \mathcal{H}$, the amount of data stored in each packet store pk_i does not exceed the packet store capacity c_i , i.e., overwriting is not allowed; (b) the whole set of data is “available” on ground within the considered temporal horizon $\mathcal{H} = [0, H]$, except an amount of residual data for each packet store pk_i less or equal to the capacity c_i ; (c) Each dump activity, md_i , is executed within an assigned time window w_j which has a constant data rate r_j . Moreover, dump commands cannot mutually overlap.

During the mission practice several decisions have been introduced as additional constraints for the problem solving. In particular, one of them strongly influences the problem solving: the *housekeeping data* describing the spacecraft internal status, need to be analyzed immediately by the MPS and consequently are to be downloaded within each operational day. Additionally, while the science packet stores can be preempted (multiple dumps are allowed), the housekeeping packet stores should be dumped with a single command. This specific constraint required us to create a hybrid algorithm that first performs a search to allocate housekeeping, then synthesizes the different science dumps on the remaining downlink window capacities.

Further requirements from the mission planners concerned the specification of priorities between different packet stores.

Additionally the mission planners had to minimize effects due to the uncertain estimation of data produced by some payloads. With respect to this we have investigated the issue of *solutions robustness*.

Algorithm 1: Dump Plan Generation

```

Input: problem P, policy parameters robust and priority
Output: Sequence of down-link commands Cmd
// Data Dump Level
// Produce a data allocation over the
// communication channel
while S uncomplete do
    S ← HousekeepingAllocation (P, priority)
    S ← MaxFlowAllocation (P, S, robust, priority)
    if No more HK allocation then
        break
// Packet Level
// Generate data commands
Cmd ← GenerateDownLink (S, priority)
return Cmd

```

Here robustness is oriented toward controlling the level of memory use in order to avoid possible loss of data due to overwriting. A possibility to overwrite data may occur when a volume of data greater than expected has to be stored and there is not enough space in the packet store. For this reason we define as robust, the solution in which a specified amount of space is preserved on each packet store in order to safeguard against overwriting. In other words, solution’s robustness is related to the concept of *distance to the overwriting state*. Hence, we consider the peaks of data in a packet store close to its maximum capacity as sources of schedule’s brittleness. A possible way to increase solution’s robustness is to *flat* these peaks by finding a different distribution of the dumping operations within the horizon $[0, H]$.

An effective hybrid solver. Given the domain entities of a MEX-MDP instance, two levels of abstraction for the problem domain have been considered: (a) a first level, *Data Dump level*, through which the amount of data to dump from each packet store for each time window, is assessed; (b) a second level, *Packet level*, that, given the results of the *Data Dump level*, generates the final dump commands. Such a problem *decomposition* is motivated by the complexity of the problem. In fact, this abstraction allows us to focus on the *dominant* aspects of the problem, i.e. data quantities, packets store capacities, and dump capability over the communication links, without considering the problem of generating dump commands. It is worth remarking that the packet level step can be automatically accomplished once a solution for the Data Dump level is computed (no failure is possible) so our main focus has been on the Data Dump level.

A high level description of the solving process is shown in Algorithm 1. The solving process contains two steps: a first which produces a data allocation over the communication channel. In particular, for each packet store and for each time window, the amount of data to download is selected. The second step, generates the down-link commands starting from the previous allocation. As said before the key aspect is the generation of the data dumps. This step is represented in Algorithm 1 by the *while* loop. Each iteration of the loop calls the following two procedures:

- *HousekeepingAllocation*: this procedure aims to find a consistent solution of the sub-set of the housekeeping packet stores. In fact these packet stores contain more important data (for spacecraft safety), no residual data are allowed, and all the data (of a single packet store) have to be downloaded by using one command (no-preemption).
- *MaxFlowAllocation*: given a partial solution from the previous step, this procedure generates the data dumps from the remaining science packet stores. This procedure is based on a reduction of the problem P (plus the solution of the previous step, S) to a Max-Flow problem: the former problem has a solution when the maximum flow in the latter equates the total amount of data to dump [4].

It is worth remarking that the max-flow approach is used only on the set of scientific packet stores and not on the housekeeping ones. In fact the last procedure is not able to stop preemption. To do this the HousekeepingAllocation is a backtracking search that generates at each step a possible dump plan for the housekeeping packet stores. These two steps will be iterated until a complete solution is found or no further alternative exists (we thus check if there is any allocation available). As we are facing a real problem we need to always give an answer. Then, at the end of the while loop we will have a solution S that is used to generate the final list of dump commands.

Additionally for all the procedures it is possible to set different parameters. The allocation in HousekeepingAllocation can be done considering the priority values of the housekeeping packet stores (parameter **priority**). The procedure MaxFlowAllocation accepts also a parameter **robust**. In this case we have an iterative max-flow based search that tries to flat possible peaks in the usage of the storage devices [4]. Also GenerateDownLink can consider the packet store priority values. In fact the input of this procedure consists of a set of data dumps for each time window. These are allocated in the interval but are not ordered, therefore they are ordered according to the priority values.

4 INSERTING MEXAR2 IN WORK PRACTICE

Besides the problem solving ability in synthesizing memory dumps, two other factors have been instrumental to the MEXAR2 adoption in work practice: (a) the seamless integration of the tool in the data flow of the consolidated work practice. Being the mission operational since more than six months, the fact that no change has been required in the format of data and in the current habit apart the fact to have a further support to the solution identification, has been very important; (b) the fact that the tool allowed a mixed initiative interaction style since its very early release. In MEXAR2 the users may interact with the tool, influence its behavior, and generate alternative plans, either changing the model or tuning the algorithm. This aspect has been a key factor for fostering users' contribution in a joint work with the tool, and for exploiting their knowledge, coming from experience and not easy to encode in the software.

These two aspects, have been instrumental to create users willingness to use the tool and ask for its modifications and improvements. During this phase several user's constraints have been made explicit, and once inserted in the tool, ended up adding value to the mixed-initiative style and to its acceptance by users. From our standpoint, it has been very important to keep the iterations for the refinements fast enough. To this aim the underlying declarative symbolic AI model has been very important.

4.1 Capturing the mission data flow

The current procedure for synthesizing dump plans with MEXAR2 in the loop is shown in Fig. 3. We first observe that MEXAR2 accepts as input directly the POR requests from the science plan, and the specification of the downlink windows from MPS. It produces as output the dump plan in the three formats expected by ESA people. This has been obtained by encapsulating the solver between two software modules: a first one responsible for processing the input files and selecting the relevant information for the symbolic model used by the solver, and a second one for generating the output according to external formats.

A second observation concerns the change of perspective offered to the mission planners. Users do not directly iterate in the attempt of "almost manually" producing the dump plan but rather establish a dialogue with MEXAR2, having access to the model of the domain and dials to tune the algorithms. From MEXAR2 they receive also additional information, for short referred to as Statistics in Fig. 3. This information enrich their ability to analyze the current solution. In general we have pursued the goal of allowing users to take more

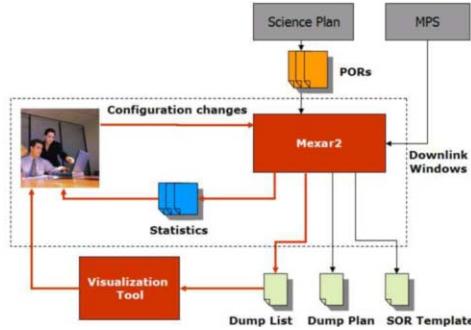

Figure 3. Mixed-Initiative Dump Plan Synthesis

strategic decisions, and maintain control over the synthesis of SORs, delegating to MEXAR2 not only the repetitive part of the work but also the proactive role of creating the dump plan. This has been achieved by exploiting MEXAR2 ability to work quickly and to consider clues given by solving strategies. Additionally MEXAR2 allows now to consider a temporal horizon previously impossible to tackle.

4.2 Fostering mixed-initiative problem solving

In Fig. 3 a dashed box underscores the main human-computer interaction loop fostered between users and MEXAR2. Given a specific dump period and an initial state of the world, the proactive role of MEXAR2 consists in computing a feasible dump plan for the period. Being relieved from the tedious and difficult part of the task, the mission planners can now concentrate on strategic decisions. MEXAR2 can be in fact iteratively configured to reproduce changes in the domain or to tune the parameters of the solving algorithms. In particular it is possible to create alternative configurations of the tool which correspond to diverse situations of the real world (e.g., different level of residual data, extra dumps based on incidental events, changes in priority of data to be downloaded, etc.) and quickly obtain the corresponding solutions from the tool.

Additionally users can tune the solver parameters (e.g., to take into consideration dangerous peaks of the packet stores level) thus actively contributing to the problem solving and guiding the search toward more intelligent and robust solutions.

A further valuable help of the mixed-initiative style is the possibility to jointly build, save and evaluate several solutions with the aim of avoiding potential data loss and more in general to look for more optimal results. Indeed, by using MEXAR2 as an active collaborator, overwrites can be quickly detected during the medium term planning process and fed back to the science community for POR update (i.e., to correct the case of anticipated data loss).

The main interaction module of MEXAR2 (see Fig. 4), reflects immediately the dialogue with the user: (a) the channel from mission planners to MEXAR2 is implemented through the pane called "Input Actions"; (b) the communication from MEXAR2 to the users is implemented mainly through the pane "Results and Statistics" that provides different output and secondarily through the pane "MEXAR2 Messages" that provides messages during each computation.

Input Actions. The basic action consists in the specification of the dump interval, the starting and ending dumping days – e.g, Starting Day 156, 2005; Ending Day 171, 2005 in Fig. 4.

Then, through three sub-panels, users communicate to MEXAR2 additional information. In particular (a) the "*configure*" action allows to specify the domain model, e.g., the specification of packet stores, their size, their respective priorities, their need to be robustified, etc.; (b) the "*initialize*" action communicates to MEXAR2 the residual memory stores from the previous temporal interval that are to be downloaded together with data related to new PORs; (c) "*selecting*" through this pane users can tune the parameters of the algorithms.

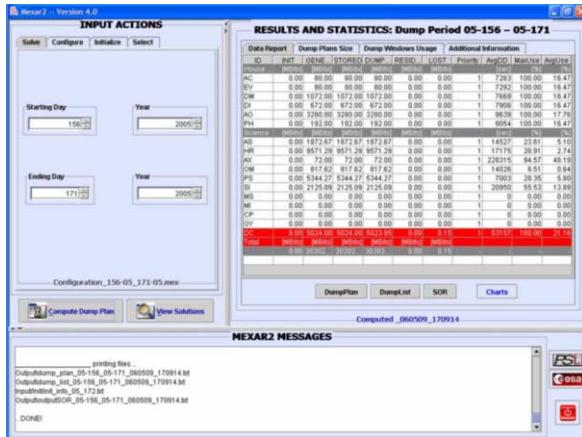

Figure 4. MEXAR2 Interaction Module

Automated solution. Once the needed context and the required parameters have been specified, users may ask the solver to compute a dump plan by clicking the “Compute Dump Plan” button. Feedback about the solver decisions is provided through the MEXAR2 Messages pane. As mentioned MEXAR2 provides different solving algorithms. A basic solving procedure looks for solutions without considering the packet stores priorities. A second one, takes into account the priorities, while a third algorithm aims at obtaining robust solutions. The pursued idea of robustness is the one of avoiding that a single memory bank is extremely full of data so that any variation at run time is difficult to be absorbed with consequent high risk of overwriting. An additional aspect that the algorithms have addressed concerns the “fragmentation” of the whole dump plan. In this respect the user can specify different thresholds, called input and output thresholds, that avoid production of commands too short or that dump too little data.

Inspection of Results. Once the solver has found a solution, the Interaction Module shows results exactly as in Fig. 4. A set of statistics are shown in the “Results and Statistics” pane that provides aggregate information on the current solution. In particular a panel named “Data Report” is shown, with entries subdivided into packet stores. This report gives the user an immediate view of the input/output data balance. Apart the Data Report table, the basic pane allows to access the three main files that are produced by the solver through three buttons (“Dump Plan”, “Dump List”, “Output SOR”). Recently ESA provided us a Visualization tool, developed in-house to validate results of MEXAR2, see Fig. 3, that has been inserted as an additional plug-in.

Computing different solutions. As said before we have worked to endow the system with functionalities that support the user in exploring different solutions. The mission planner can indeed generate different *use profiles* of the tools acting on the “configure” and “select” features and compare various results. To facilitate this activity we have also introduced an additional structure called *Solution Data Base* that, for any time interval, shows a table with all the solutions computed for the period. For each solution in the table, users can see the settings used to obtain it and a summarization of different metrics for evaluation (further details are omitted for lack of space).

5 SUMMARY OF ACHIEVEMENTS

In evaluating the main results obtained with MEXAR2 we consider two perspectives, namely the advantages for mission planners and the advantages for science management.

With respect to MPS a considerable advantage stems in the mixed-initiative style of the tool. The role of software which supported the

decision making in previous practice was really secondary and relegated to constraint checking tasks. On the contrary MEXAR2 is proactive with respect to plan synthesis while fosters, at the same time, human intervention and control during problem solving. In general data dump generation can now be performed quicker and with less effort and the quality of plans exceed that provided by the tools previously used. The problem of uncertainty in data production is addressed very satisfactorily from the user standpoint and the time saved for producing plans has been estimated to 50%.

The ability of MEXAR2 to generate plans over multiple days very quickly, allows mission planners to consider alternative solutions in order to avoid data loss. It is worth noting that before the introduction of MEXAR2 in the Mission Planning System, mission planners were satisfied with a single solution, while the tool guarantees the possibility of interesting optimizations. In fact, this allows to identify problematic intervals in the near future and negotiate with scientists alternative allocation of involved Payload Operation Requests thus minimizing overwrites.

The science community benefits from MEXAR2 as well: data from observations are available earlier and loss of data minimized. As already said potential overwrites can be quickly detected and fed back to the science community for PORs update. Thanks to MEXAR2 the use of the downlink channel is optimised and more data can be down-linked, thus allowing increase of science return from the mission.

6 CONCLUSIONS

AI planning and scheduling technology have been operationally used in US space missions from NASA and JPL [3, 6, 1, 2]. This paper has presented MEXAR2 the first case of operational use of such technology within ESA programs. We have described how a key aspect for the success have been the seamless integration of the tool in the work practice and the choice of developing an interacting software companion more than an isolated solver. Enabling conditions have been the fact that the dump plan synthesis problem was very critical during actual mission operations and that the very initial version of MEXAR2 have been soon able to cope with the real data flow at MPS.

Acknowledgements. This work has been sponsored by the European Space Agency (ESA-ESOC) under contract No. 18893/05/D/HK(SC). The authors would like to thank the MARS EXPRESS mission control team at ESA-ESOC for the valuable feedback received and in particular Erhard Rabenau and Alessandro Donati for their continuous assistance.

ECUE: A Spam Filter that Uses Machine Learning to Track Concept Drift

Sarah Jane Delany¹ and Pádraig Cunningham² and Barry Smyth³

Abstract.

While text classification has been identified for some time as a promising application area for Artificial Intelligence, so far few deployed applications have been described. In this paper we present a spam filtering system that uses example-based machine learning techniques to train a classifier from examples of spam and legitimate email. This approach has the advantage that it can personalise to the specifics of the user's filtering preferences. This classifier can also automatically adjust over time to account for the changing nature of spam (and indeed changes in the profile of legitimate email). A significant software engineering challenge in developing this system was to ensure that it could interoperate with existing email systems to allow easy management of the training data over time. This system has been deployed and evaluated over an extended period and the results of this evaluation are presented here.

1 INTRODUCTION

Spam email has proved to be a problem that is enduring and difficult to solve. In January 2004 Bill Gates predicted that spam email would be eradicated as a problem within two years⁴. The fact that this prediction did not come to pass demonstrates the severity of the problem. Spam is difficult to prevent because of the very open nature of electronic email and because the cost of sending email is close to zero. So even if the rate of return from spam is very small (less than a fraction of a percent) the practice is still worthwhile and there is a constant *arms race* between spammers and email system administrators as each moves to circumvent the initiatives of the other.

Of the wide range of strategies that have been employed to combat spam some of the more effective have been; whitelists and blacklists⁵, authentication based techniques⁶, collaborative filters[10] and content-based filters. In this paper we describe a system called ECUE (Email Classification Using Examples) that belongs to the category of content-based filters. The objective in the design of ECUE has been to produce a filter that learns from examples and can update itself over time to handle the changing nature of spam. ECUE is a fully engineered system that has been deployed in trials over an extended period with a number of users. ECUE interoperates with, but is independent of, the mail user agent (MUA) of these users and the

trials show that it is effective at tracking the changing nature of spam (see section 4).

Since the focus in ECUE has been on handling *concept drift* in email, the two main challenges in the development of the system have been to select an effective case-base from the volume of training data available and to update this case-base over time [7]. The issue of managing the volume of training data requires a case-base editing policy that selects those training examples that are better at prediction than others. This case-base editing technique is called Competence Based Editing (CBE) and has two stages, a noise reduction phase called Blame Based Noise Reduction (BBNR) and a redundancy elimination phase called Conservative Redundancy Reduction (CRR) [5].

The case-base update policy that handles concept drift centers on two hierarchical levels of learning. The first and simplest level is a continuous case-base update with training examples that have been misclassified by our filter. The second level is a periodic retraining of the classifier to reselect features that may be more predictive of spam and legitimate email. We will show how this update policy combined with the initial CBE case-editing procedure can effectively handle the concept drift that is so evident in the spam filtering domain.

In addition to these research challenges, the deployment of ECUE involved the software engineering challenge of integrating the filter with the users' MUA. The overall architecture of the system is described in detail in section 3 and an assessment of the performance of the system in filtering spam is described in section 4. Before that, a review of other work on using machine learning techniques for spam filtering is described in the next section.

2 REVIEW

Research into the use of machine learning techniques for building spam classifiers fall into two categories, those that are evaluated on static datasets in offline environments and those that are evaluated in online, real-time environments. The majority of the research falls into the former category [2, 4, 8, 9, 11, 13, 18, 19] with little published research showing how effective these techniques are at actually filtering real email over time. There are two key machine learning systems that have been evaluated against live email; Filtron [15] and Spamat [1].

Filtron is a prototype anti-spam filter that was designed based on a comprehensive off-line empirical evaluation of four learning algorithms, Naïve Bayes, Flexible Bayes, LogitBoost and Support Vector Machines (SVMs) [3]. It is a Java implementation that runs on Unix platforms only and was evaluated by a single user over seven months. The classifier used was an SVM as that showed the best performance in the offline evaluation, although the system is configurable and dif-

ferent classifiers can be selected. The system was initially trained on 2313 legitimate emails received by the user and 1826 general spam messages and used 520 features. It was never retrained over the period it was used and the performance was very good with 52 False Positives (legitimate emails incorrectly classified as spam) reported out of 5109 legitimate mails received (approx 1.0%) and 173 out of 1623 spam received missed by the filter (10.6%).

Albrecht et al.'s Spamat filter [1] is an open extendable spam filter framework implemented in Java utilising a plug-in filter architecture. The author's initial beta-test evaluation used a variety of plug-in filters including a number of URL-based filters, a Naïve Bayes classifier, a rule-based filter and a collaborative filter. This evaluation which filtered approximately 90,000 messages from a dozen users, resulted in 0.5% False Positives and 7% spam emails that were missed by the filter.

3 ECUE

A key requirement of our spam filtering system is that it integrates with or works alongside the MUA or mail reader rather than replacing it. This allows the user to continue to use the mail reader software with which they are familiar. To this end, the system architecture has been designed to support initially the Internet Message Access Protocol (IMAP) protocol [12]. One advantage of IMAP over POP3 (the other mail protocol) is that IMAP supports the storing of messages on the central server for access from multiple sites. By using IMAP to access the mailbox, messages can be filtered and flagged on the server and this allows the user to use any client mail reader application that supports IMAP to access and read their email. All the popular mail reader applications including MS Outlook, Mozilla, Netscape and Thunderbird support IMAP.

The user and the spam filtering system have to be able to interact for two reasons. Firstly the filter has to let the user know of emails categorised as spam and secondly the user has to be able to alert the filter to emails have been classified incorrectly. Since a requirement of the system is to integrate with existing mail readers rather than replace them, it is important to define a way of interacting with the user that is consistent across mail readers.

ECUE uses the IMAP mail folders as the means of system-user interaction. The filter places any emails it categorises as spam into a user-defined spam folder. It leaves any email that it classifies as non-spam in the Inbox. If the user finds any mails classified incorrectly they indicate this to the system by moving the emails from the folders they were in to or from the spam folder. So a False Positive (FP) email should be moved from the spam folder (where the filter had placed it) into any other folder, indicating that it should not be in the spam folder. Similarly a False Negative (FN) email, a spam email missed by the filter, should be moved to the spam folder to indicate that it should have been classified as spam. With this model for system-user interaction, existing mail clients do not have to be extended to enable them to be used with the spam filtering system. All interaction is at the mail server level. This is also a familiar spam interaction model for users. Figure 1 depicts the state transition diagram for an email message which shows all the possible states for an email message.

The main drawback of this process of user interaction is the requirement to monitor the spam folder for false positives. To address this ECUE produces a measure of classification confidence that can be used to partition messages classified as spam into definitely-spam and maybe-spam categories. The definitely-spam category need not be monitored for FPs [6].

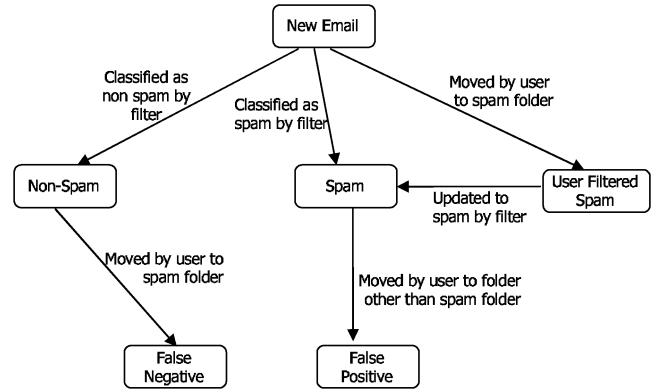

Figure 1. State Transition Diagram for an email message

In order to track the email message as it arrives and is filtered, an ECUE application specific header field is added to the email message. The value of this header field, which represents the state of the message as described in Figure 1, in conjunction with the folder the message is in indicates if and how the email has been moved by the user.

Mail folders are also used to identify the initial training data for the ECUE system. The user identifies the training emails which are to be used for the initial case-base set up by placing examples of their spam and legitimate emails into separate 'training' mail folders. These folders are identified in ECUE's configuration file and all emails in these folders are taken to be the initial training data.

3.1 The ECUE Learning System

The architecture of the learning system is described in Figure 2. The system uses previous examples of both spam and legitimate email received by the user as training data. In the initial training phase, the first process that the emails undergo is Feature Extraction which involves parsing or tokenising the text content of the training emails into features. No stop-word removal or stemming is performed on the text. Email attachments are removed before parsing but any HTML text present in the email is included in the tokenisation. As ECUE is a personalised filter, the header fields may contain useful information and a selection of header fields, including the *Subject*, *To* and *From* headers are included in the tokenisation. This idea is supported by a number of researchers [8, 17, 19] who concluded that the information from the message header is as important as the message body.

Three types of features are extracted; word features, letter features and statistical or structural features. The feature extraction process results in a large number of features for each training email. In addition, the representation of each email will be sparse, with only a small number of the total feature set having a value greater than zero. The Feature Extraction process for a typical training corpus will produce some tens of thousands of features. The task of Feature Selection is to identify which of these features are most predictive of spam or legitimate mails. The technique used for feature selection is Information Gain [16]. The output of feature selection is a reduced feature set where each training example email has a reduced set of feature-value pairs, including only those features identified as the most predictive. The number of features used by ECUE is configurable.

The task of Case Selection is to apply the Competence-Based Edit-

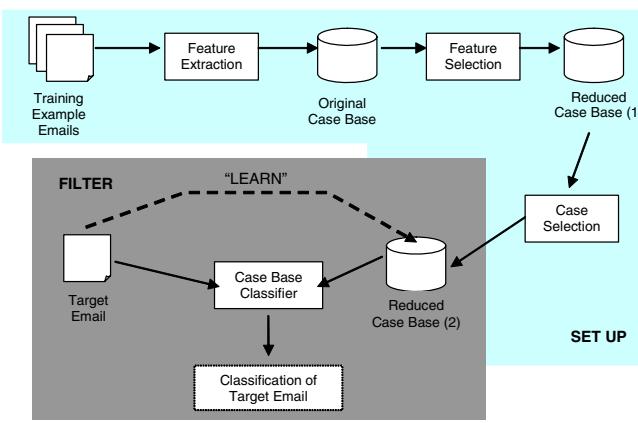

Figure 2. ECUE application structure

ing technique [5] which uses the competence properties of the examples in the case-base to remove noisy and redundant cases from the case-base. In effect Case Selection reduces the size of the case-base while ensuring that the generalisation accuracy of the system is not adversely affected.

In an example-based learner such as ECUE, the training examples are represented as cases in a case-base. Each training example is a case e_i represented as a vector of feature values, $e_i = (f_{1j}, f_{2j}, \dots, f_{nj}, s)$. The classification of new (or target) emails is performed using the k -Nearest Neighbour algorithm. As the case representation is binary, i.e. if the feature exists in the email the feature value $f_{ij} = 1$ otherwise $f_{ij} = 0$, a Case Retrieval Net [14] was implemented to speed up the retrieval process. The value of k is configurable and set up in the configuration file. A value of $k = 3$ was used for all evaluations presented in this paper. Due to the significance of FPs the classification process uses unanimous voting to bias the classifier away from such FP classifications. ECUE's unanimous voting requires all k neighbours retrieved by the Nearest Neighbour algorithm to be of class *spam* before the target case can be classified as spam.

ECUE uses different training data depending on the case-base that has to be built. If it is the first time the application is run after installation, ECUE uses training data that is placed by the user into two training folders in their mailbox. If a case-base is required to be built at any other time, e.g. when a feature reselection occurs, ECUE uses the most recent emails received by the user as training data. In these circumstances a percentage of the training data is made up of a selection of the most recently misclassified emails. The total number of emails to be used as training data is configurable as is the proportion of the training data that should comprise recently misclassified emails. This percentage is made up of all the FP emails previously identified (this number will be small) and an appropriate number of the previously identified FNs, randomly selected. An appropriate number of most recently correctly classified spam and non spam are then added to bring the training set up to the specified size.

When the user identifies emails that have been incorrectly classified by the system learning should take place. There are two levels of learning built into the system [7]:

- (i) incorrectly classified emails with their appropriate classification are regularly added to the current case-base;
- (ii) a feature re-selection process and a case-base rebuild is periodi-

cally performed on more recently received emails.

In order to help reduce and eliminate false positives, the system includes simple whitelisting which operates at two levels: Firstly, the user can define, in the configuration file, domains that will be acceptable to the filter. Any email that comes from these domains will be considered as legitimate. Secondly, the sender of all legitimate emails are maintained on a list and for all emails a case feature is set that indicates whether the sender is on the whitelist or not. This feature is used in the case-base retrieval process when identifying the most similar neighbours of the new email.

4 EVALUATION

ECUE was evaluated in a real-time online setting. The aim of the evaluation was to install the example-based spam filter in a 'live' environment and evaluate its performance. Since ECUE was designed to handle the concept drift in email the specific objective of the evaluation was to assess the *online* learning capabilities of the system. Over the evaluation period records were maintained of how ECUE performed both with and without the learning facilities.

ECUE was installed on the PCs of a number of users within the Computer Science department in two third level institutions in Dublin. The users were lecturers, postgraduate students and researchers within the departments. Since both institutions run a gateway spam filter (SpamAssassin) some users was asked to turn off SpamAssassin and to use ECUE for filtering their email. Others used ECUE as a second-level spam defense, filtering email that had passed through the gateway filter first.

When users identified emails that were misclassified by ECUE, they were asked to move the emails to the appropriate mail folders. Users were asked to initiate a feature reselection process when they felt that the performance of the filter was deteriorating or at least every couple of weeks.

The evaluation metrics used include:

- (i) The error rate; the overall proportion of emails that ECUE did not filter correctly (labeled %Error in all diagrams)
- (ii) The FN rate; the proportion of spam emails that ECUE missed (labeled %FNs).
- (iii) The FP rate; the proportion of legitimate emails that ECUE classified as spam (labeled %FPs).

For all these measures, figures are included for how ECUE performed when it attempted to handle the concept drift (i.e. with learning capabilites), labelled *with update*, and when the ECUE simply used the initial training data in filtering and did not attempt to handle the concept drift, labelled *no update*.

4.1 Evaluation Results

The evaluation was split into two phases. A preliminary evaluation involved an initial version of ECUE which included the case-base update facility, the first level of learning. The main online evaluation included both levels of learning, the regular update capability and the periodic feature reselection capability.

4.1.1 Preliminary Evaluation

Table 1 presents the results of the preliminary evaluation for six users. In addition to the performance figures, the table lists for each user the number of days that ECUE filtered the user's email and the

number of spam and legitimate emails that were filtered during that time period.

Table 1. Preliminary evaluation results

User	1	2	3	4	5	6
#days	28	34	30	50	70	41
Emails	#spam	969	618	80	890	3053
Filtered	#legit	191	422	390	2110	747
% Error	No update	8.1	9.6	7.5	20.7	22.0
	With update	5.6	6.5	4.5	8.0	10.7
% FPs	No update	1.6	2.4	5.0	0.6	1.5
	With update	1.0	2.1	1.8	0.7	2.7
% FNs	No update	9.4	14.5	20.0	68.3	27.0
	With update	6.5	9.5	17.5	25.4	12.6
						18.2

Analysis of these results show that ECUE performed better in all cases when update was enabled. Figure 3 shows a graph of the performance of ECUE for User 4. The graph shows the accumulated error (y-axis) over a certain number of emails (x-axis).

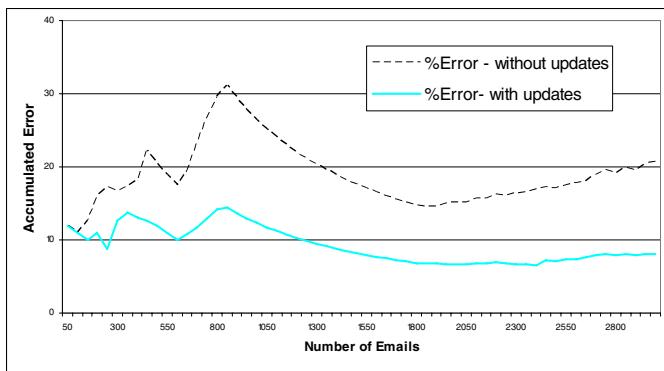

Figure 3. Performance of ECUE for User 4 in the preliminary evaluation.

However, improvements in the FP rate are not as consistent as the improvements in the FN rate. Four of the six users show improvements in the FP rate. Of the two remaining, one user (user 5) shows a considerable increase in FP rate from 1.5% without updating to 2.7% with updates. This may be explained by the fact that this user received very high levels of spam and the evaluation ran for a long period (70 days). As ECUE was very successful in handling the concept drift in the spam emails (the FN rate dropping from 27% to 12.6%) the system is being updated with a large number of spam emails to cope with this change and as a result becomes biased toward predicting spam.

The preliminary evaluation also showed that ECUE did not perform as well for users who receive high numbers of spam emails (users 5 and 6). These users had less than 90% of their email classified correctly whereas all other users had 92% or higher classified correctly. This indicated that it is necessary to include a further level of learning to allow a feature reselection to be performed to better handle the concept drift in the spam emails.

4.1.2 Full Evaluation

Table 2 displays the results of the full evaluation of ECUE. For each user the table lists the start and end date that ECUE ran on the user's

PC and the number of spam and legitimate emails that were filtered during that time period. The table also lists information about the training data used - the number of emails used (*initial size*) and what proportion of the training data was spam email (*%spam*). The number of times the user initiated the feature reselect process during the evaluation period (*#ftr reselects*) is included along with the performance achieved both with and without update, when update included a feature reselection process.

Table 2. ECUE full evaluation results

User	1	2	3	4
Filter Period	Start date	18-11-04	9-3-05	20-4-04
	End date	15-07-05	15-07-05	16-10-05
Emails	#spam	3689	4081	742
Filtered	#legit	1161	469	1480
Casebase	Initial size	308	299	201
	%spam	56%	54%	79%
	#ftr reselects	3	3	1
% Error	No update	32.8	21.8	17.3
	With update	6.1	4.7	12.1
% FPs	No update	0.3	0.0	1.3
	With update	0.7	0.2	1.1
% FNs	No update	43.2	24.4	49.3
	With update	7.8	5.2	34.0

Analysis of these results also show that ECUE performed better with update in all cases. Figure 4 shows a graph of the performance of ECUE for user 1.

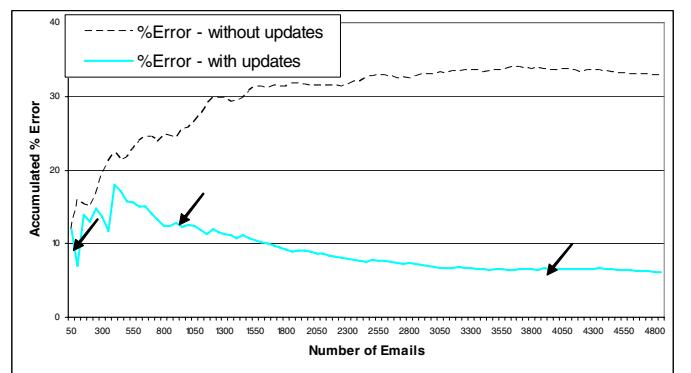

Figure 4. Performance of ECUE for User 1 in the full evaluation. The arrows show when the feature re-selection process occurred.

ECUE learned to recognise new examples of spam over the time period as is evident from the reduction in the FN rate for all users except user 4. The FN rate of user 3 did not drop as significantly as that of the others. This may be accounted for by the fact that all email received by user 3 was subject to initial organisation-level spam filtering on the mail server before it was forwarded to user 3's personal mailbox. As such, the spam email received by user 3 was spam that had been missed by the organisation-level filter and is possibly more difficult to recognise as spam. ECUE still identified 66% of user 3's spam correctly.

The bias of the classifier appears to be influenced to a large extent by the proportions of spam and legitimate email in the training data. User 4 received more than 12 times the amount of legitimate email as spam (possibly due to the success of the organisation level filter to

which user 4's email was subject). User 4 has a significant increase in FN rate, possibly due to the classifier becoming biased towards predicting non spam over the period of the evaluation. Similarly, users 1 and 2 receive significantly more spam email than legitimate email and display a slight increase in the FP rate. For these users the system is being updated constantly to try to cope with the spam concept changes and as a result loses some accuracy in the prediction of legitimate emails. Increasing the value of k in the k -NN classifier may be a way of controlling this bias.

A shortcoming evident from the preliminary evaluation of ECUE was that it did not perform as well for users who receive high numbers of spam emails. These users had less than 90% of their email classified correctly. Users 1 and 2 in the full evaluation have this profile with the proportion of spam received varying from 76% to 89% respectively. Both of these users had over 93% of their mail classified correctly. (93.9% for user 1 and 95.3% for user 2). In addition the average error across both evaluations dropped from 8.15% in the preliminary evaluation to 6.8% in the full evaluation indicating that the additional level of learning, the periodic feature reselection process, allows the system to better handle the concept drift in the spam emails.

5 COMMERCIAL PROSPECTS

Our preliminary commercial analysis suggests that the commercial prospects for message classification systems that can learn are considerable. While this area of spam filtering is a rather crowded market there is a range of other areas where large volumes of messages need to be filtered or routed. There is considerable potential for message routing systems for incoming email into volume accounts such as info@company.com. Compliance legislation such as the Sarbanes-Oxley Act in the US⁷ generates a requirement to be able to monitor outgoing message streams to ensure compliance. There is also a considerable market for systems for routing XML messages in the financial sector. An attractive aspect of many of these application areas is that a low level of error can be tolerated. If a message arrives at the wrong destination it can simply be re-routed manually.

6 CONCLUSIONS

In this paper we describe ECUE, an example-based spam filtering application that learns from new examples of spam and legitimate email. We believe that this is a landmark deployment of an AI application that incorporates online-learning in an unobtrusive way. As a lazy local learner, ECUE offers distinct advantages over alternative eager approaches to spam filtering such as Naïve Bayes or Support Vector Machines, approaches that are more common in commercial filters. It provides capabilities to learn seamlessly without the need for a separate learning process. Also, the fact that spam is a diverse concept makes a local learner, an appropriate choice.

The evaluations show that ECUE is successful at filtering mail at a personal level, identifying between 92% and 94% of spam correctly with less than 1.0% false positives identified. For users who used ECUE as a second-level spam defense, operating the filter on email that had already been passed through a organisation-level gateway spam filter, ECUE still successfully filters between 48% and 66% of the spam correctly albeit with a slightly higher false positive rate for one of these users of just over 1%.

⁷ <http://www.sarbanes-oxley.com/>

To conclude, there is no single approach that will be 100% effective at handling spam. The solution to spam is currently a multi-layered approach, utilising legislative measures, authentication techniques and filtering. Filtering plays and will continue to play a significant role in this fight against spam. We believe that ECUE, our example-based approach to filtering can be an important contributor to content-based spam filtering. We have shown how it can handle the changes in spam emails with relative ease without putting too much burden on the individual using it.

Knowledge-Based Recommendation: Technologies and Experiences from Projects

Alexander Felfernig¹ and Klaus Isak and Christian Russ²

Abstract. Recommender applications are used to support intuitive and personalized product and service selection processes for customers and sales representatives. In this paper we present a knowledge-based recommender environment which assists users in the identification of appropriate solutions from complex product and service assortments. We show how intelligent query relaxation, personalization and intuitive knowledge acquisition support the implementation of customer-friendly sales dialogues and report experiences gained in industrial recommender projects.

1 Introduction

Selecting from a large assortment of potentially complex items (e.g., financial services, computers, news, etc.) is still a challenging task since in many cases those items are offered using simple query interfaces under the assumption that customers have sufficient product domain knowledge [1]. Recommender technologies [2, 5, 11, 12, 16] improve this situation by providing support in the product selection process. An overview of different applications of recommender technologies can be found, e.g., in [13]. Compared to collaborative filtering [11] and content-based filtering approaches [3], knowledge-based recommender applications (advisors) [2, 5, 12, 16] exploit *deep knowledge* about the product domain for determining solutions fitting to the wishes of the customer. Using knowledge-based recommender technologies, the relationship between customer requirements and products can be explicitly modelled in an underlying knowledge base [5].

CWAdvisor³ is an environment supporting the effective development of knowledge-based recommender applications. The major innovations of CWAdvisor compared to other knowledge-based recommender approaches [2, 12, 16] are outlined below. Firstly, CWAdvisor includes a *graphical development and test environment* which supports the design, test and debugging of recommender knowledge bases and recommender process definitions [6, 5, 9]. This allows rapid prototyping processes by automatically translating graphical models into a corresponding advisor. Secondly, *model-based diagnosis techniques* [15, 6, 9] actively support customers in situations where no solution could be found. CWAdvisor can

identify *minimal relaxations* of filter constraints and determine a *minimal set of repair actions* for customer requirements, which guarantees that a solution can be found. Finally, recommender dialogues in CWAdvisor are *personalized* on the basis of an underlying finite state model [9] which describes possible interaction sequences. Using such representations, formulations of questions, answers, explanations, etc. can be personalized to the domain knowledge level and preferences of customers. Additionally, results of a recommendation process can be ranked using *multi-attribute object rating* [1].

We have successfully deployed a number of commercial recommender applications in domains such as financial services, e-government services, and typical e-Commerce application domains such as digital cameras, computers or TV sets. In order to show the utility of advisor technologies, we present an evaluation of deployed financial service recommender applications. Financial services recommendation is a knowledge-intensive task which in many cases overwhelms customers as well as sales representatives. Since the product assortment is quite manifold (investment, financing, pension, etc. - on an average about 40-60 products), many sales representatives focus on selling only a restricted set of products which leads to sub-optimal offers. The goal here is to identify a solution which fits to the wishes, needs and financial restrictions of the customer but also conforms to the sales strategy of the company. Furthermore, due to regulations of the European Union [17], financial service providers are forced to improve the documentation of customer advisory sessions. Detailed reporting is required which includes explanations as to why certain products were offered. For these reasons, financial service providers are extremely interested in tools providing an intuitive access to their product assortment.

The remainder of this paper is organized as follows. In Section 2 we introduce the CWAdvisor development and test environment. In Section 3 we discuss the set of AI technologies which are implemented in CWAdvisor. Finally, in Section 4 we summarize experiences from industrial projects and present an evaluation of successfully deployed applications.

2 System Architecture

The overall CWAdvisor architecture is depicted in Figure 1. Firstly, *CWAdvisor Designer* supports the graphical design of recommender knowledge bases. *Process Designer* allows the graphical design of recommender processes which describe the intended behavior of a recommender user interface [9]. *Test Designer* is responsible for the automated generation of test cases for recommender knowledge bases [8] and the interac-

tive debugging of recommender knowledge bases [6] and recommender process definitions [9]. Finally, *CWAdvisor Server* is responsible for executing recommender applications.

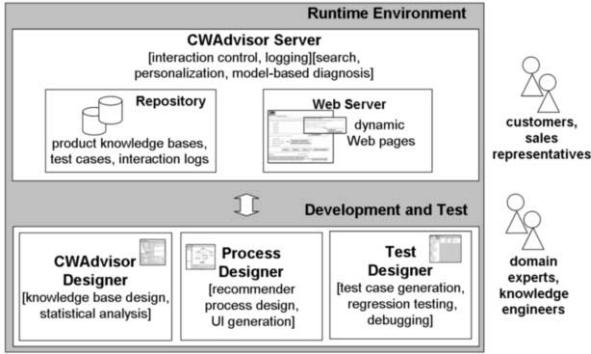

Figure 1. CWAdvisor Architecture.

CWAdvisor Designer. CWAdvisor Designer supports the graphical design of recommender knowledge bases. Such a knowledge base consists of the following parts [5].

1. Product properties are descriptions of the provided products, e.g., life insurances can be characterised by the possible length of life insurance policies, premiums of life insurance policies, or links to additional product documentation. Digital cameras can be described by their resolution, name of the producer, weight of the camera, etc.
2. Customer properties describe possible instances of customer requirements, e.g., within an investment advisory process the question *under the assumption that your investment of 10.000 EUROS decreases in value, at which value would you sell your investment?* is related to the willingness to take risks. In the digital camera domain, examples for customer properties are preferred motives (e.g., landscapes, portraits, etc.) or the maximum price of a camera.
3. Constraints restrict the possible combinations of customer requirements and products, e.g., return rates above 9% require the willingness to take risks or high resolution cameras are not provided in a low-price segment. Selection rules for products are denoted as *filter constraints*.

Process Designer. Besides the description of the relevant set of products, customer requirements and constraints, a process definition is needed to complete the model of a recommender application. A recommender process represents possible navigation paths which define the way the system adapts its dialogue style to the knowledge level and interests of the customer. Such process definitions are based on a specific type of finite state automaton [9] which represents navigation paths of a recommender application.

Test Designer. The increasing complexity of recommender knowledge bases makes quality assurance a critical task [14]. Within CWAdvisor, process definitions are the starting basis for automatically generating test cases for recommender knowledge bases [8]. Input sequences (examples for customer requirements) are automatically generated for selected paths of a recommender process definition, i.e., test case generation in CWAdvisor follows a path-oriented approach. A test case is the composite of one input sequence and a set of corresponding results. Generated test cases can then be presented to domain experts who decide on their validity (result

validation). Test cases that are considered as correct by the domain expert are used for future regression testing [10], i.e., if changes are made to the current version of the knowledge base, validated test cases are used to check the consistency of the new version of the knowledge base. On a more technical level, test case generation is based on the derivation of conjunctive queries from a given recommender process definition. For this purpose, a set of paths of a recommender process is selected. For each path in the set, a conjunctive query is generated and executed. Our experiences from developing recommender applications show that domain experts agree to accept the efforts related to the inspection of test sets since the quality of the recommendations is of serious concern, e.g., recommendations calculated for customers in the financial services domain must be correct in every case. The disposable time domain experts have for testing is restricted, therefore, we provide mechanisms which additionally reduce the number of test cases (see [8]).

Having completed the design and test of the recommender knowledge base and the recommender process definition, a corresponding recommender application can be automatically generated. An example for the user interface of a financial services recommender application is depicted in Figure 2.

3 Supporting Technologies

CWAdvisor supports a relational query-based approach, where a conjunctive query is dynamically composed from a set of filter constraints. The initial set of products to be presented as a solution to the customer is determined by executing the corresponding query on the product catalog.

Relaxation of Filter Constraints. Filter constraints describe the relationship between customer requirements and products, i.e., filter constraints determine which products are selected for a specific customer. A filter constraint is *active* if the given customer requirements are consistent with the precondition of the filter, e.g., if a customer is interested in short investment periods and a filter constraint enforces the selection of products with an investment period of less than two years in the case that a customer prefers short investment periods, the filter is active. There are situations where no solution can be found for a given set of customer requirements, i.e., the set of active filter constraints induces an empty set of selected products. In such a situation we support the *relaxation of filter constraints*. We apply concepts of model-based diagnosis [15] in order to identify a minimal set of filter constraints which have to be ignored in order to be able to calculate a solution fitting to a given set of requirements. Selection criteria for filter constraints are priorities, i.e., filter constraints with the lowest priority are first considered as candidates for a relaxation. Priorities can be defined a-priori by domain experts, or set during an advisory session.

Repair of Customer Requirements. In the financial services domain, in many cases filter constraints cannot be ignored or relaxed due to, e.g., legal restrictions or quality aspects of the recommended set of services. Simply reporting a retrieval failure, i.e., that no product matches all of the requirements, without making any further suggestions how to recover from such a situation is not acceptable or at least highly undesirable. Therefore, if we are not allowed to change the recommendation rules (filter constraints), we have to iden-

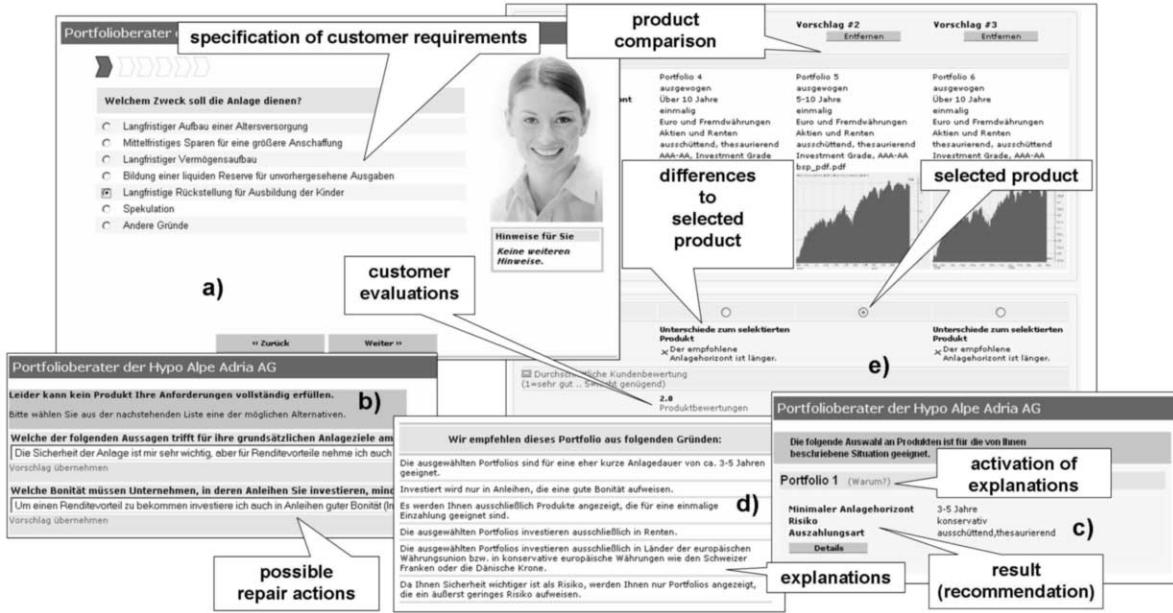

Figure 2. Example financial services advisor: questions are posed to customers and - depending on the given answers - further questions are determined (a). If no solutions can be found, a set of repair actions is presented (b). In the following, a set of alternative solutions including the corresponding explanations is presented (c,d). Finally, users can activate a product comparison component (e).

tify those requirements the customer is accepting to change in order to find a solution. Thus, our goal is to find a set of compromises (repairs) to be presented to the customer.

Similar to the relaxation of filter constraints, the computation of repair actions is based on concepts of model-based diagnosis [15]. The model-based diagnosis approach starts with the description of a system which is in our case the recommender knowledge base. If the actual behaviour of the system (set of customer requirements imposed to the knowledge base) conflicts with the intended system behaviour, the diagnosis task is to determine a *minimal* set of customer requirements which, when assumed to be retracted from the set of customer requirements, will explain the discrepancy between the actual and the intended system behaviour. Consequently, the goal is to identify a minimal set of variable settings in a given set of customer requirements which can be changed in order to identify a solution for the customer (i.e., the imposed customer requirements should be changed as little as possible).

An example for the calculation of repair actions in the financial services domain using model-based diagnosis is the following. Let $V = \{rr, wr, ip\}$ be the set of customer properties, where rr denotes the expected return rate ($\text{domain}(rr) = \{1-3\%, 4-6\%, 7-9\%, >9\%\}$), wr denotes the customers willingness to take risks ($\text{domain}(wr) = \{\text{low, medium, high}\}$) and ip denotes the investment period preferred by the customer ($\text{domain}(ip) = \{\text{short, medium, long}\}$) and $CR = \{c_1: \neg(rr > 9\% \wedge wr = \text{low}), c_2: \neg(rr > 9\% \wedge ip = \text{short})\}$ be the set of constraints in the recommender knowledge base. Furthermore, let $S = \{rr > 9\%, wr = \text{low}, ip = \text{short}\}$ be a given set of customer requirements ($S \cup CR$ is inconsistent). In this context, a repair is a *minimal* set of changes to S (resulting in S') s.t. $S' \cup CR$ is consistent. One possible repair S' for S is to change the requirement related to the return rate $rr > 9\%$ (to, e.g., $rr = 7-9\%$) which makes $S' \cup CR$ consistent. The second alternative is to change requirements related to the investment

period (e.g., $ip = \text{medium}$) and the willingness to take risks (e.g., $wr = \text{medium}$) which makes $S' \cup CR$ consistent as well.

Multi-Attribute Object Rating. A solution for a recommendation task is a set of products (e.g., financial services or digital cameras). The order of solutions should strictly correspond to the degree a solution contributes to the wishes of a customer (utility of a solution). CWAdvisor supports multi-attribute object rating [1], where each solution entry is evaluated w.r.t. a predefined set of dimensions. *Profit*, *availability* and *risk* are examples for such abstract dimensions in the financial services domain. Depending on the weighting of these dimensions for a specific customer (e.g., a customer is strongly interested in products with high return rates, i.e., compared to availability and risk, profit is important) solutions are ordered correspondingly (for details see, e.g., [5]).

Product comparisons. Comparison rules specify which argumentations are used to compare different products part of a recommendation result, e.g., if the risk rate of the selected (reference) product is lower than the risk rate of another product part of the result, then the comparison component should display the explanation *the risk level of this product is higher* (if product 1 is selected as reference product the explanation is given for all other products with a higher risk level).

Debugging Recommender Knowledge Bases. If a recommender knowledge base has been changed, regression testing (using Test Designer) is performed on the new version of the knowledge base. If there are (positive) test cases which are inconsistent with the new version of the knowledge base, a debugging process is triggered which calculates a minimal set of constraints to be changed in order to make the new version of the knowledge base consistent with the test base. The determination of such minimal sets is based on the application of model-based diagnosis (for details see [6]).

Debugging Process Definitions. In addition to the identification of faulty constraints in a recommender knowledge

base, we support the calculation of minimal sets of faulty transition conditions in recommender process definitions. When developing recommender user interfaces, mechanisms have to be provided which support the effective identification of violations of well-formedness properties of process definitions, e.g., if an input sequence reaches state q_i , there must be at least one extension of this input sequence to a final state (extensibility of input sequences). Path expressions form the basis for expressing such well-formedness properties on recommender process definitions. Details on the debugging support for developing recommender process definitions are provided in [9].

4 Experiences from Industrial Projects

Evaluations of Recommender Applications. We have deployed advisors in domains such as, e.g., financial services or digital cameras (see Table 1). In the following we present related evaluations.

Project	deployed in	number of users
Wüstenrot	2004	1.400
Fundamenta	2005	500
Hypo Alpe-Adria-Bank	2003	200 monthly
Geizhals	2003	10.000 monthly
Quelle	2005	600 monthly

Table 1. Examples for deployed recommender applications.

We have implemented financial services recommenders for online customers of the *Hypo Alpe-Adria* bank (www.hypoalpe-adria.at) (portfolio recommender and investment recommender). We evaluated those applications on the basis of an online questionnaire ($n=152$ participants, 23% denoted themselves as experts, 40% as beginners, the rest as having average knowledge in the financial services domain) where about 51% of the participants actively applied the recommender applications. Of those who applied the recommender applications, 98.5% were judging the provided recommender functionality as very useful when searching for financial service solutions. Within the scope of the questionnaire, the participants had the task to identify a specific type of product on the bank's homepage. In this context we have compared search times of those participants using a recommender application and those simply browsing Web pages of the bank (product fact sheets, etc.). In a comparison of the search efforts of the two groups we have identified a clear potential for reducing search costs. The average search time without recommender application support was about 10.5 min., a one-sample z-Test ($z=2.75$, $p < 0.01$) indicates that participants invested less time for product search if they used a corresponding recommender application. In addition to search efforts we also analyzed the subjective satisfaction with the provided advisory functionality of the homepage. The result of this analysis indicates an increased satisfaction with the overall advisory quality if a recommender is applied ($z=3.04$, $p < 0.01$). Additionally, CWAdvisor has been deployed for sales representatives of www.wuestenrot.at and www.fundamenta.hu. In both cases, financial service recommenders have been integrated into an existing Customer Relationship Management (CRM) environment that supports sales representatives in the dialogue with their customers (preparation, conduction and summary of sales dialogues). The motivation for the development of knowledge-based financial services recommender applications was twofold. Firstly, time efforts related to sales dialogues

should be reduced, i.e., time efforts related to the preparation and conduction of sales dialogues and time efforts related to the completion of sales dialogues (e.g., offer preparation). Secondly, a detailed documentation of advisory sessions should be supported in order to take into account regulations of the European Union [17] related to the documentation of advisory sessions in the financial services domain. On an average, a sales representative sells about 60-70 products per year, high performers, i.e., sales experts sell up to 500 products per year. One and a half years after the initial deployment of the recommender applications, we interviewed sales representatives of the *Wüstenrot* building and loan association ($n=52$), where about 23.1% of the interviewees were beginners (focus is on selling 1-3 different types of products), 28.9% were advanced sales representatives (selling more than 3 different types of products) and about 48.0% were experts (selling all products part of the assortment). Most of the sales representatives (81.8%) reported to use CWAdvisor functionalities throughout the sales dialogue or for the generation of documentations for completed advisory dialogues. Each such documentation includes a summary of customer preferences, a listing of recommended products, and an argumentation as to why the recommended products fit to the wishes and needs of the customer. In addition, about 53.8% of the sales representatives are applying financial service recommenders at home in order to prepare for the sales dialogue with the customer. In order to evaluate the satisfaction of sales representatives with the provided advisor functionalities, we have compared the evaluations of the CRM environment with and without advisory support. A one-sample z-test [4] resulted in a significant increase of the average level of satisfaction with the provided advisory functionality ($z = 10.83$, $p < 0.01$). No dependency exists between the expertise level of interviewees and the level of satisfaction with the provided advisory functionalities. On an average, interviewees specified the reduction of time efforts related to financial services advisory with 11.73 minutes per advisory session, where the majority of the reductions are explained by the automated generation of advisory protocols at the end of an advisory session and available summaries of previous dialogues at the beginning of a new advisory session. This corresponds to about 30.0% reduction of time efforts in the start phase and the final phase of an advisory session. Assuming that an average sales representative conducts about 170 advisory sessions per year, this results in a time effort reduction of about 33 hours per year for each person. A number of additional applications have been implemented on the basis of CWAdvisor, e.g., recommenders for www.quelle.at, one of the leading online selling environments in Austria and the digital camera advisor for www.geizhals.at, the largest price comparison platform in Austria.

Customer Acceptance of Advisor Technologies. Within the scope of COHAVE⁴ we have conducted a study [7] in which the key factors influencing the acceptance of knowledge-based recommender technologies by end-users were investigated. Examples for results of this first study within the scope of COHAVE are the following:

- Knowledge-based advisors clearly outperform simple product lists w.r.t. dimensions such as the overall satisfaction

⁴ COHAVE (Consumer Behavior & Decision Modeling for Recommender Systems) is a research project funded by the Austrian Research Fund (FFG-810996).

- with the advisory support, trust in that the advisor recommended the optimal solution or correspondence between recommendations and product expectations.
- Explanations of recommendation results significantly contribute to an increased trust in the recommended products, this is also associated with an increased perceived conformance between expected and recommended products.
 - Recommender versions including product comparison functionalities outperform all other versions (without comparison support) w.r.t. to all investigated variables. The reason for that is a lower mental workload of users when differences between products are clearly visually presented.

Knowledge Acquisition and Maintenance. Graphical knowledge acquisition is a major prerequisite for guaranteeing the maintainability and extensibility of recommender applications. In the financial services domain, the implementation and maintenance of knowledge bases must be supported for domain experts (typically non-programmers). Consequently, the knowledge acquisition component must provide intuitive and understandable modelling concepts. The most important functionality which has to be provided, is the automated generation of recommender applications. Domain experts want to experiment with different solution alternatives. This requires the support of prototyping-oriented development processes for recommender applications. In the case of www.wuestenrot.at, three domain experts are responsible for the development and maintenance of knowledge bases (investment & financing, pension & life insurance, property insurances).

We conducted a study with the goal to show the reductions of development and maintenance efforts triggered by the application of CWAdvisor automated debugging technologies. The study evaluates CWAdvisor technologies w.r.t. their advantages when identifying and correcting faulty constraints in recommender knowledge bases. Ninety-seven participants were confronted with a scenario in which they had to identify solutions for different types of error detection tasks. All the participants had experiences in the development of knowledge-based systems, especially experiences in implementing knowledge-based recommender applications. For each faulty knowledge base, one group of participants had to solve a diagnosis and repair task and one group (the control group) had only to solve a repair task with a predetermined diagnosis. Following this approach, we were able to compare efforts related to knowledge base development and maintenance with and without the support of automated debugging techniques. The major result of the study was that efforts related to the development and maintenance of constraints in recommender knowledge bases can, on an average, be reduced by about >30% when using an automated debugging support.

5 Conclusions and Future Work

Effective knowledge base development and maintenance and interaction mechanisms actively supporting users in the product selection process are crucial for successful recommender applications. In this paper we have presented the CWAdvisor environment which provides innovative development, maintenance and testing concepts allowing the effective handling of recommender knowledge bases. Furthermore, we have sketched the integration of model-based diagnosis and multi-attribute object rating concepts into the dialogue manage-

ment of recommender applications. These concepts allow the determination of minimal changes to a given set of customer requirements which can guarantee the retrieval of a solution and the ranking of recommendations in situations where more than one solution exists. The applicability of the presented concepts has been shown by an evaluation of successfully deployed advisors. There are different directions for future work such as, e.g., *automated test data generation and management* where we are working on the development of additional mechanisms supporting the selection of relevant test cases from a potentially very large set of candidates or the *integration of psychological theories from the area of consumer buying behavior* into design processes with the goal to increase acceptance and conversion rates of recommender applications.

Diagnosing Highly Configurable Products: Troubleshooting Support for Airbus Final Assembly Line

Andreas Junghanns and Mugur Tatar¹

Abstract. In this paper we describe the successful introduction of the model-based technology in a troubleshooting support tool for aircraft wiring under industrial conditions at Airbus, where strict cost/benefit analyzes decide over success or failure of a tool.

Aircraft built at Airbus Deutschland GmbH are highly customized products: virtually no two aircraft are identical. Troubleshooting support cannot be built in the traditional way of compiling static decision trees once and for all aircraft. Rather, diagnosis dialogs must be computed on demand for each individual aircraft.

Our solution is based on dynamically generating the diagnosis dialogs from on-line generated electrical signal nets. Generating diagnosis dialogs on demand is a considerable technical challenge. We have solved this with a combination of intelligent document extraction services and model-based diagnosis technologies. However, the paper focuses less on technical issues and more on the non-technological aspects that highlight the challenges of deploying well established intelligent technologies in industry.

For example, while existing engineering data is correctly interpretable by “fault tolerant and flexible” humans, it remains a challenging input for algorithms. Furthermore, some psychological aspects remain a challenge to the acceptance of the proposed tool.

1 Introduction

Providing troubleshooting support for highly configurable products is a challenge for the traditional methods based on “pre-compiled” troubleshooting manuals or decision trees. The model-based techniques [1] have the potential to overcome some of the problems in this context. However, specific challenges for this technology are the provision of cost-effective - if not fully automated - model building, and the reduction of the problem size to manageable dimensions. In this paper we describe the successful introduction of the model-based technology in a troubleshooting support tool for aircraft wiring under industrial conditions at Airbus. From a technological point of view, key solution features are: (i) the fully automatic model generation from on-line generated signal nets, and (ii) the problem size reduction based on the use of intel-

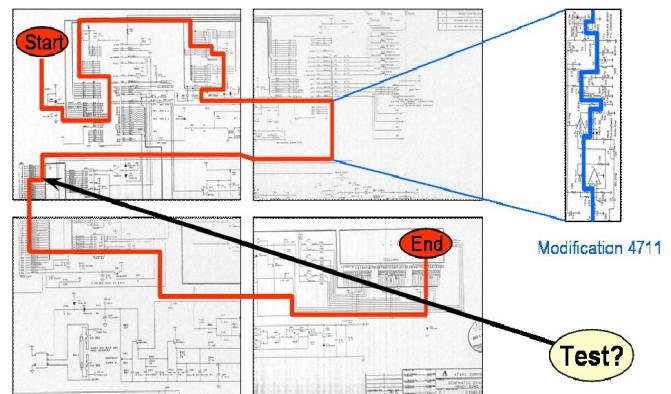

Figure 1. Example for Manual Wire Tracing

ligent documentation services that make use of connectivity information of components and subsystems and solve also all questions raised about the particular aircraft configuration.

2 Problem Environment

Airbus Deutschland GmbH assembles A318, A319 and A321 (short: single-isle) aircraft in Hamburg Finkenwerder from parts produced multi-nationally throughout Europe (Spain, UK, France and Germany) and delivers the completed Airbus to the client. The Final Assembly Line (FAL) is the central production unit for this process. Here is also where the testing of the aircraft’s electrical system is located. Even though all sub-assemblies are tested on their own, the aircraft is subjected to a rigorous, individualized, semi-automated system testing procedure. A computerized test system, called ESAO [4], is connected to the aircraft’s electrical system via multiple connectors and runs scripted test sequences. While executing a test script, ESAO uses peripheral devices

- to stimulate signals in the electrical aircraft system,
- to issue requests to the test personnel to manually change the state of the aircraft, e.g. to set switches or circuit breakers, and
- to read signals (sensors) from the aircraft’s system to compare against expected values.

Troubleshooting begins, when a difference to an expected value is detected. The following steps are currently undertaken

¹ DaimlerChrysler AG, Research & Technology, Berlin, Germany, E-mail: {Andreas.Junghanns,Mugur.Tatar}@DaimlerChrysler.com

by the test personnel:

- 1. Documentation:** Documentation is taken from a variety of sources, such as drawing databases, norm and standard documentation, applicable manufacturing rules etc.
- 2. Problem Reduction:** From all the available documentation the applicable (which aircraft) and desired (which subsystems) data needs to be extracted. Often, signals need to be traced by hand over several drawings of the specific aircraft currently under test (see Figure 1).
- 3. Diagnosis:** The test personnel can now change the state of the aircraft, stimulate and read signals in the electrical system in order to locate the faulty component(s).

Repair can begin after successful troubleshooting. No automated support or pre-fabricated information is currently available for the above process steps 2 and 3. Both troubleshooting steps are currently performed manually.

Airbus contracted DaimlerChrysler Research and EADS-M to analyze Airbus processes and suggest ways to increase the efficiency of the troubleshooting process at the FAL. Supporting the documentation phase, including the important wire tracing functionality, was the responsibility taken by EADS-M, while DaimlerChrysler Research assumed responsibility for improving the diagnosis process. A pilot (“proof-of-concept”) was implemented in 2003 to evaluate the suggested concepts and estimate the cost/benefit ratio for a production solution. The positive results lead to a contract to deploy a production version which was successfully installed in September 2005.

3 Project Analysis

At the beginning of the pilot project we concentrated our efforts on finding all the relevant *existing* data sources that were maintained well and could be expected to remain maintained in the foreseeable future. Our goal was to introduce troubleshooting support technology at the lowest possible cost, which means with existing data. Only when absolutely necessary we would consider gathering additional data. Then, after proofing the initial concepts, we could suggest possible extensions, including their cost/benefit estimates.

In a lengthy process of interviews and data analysis, we gathered information on data sources, internal data flows, information systems and responsibilities, compatibility of databases and future plans for these systems and their successors.

Furthermore, we spent several days at the final assembly line to learn about troubleshooting aircraft electrical systems first hand, getting to know tools and processes in order to understand how to support troubleshooting most effectively.

The data analysis interviews and visits at the FAL resulted in reports and recommendations and most importantly, in a list of solution requirements. The following subsections contain the most important of our findings.

3.1 Wire Tracing Data

Aircraft wire lists (AWL) and equipment lists are two fundamental ways to document in the aircraft industry. We were able to build on this information for the wire tracing functionality because most of the necessary information is contained in these lists.

Wire lists deliver connectivity information: Which wire connects which pins of which devices. In order to know which way the signal travels through a device, so-called shunt information is needed. This shunt information is part of the norm (standard) of the device. Equipment lists contain the part number of a specific device. Part numbers are usually norm identifiers which specify the device’s technical properties and behaviour, such as the time delay of relays, pin names and voltage requirements. Norm information is stored in so called master data.²

3.2 Norms and Specifications

While connectivity data is generally of high quality and therefore suitable for automatic model generation, we encountered challenges with the norm entries in the equipment lists, when reading it with our algorithms.

For instance, some low-volume, special order items do not have a proper norm. These devices are described by specifications to the supplier. Unfortunately, these specifications are usually drawings and documents. These drawing IDs are specified instead of a norm ID in the equipment lists. Furthermore, norm IDs are strings and are subject to different spellings, resulting historically from different national systems and styles.

Humans have no problem “solving” these irregularities because it is “obvious” to them how to distinguish between a norm ID and drawing ID, or how to adjust for missing/additional characters in a norm’s ID. In some sense, this data is correct given the contextual knowledge humans routinely have, but cannot be interpreted directly by a machine.

For the pilot project we added a few heuristic rules to catch a large number of the more obvious spelling styles. And still, we are unable to interpret 10-15% of the norm IDs. In these cases, the algorithms will detect a reference to an unknown norm and the wire tracing will stop at such a device prematurely, showing only part of the potentially larger signal net.

For the master data itself, pin information³ is generally available in machine readable form, shunt information is not. Because norms are not expected to change, we manually entered shunt information from standard sheets for the majority of the necessary norm IDs.

3.3 Diagnosis Data

For basic diagnosis functionality, nothing more than the wire tracing data is needed. However, with additional information, such as component fault probabilities, cost estimates for certain actions, such as state changes and tests, or signal types for each wire, the diagnosis dialog could be made more informed. However, and despite many attempts, we did not locate reliable, machine-readable sources for this kind of data and our solution had to do without these “nice-to-have” additions.

We analyzed close to 1000 troubleshooting reports and classified the problems found. We found out that if we could diag-

² For example, a norm would specify that pins A1 through A5 are all internally connected in a shunt of a terminal block. Or, that pins S1 and T1 of a relay are connected in neutral and S1 and U1 are connected when X and Y pins are subjected to a voltage drop.

³ Pin information specifies how many pins a device has and what their names are. In rare cases shunt information is encoded in those names.

nose “shorts to ground”, “broken components”, and “shorted to other signal”, we could support troubleshooting of well over 95% of all electrical problems. The remaining electrical “troubles” are failures such as wrong relay types (wrong time delay), resistor out of tolerance, temperature sensor defect or discharged battery.

In order to know where ESAO is connected to the electrical system of the aircraft, we used a database describing ESAO capabilities. Unfortunately, this system was designed for human use only. Therefore, substantial cleanup will be necessary in order to make this data complete and correct. We are currently using only a small subset of verified data.

4 Solution Description

This section sketches the technologies and tools used and the system architecture. The *documentation* and the *problem reduction* steps of the troubleshooting process are supported by the on-line intelligent documentation services. The *diagnosis* step is supported by on-line model-based diagnosis and test proposal services provided by our tool MDS [5].

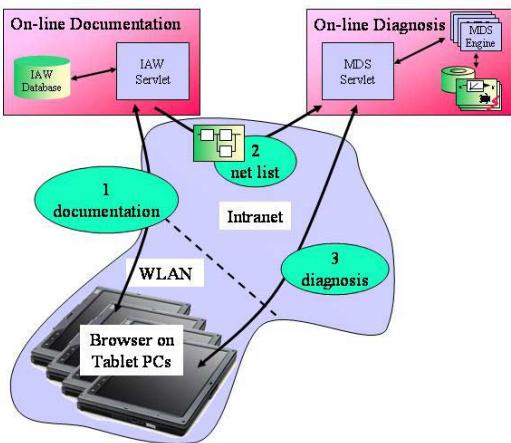

Figure 2. Solution Architecture

Figure 2 illustrates the solution architecture. The user interacts mostly with the remote documentation server (1). When requesting diagnosis support, the documentation system sends net lists to the diagnosis system (2). The user then interacts with the diagnosis support system (3).

4.1 Intelligent Documentation Services

The Customer Support Department at EADS-M in Ottobrunn has a long standing history in providing integrated product documentation technologies for different kinds of aircraft. Their key customer, the German Federal Armed Forces, deploys their Interactive Electronic Technical Documentation (IETD) software as stand-alone documentation without paper backup. The product documentation department imports data from engineering information systems into their production database. The import format is standardized by AECMA 2000 [3], providing an open interface to their software functionality. The production database integrates the data from

three nations and multiple engineering sources, verifies and re-compiles the data into internal database formats. This data contains all the necessary information about the individual aircraft, including configuration management and modifications. Error reports are generated when errors or conflicts are found.

The resulting database annotates the wiring data for fast retrieval. A highly configurable retrieval software offers multiple views on that data: classic wire and equipment lists, linked to master and norm data, aircraft manuals of all kinds.

The wire tracing functionality is important in our context. Given an arbitrary electrical component, all connected *signal nets* are generated and displayed. We call this component the *root of the signal net*. It is possible to focus the display on a single pin of the device. The resulting signal net is defined by all electrical wires and (simple) devices that carry the same signal. Nets are followed through wires, plugs and connectors, terminal blocks and splices, relays and switches to all meaningful signal ends. These are usually connectors into more complex devices. The display does not contain a classical wiring diagram, but a simplified network of devices and wires, annotated with device and wire IDs, offering pop-up menus with device properties, such as wire colour, gauge, EMC-class etc.

These nets can reach sizes of well over 400 wires connecting about 150 to 200 devices. However, these are manageable model sizes for the current capabilities of our model-based technology. Note that, this is a significant focus reduction compared to the tens of thousands of electrical devices and over 100.000 wires contained in each aircraft.

4.2 Model-Based Diagnosis Services

Model-based diagnosis is a well understood technology [1]. Its principles are beautifully simple and intuitive, and the technology's benefits are easily argued, theoretically.

In order to analyze a technical system using model-based technology, we need formally modelled component behaviour, e.g. based on qualitative or quantitative constraint models that capture physical and / or functional aspects of behaviours. Temporal aspects of behaviours are described by non-deterministic constraint automata in our system. Component type models are stored in a reusable model library. The system structure is needed in order to establish how components in a larger system interact with each other. Beside nominal behaviour, behavioural models for frequent faults, such as broken or shorted wires, are also specified. Assuming certain faults for components, we can evaluate the system model. All fault assumptions that produce simulation results consistent with the observed behaviour (measurements) are plausible faults. The diagnosis engine then proposes discriminating tests in order to reduce the number of alternative fault hypotheses. This troubleshooting cycle stops when either a unique fault is found, or no further tests reducing the set of plausible faults can be found. For an in-depth treatment of this technology see [2].

One of the advocated advantages of model-based technologies is the reusability of modelling effort when using model-libraries: Modelling the behaviour of an electrical component once allows its multiple reuse later, possibly parameterized to adjust the behaviour slightly. Usually, systems are assembled

by manually selecting and connecting components. When testing and diagnosing high-volume products, the cost for manual system assembly is easily amortized. However, at Airbus we are concerned with highly configurable and customizable systems - almost every aircraft is unique. The cost of manual system assembly would by far outweigh the benefits of diagnosis support. Therefore the solution used here is automated, on-line system assembly using components from a library and connectivity information from the on-line documentation services of the troubleshooting support.

When available, our system can deal with relatively detailed and complex component models that mix quantitative and qualitative constraints. However, there is a tradeoff between the additional benefit of using more elaborate models and the additional cost for acquiring (or cleaning up) the necessary data. Such an effort is in the present case not cost effective. The component models used here are rather simple, purely qualitative models - in effect, also the diagnostic support is quite basic. The bundle of the diagnosis technology with the product documentation doubles the benefit of the effort of maintaining the data and improves cost/benefit ratios.

The diagnosis and failure analysis software used in the project was developed over a period of several years and was already available before project start. A description of a previous version of the system can be found in [5], some specific aspects of the technology can be found in [6]. Numerous industrial projects and demonstrators for various clients have enabled us to create a powerful analysis tool fulfilling industrial requirements. Generation of guided diagnosis dialogs is but one functionality offered: others are decision tree generation, sensor placement, automated failure modes and effects (and criticality) analysis, model checking and others. This application only uses a fraction of the available functionality.

The test personnel, however, is never exposed to the complete tool functionality and complexity. A specially trimmed and simplified user interface was designed for the interaction with the test personnel (see Figure 3).

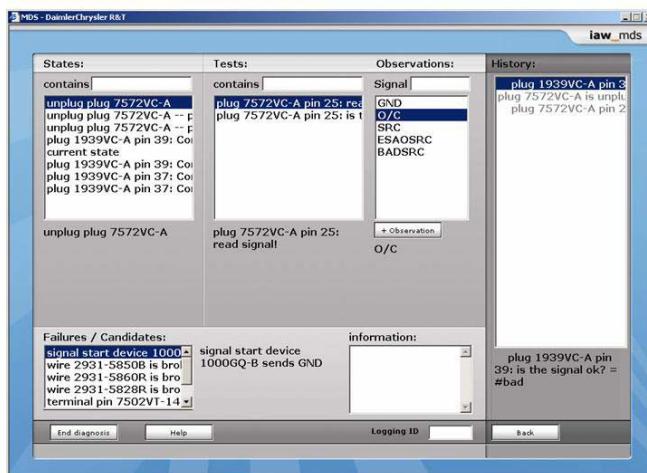

Figure 3. The Diagnosis Dialog

The user actions focus on the three central input lists:

1. Selecting one of the system states, possibly changing the

current state of the aircraft through control actions like changing the setting of a switch or by (un-)plugging a plug in left-most list,

2. Selecting a test from the second, sorted list, and
3. Selecting the result of the test in the third window.

Progress can be monitored in the lower left list of plausible failures. Adding more test results ideally reduces the number of plausible faults until no further discriminating tests can be found. Further features to support the user are history functions and filters.

This extremely simple, but highly intuitive dialog structure was deliberately chosen in order to make the basic functionality easily accessible to the tester and to avoid overwhelming them with too many complex features.

4.3 Uncertainty about the State of the World

Our diagnosis engine maintains consistent instantiations of the possible states of the system under test. Not only the correct or faulty states of the components are not known fully, also other state variables are incompletely known, for instance the connectedness of all switches, connectors, test equipment, etc. If one would inquire about all those details of the real-world state, the expected benefit of the system would quickly vanish, at least the users would run out of patience before the first viable suggestion would be made. Thus, assumptions have to be made. These additional state assumptions are treated by the diagnostic algorithms exactly like the correctness assumptions, but they are stripped out from the suggested diagnoses shown to the users. One way to deal with this uncertainty is to pick the most likely world state. Another one is to work with a superset of the most plausible worlds. We found the second approach to be the appropriate for user acceptance. Therefore we rather show too many test proposals and plausible faults than too few. Because the users know sometimes more about the state of the world, they can ignore inefficient or impossible choices.

4.4 Component Models

We were faced with a large number of Airbus components: tens of relays and switches and hundreds of typed terminal blocks and connectors. We have managed to reduce that set to a relatively small set of basic model elements. Let us consider the case of connectors as an example. We could have modelled all n-pin connectors explicitly. But this would not just mean an extremely large component library, but also many unused pins that are not part of the currently (reduced) signal net. Moreover, every pin of the connector, used or unused, increases the search space of possible faults by one more choice variable. Therefore, we compose connector instances from many basic pin models.

Detecting an unexpected symptom could also be caused by a problem in the test equipment, e.g. a broken wire from test computer to connector, a bent or broken pin of the connector. Since test equipment is under extreme stress because of its location in a production environment, such test equipment failures are more likely than aircraft electrical failures.⁴

⁴ The test personnel is first re-checking the setup of the test and its equipment, before starting a thorough troubleshooting session.

For all component types, beside nominal behaviour, we model mainly 3 types of component faults: shorts to ground, broken (no continuity), and connected to wrong signal (captures everything from badly isolated wire to bent connector pins). Again, we trust the intelligence of the tester; if we can blame a component with an abstract fault like “connected to wrong signal”, the tester has to be able to figure out the rest. The idea is to help narrow down the search to as few components as possible and leave the rest to the test personnel.

Because we generally lack quantitative information about signal types, we are using a finite set of generic signal types. If a wire or component is broken, that signal is interrupted (“O/C” is sent instead), and lack of continuity can be determined by comparing this value to the reference value, which assumes all components function properly.

Control actions, e.g. setting switches, unplugging and plugging connectors and test equipment, change the state of the system. They are part of the used component and system models based on the constraint automata framework used by MDS [6]. Test proposals, possibly also including required sequences of control actions, are generated for reading signals at all kinds of components, e.g. reading the signal on a pin or wire, or checking if an introduced continuity signal is present. Note, that reading the signal from a connector pin requires this connector to be unplugged (open). Since open connectors do not allow the signals to travel across, the maintenance of the correct state of the world, as affected by the (assumed or real) temporal sequence of control actions, is vital.

5 Technology Evaluation

The pilot implementation verified the technical feasibility of the solution. With a few changes, mainly to improve the flexibility and comfort of the user interactions, e.g. override system pre-sorting of tests, filters, undo and redo functions, we successfully built a production system. The feedback we received during training sessions with the test personnel strongly suggests that user acceptance will be high. Usage data is not yet available. Our tool helps to locate over 95% of all electrical faults. Systems exceeding 400 wires connecting around 150 to 200 devices can be diagnosed. Response times of the diagnosis engine is even for the largest systems within a few seconds.

Executing the test scripts with ESAO is a strictly guided and repetitive task. Many of the testers draw their job satisfaction from the intellectually challenging troubleshooting interludes. In fact, they pride themselves in their efficiency during troubleshooting. Providing a tool that reduces the challenge (fun) of the job does not find many friends.

Furthermore, efficiency is also a way to establish “seniority” among testers. Established hierarchies get challenged when helping the less efficient. Furthermore, the value of the tool for a senior tester is necessarily less than for a new employee. However, management is usually asking senior testers about their assessment of the tool.

It was interesting to see testers react to example diagnosis sessions with the pilot implementation. Humans are usually thinking linearly: When trying to find a discontinuity in a signal path, linear bi-section is the method of choice among most of the testers. This is also true because previously tracing a signal path was very tedious and very few testers bothered tracing the entire signal net (instead of the path alone).

But sometimes, it might be possible to exclude a number of plausible faults on the critical signal path by observing the signal off that critical path, for example because a connector out there is already open or more easily accessible. After observing the suggestions of the diagnosis engine a few times, the test personnel is usually quick to catch these patterns. And with the improved visualization given by the intelligent documentation system, this is also more intuitive. Of course, after the testers witness a couple of these patterns, it becomes increasingly harder to improve their efficiency with a guided diagnosis dialog. This training effect, especially for new test personnel, or radically new aircraft configurations, such as the A380, is an additional benefit for Airbus.

6 Summary

Building a real world application around a mature technology, such as model-based diagnosis, is still a non-trivial task. To achieve positive cost/benefit ratios, the use of existing data sources and the integration with the existing testing tools and processes is mandatory. Our solution takes this into account and demonstrates that even only with existing engineering data substantial troubleshooting support for highly varied products can be generated on the fly.

Packaging our solution with an intuitive, easy to use interface, hiding unnecessary details while maintaining usage flexibility, proved to have a vital effect on the user acceptance at Airbus.

7 Acknowledgements

The work presented here is an integration effort of two major software tools. Such an integration is impossible without the support of the teams involved. In Ottobrunn we would like to thank, first and foremost, Claudia Haubach-Lippmann and Johannes Gruber. In Berlin thanks go to the MDS team members Jakob Mauss and Volker May. We owe thanks to those supporting us at Airbus Hamburg: Olaf Kapitza, Martin Nagel, and Thomas Uhlendorf.

Web-Based Tools for Codification with Medical Ontologies in Switzerland¹

Thorsten Kurz² and Kilian Stoffel³

Abstract. This paper presents three aspects through which code retrieval from an medical ontology can be improved. First, the recall of correct codes can be increased by the application of appropriate morphological operations on query terms and the enhancement of concept names with synonymous terms. Secondly, the efficiency of a manual selection process from a result set can be improved by structuring the result set correspondingly to the original ontology. Finally direct enhancements to the structure and content of the ontologies can be made in order to personalise it. These methods were implemented and evaluated in tools for two ontologies of major importance in the Swiss health care system: the ICD 10 and the TARMED ontology.

1 INTRODUCTION

The use of ontologies has a long history in the biological and medical domain. Currently there are two medical ontologies that are playing a major role for all hospitals in Switzerland and that are used for exchanging information with external entities.

1.1 ICD 10 and TARMED

One of the oldest medical ontologies still in use today is the International Classification of Diseases (ICD) [5]. Its structure and its content have evolved and through the years and its domain of application has widened from a pure classification of death causes to a statistical tool for the surveillance of diseases. The roots of the first version of this ontology go back to the late 19th century, the current version is the 10th revision, the ICD 10. This is the version that is used by the Federal Office of Statistics in Switzerland to record the frequencies of diagnosed diseases, thus hospitals in Switzerland are obliged since 1998 to codify their patient records with codes from the ICD 10 ontology.

The ICD 10 contains 26400 concepts that are organised in hierarchical chapters. For each concept there exists one title and many synonymous names. Each concept has a unique code, by which his place in the hierarchical structure can be found clearly without ambiguity. These codes are used to refer to the concepts. In contrast to ICD 10 the TARMED ontology has been created recently starting from zero [8]. The purpose of TARMED is the exchange of billing information between hospitals and health insurances. Its use is mandatory in the Swiss health care system since January 2004. The TARMED

ontology contains about 4600 concepts to codify therapeutic and diagnostic medical acts. These concepts are structured into 38 chapters with sub chapters, some of these concepts can be also found in the 20 service blocks or in the 36 service groups where the concepts are grouped according to different criteria like medical processes or medical qualifications. TARMED concepts have titles, but they have no synonymous names in the versions that have been released so far.

TARMED concepts have unique codes too, although here the codes do not indicate the place of a concept in the hierarchy. Selecting precise codes from ICD 10 or TARMED is crucial for obtaining precise statistics or correct hospital bills. However in discussions with medical doctors, we found a rather low motivation to spend much effort on searching correct codes in the ICD 10 ontology. This is not too astounding, considering that the coding is often done by young assistant doctors without proper training in coding, and the coding is usually done at the end of a busy day with no real perceived need for correct coding. Very much in line with our impressions, a study of the coding quality in the two cantons Vaud and Valais found that the accuracy of the applied principal diagnostic codes is as low as 56.5% in the canton Valais and 65.3% in the canton Vaud [6]. It is to be expected that better results can be achieved by offering tools that make coding easier and more efficient.

The fact that TARMED is used for billing is leading now to an increased interest in correct coding. In contrast to the Federal Office of Statistics, insurance companies are applying a strict validation with the help of various software that ensures that codes are accumulable among each other as well as compatible with the age and the gender of a patient and last but not least with the qualification of the medical staff. For the hospitals coding therapeutic or diagnostic acts with TARMED means now to keep the balance between billing too little due to overseen applicable codes and getting bills refused due to not allowable codes.

1.2 Practical issues with ontologies

While the application domains of the ICD 10 and TARMED ontologies differ, the practical issues with those ontologies are quite similar:

1. Using an ontology, either for coding or for document classification and retrieval necessitates the ability to locate concepts and codes in the ontology. This is not as obvious as it sounds, especially not if a user is not familiar with the structure of an ontology.
2. There are concepts that are mutually exclusive or can only be combined with a limited number of other concepts. Other concepts can only be used in combination with some prerequisite concepts.
3. In different hospitals, there is often a local terminology in use that

¹ This work was supported by the Swiss National Research Foundation: grant number 2100-066898.01/1

² University of Neuchâtel, Switzerland, email: thorsten.kurz@unine.ch

³ University of Neuchâtel, Switzerland, email: kilian.stoffel@unine.ch

is not exactly corresponding to the terminologies used in the ontologies.

4. Some hospitals do already have code-based accounting systems in place that have to be mapped to the new TARMED ontology.

This paper is about methods that can make codifying more reliable and more efficient and about the tools, which implement such methods. Section 2 presents morphological operations on query terms, Section 3 discusses how to personalise ontologies, Section 4 describes the resulting tools, and Section 5 evaluates the performance of a current prototype.

2 FINDING CODES AND CONCEPTS

A strictly hierarchical access to the concepts through chapters and sub-chapters can only be efficient, if the chapter titles are sufficiently explicit about their content, and even in this case it is possible that a code belongs semantically to more than only one chapter. To find a concept in an ontology in this way is far from obvious, especially if the user is not familiar with this ontology. In health care services, where a large part of the coding is done not by coding experts, but by young assistant doctors and nurses, this is one aspect that leads to bad coding.

Therefore it is a promising idea to allow for an alternative access to the concepts, based on keywords and other methods from the information retrieval (IR) domain [9]. Each concept has a name consisting of at least one, but most times several words that can be searched for. Like in a search engine a query field is provided, which is used to search concepts by their keywords.

For clustering the results of a query the hierarchical structure of ontologies turns out to be very useful. Instead of displaying the resulting concepts as a flat list, the concepts of the result set are presented in the hierarchical structure that is obtained by using the original ontology, and keeping only those branches of the hierarchy that contain a class of the result set. This is especially effective for large result sets with more than 10 results [4].

2.1 Morphological operations with medical terms

A well-known morphological operation in IR systems is stemming, which is applied to words in order to reduce variant word forms to common roots. This operation improves a systems ability to match query and document vocabulary. Basically, it consists in removing the plural, verb or attribute endings of words, e.g., the words *hopeful*, *hopefulness*, *hopes*, and *hoping*, are reduced to their stem *hope*.

Medical terms differ from common language words in such as that they are often combinations of several Latin or Greek words. Each of these words carries meaning and contributes to the meaning of the term. Sometimes such word parts can stand alone as well as being part of a more complex word. That means that for one medical concept there can be many more or less similar synonymous expressions. For example the following lines are synonymous in ICD 10:

1. Kératoconjonctivite
2. Kérato-conjonctivite
3. Kéратite superficielle avec conjonctivite

Here it would not be enough to simply cut off the endings. To be able to do a successful matching of the expressions above, it is necessary to cut the complex words into their meaningful parts. Consequently a stemming algorithm has been developed that reduces a medical terms into the smallest possible meaningful parts and cuts

off meaningless pieces. Basically the algorithm works similar to the Porter algorithm [7] with the difference that its structure is more modular, which permits to adapt it progressively to the characteristics of the endings of medical expressions. Additionally there is a component recognition module that uses a list of known word components of medical terms [3].

2.2 Proposing alternative query terms

The current version of our search engine returns all concepts in which all words in the query are present (logical conjunction, AND). Being too specific in a query can therefore be inhibiting and prevent any concepts from appearing in the results, whereas a less specific query might eventually return a result set with concepts that satisfy the requirements of a user.

Trying out different modified versions of a query manually is annoying and time consuming. A better approach is to let the system propose less specific, potentially successful alternative queries with less keywords in case that a query is unsuccessful and returns zero results.

3 PERSONALISING ONTOLOGIES

The hierarchical structure and the vocabulary used in an ontology reflect necessarily the application domain for which it was conceived and the world view of its editors. This is not much of a problem, if the application domain stays the same over the time and all users share the same world view. But there are different points of view for an health insurance company, for the accounting department in an hospital and for a medical doctor or a nurse describing their therapeutic acts. And such differences exist not only between different types of organisations, but also between organisations of the same type, e.g., there can be differences in the vocabularies that are used in different hospitals.

There are hospitals, which have established an internal extension to the ICD 10 concepts that provide a finer distinction of diseases combined with their own vocabulary. Most of the Swiss hospitals are also already using their own creations or modifications of classification systems for therapeutic acts for internal accounting. And of course those classification systems are far from compatible with the logic imposed by the TARMED ontology.

With all these differences it is clear that there is a need for a common ontology to provide a common ground and a shared language, but there is also need to maintain a localised, even personalised access to the concepts in an ontology.

3.1 Adding synonyms

If codes are retrieved through an interface that supports keyword queries, the easiest way to provide a personalised vocabulary is to allow personal expressions and keywords for each concept to be used.

This can be accomplished by either changing the concept names to user-specific names or by attaching user-specific synonyms to each concept. The second solution was implemented in the here presented retrieval systems. The integration of a medical synonym dictionary was considered too, but this approach turned out to be too unspecific, resulting in a considerably decreased precision for the queries.

3.2 Adding access paths

In TARMED we find parallel to the hierarchical organisation of concepts in chapters also service groups and service blocks that allow

to access the same concepts based on different criteria like different branches and qualifications.

Swiss hospitals most times have already local classification systems for therapeutic acts in use and contrary to TARMED the doctors and nurses are familiar with these systems. So the most obvious step is trying to translate the existing concepts to new concepts in TARMED. Due to differences in the definition of the concepts e.g. TARMED is quite specific about the qualification required to carry out a medical act, duration of the act and inclusions or exclusions of other concepts - there cannot be an automatic direct one to one translation from the existing local concepts.

However it is possible to reuse the structure of existing local classification systems and to add to each local concept the potentially applicable TARMED concepts. Or otherwise to define a new hierarchy in order to structure the TARMED concepts according to departments, services or other personal criteria.

To support this, we have created an web-based ontology editor that allows to add new concepts and relations between concepts to an existing ontology, to assign to concepts different labels and to modify them.

4 ONTOLOGY TOOLS

Prototypes for ICD 10 and TARMED code retrieval systems were build with high performance knowledge bases as backed [2, 1]. The systems implement the methods presented in Section 2 and Section 3 to various degrees and are accessible through standard web browsers. The ICD 10 Explorer (c.f. Fig. 1) was our first prototype system and its query processing is not as advanced as that of the TARMED Explorer, i.e. the ICD 10 Explorer does a matching of the query with the ontology and returns the highest ranking results, even if they do not match a 100% of the given keywords.

Figure 1. The ICD 10 Explorer. Appearances of the query terms in the ontology are highlighted yellow. The concepts in the red box in the upper half of the screen are references to other chapters that contain also matching concepts, but are mutually exclusive with concepts from the current chapter.

The TARMED Explorer on the other hand returns only results that match 100% of the given keywords, but it proposes less specific queries that would lead to results, if no results are found for the original query. Neither the ICD 10 nor the TARMED Explorer allow online editing and enhancing of ontologies so far, this is the domain of another system, the TARMED Editor (c.f. Fig. 2), which offers only ontology editing so far, but no keyword search.

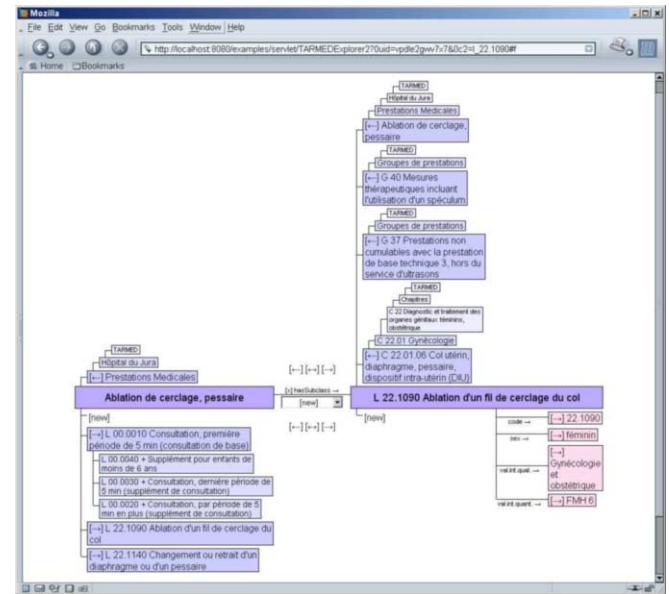

Figure 2. Mapping a local classification system for accounting to the TARMED ontology with the TARMED Editor.

5 EVALUATION

5.1 Code retrieval processes

The online prototypes of the ICD 10 and TARMED code retrieval systems have found many regular users in different hospitals in the French-speaking part of Switzerland and France. Among them is a French hospital that has made the ICD 10 system part of its coding procedure, so that we have currently the data of more than 40000 code retrieval processes to evaluate. An analysis of the log file shows a wide user base ranging from one-time users to users that come back frequently on a very regular basis (c.f. Table 1).

Table 1. Distribution of code retrieval processes per IP address (user).

Code Retrieval Processes per IP Address (User)	IP Addresses	Retrieval Processes
1-4	6811	(90.9%) 11211 (26.5%)
5-49	603	(8.1%) 8983 (21.2%)
50-499	68	(0.9%) 10526 (24.8%)
≥500	10	(0.1%) 11635 (27.5%)
total	7492	(100.0%) 42355 (100.0%)

A typical code retrieval process starts with a query from the user. The system uses the chapter hierarchy of an ontology to build a result tree and displays consequently only these chapters that contain codes that match the query. Then the user can start to browse through the result tree and eventually reformulate his query if necessary. All user actions are registered in a log file, which contains IP addresses, access times and dates, query expressions and the chapters and concepts that were visited. Thus we define a code retrieval process as a continuous sequence of queries and consequent browsing actions that are generated by one IP address, in which the queries have a similarity either in regard to their keywords or in regard to their results. *Continuous sequence* means that the sequence of actions is not interrupted for longer than a specific time interval. A visual log file

analyser gives a semi-structured view on those code retrieval processes (c.f. Fig. 3).

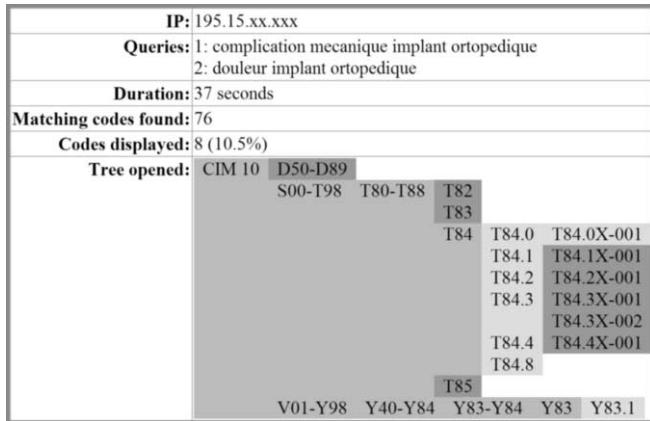

Figure 3. A semi-structured view of a code retrieval process with two queries that shows which parts of the result tree have been visited or ignored. Medium grey: Chapters of the result set that have been opened by the user. Dark grey: Chapters and codes of the result set that have been ignored by the user. Light grey: Codes that have been viewed by the user.

5.2 Efficiency, recall and precision

The average number of queries in a code retrieval process is 1.4, actually for 76% of the code retrieval processes only one single query was sufficient. The causes for code retrieval processes with larger query numbers are spelling errors, attempts to find a concept through a synonym that is unknown to the system and last but not least too unspecific queries that lead to too many results. Since the original report or bill that a user tries to codify remains unknown, it is never possible to make an absolute judgement if a returned code is correct purely based on the log data. Here it turns out to be helpful that results are not presented as a flat list, but as a tree structure. So instead of browsing through all results, the user decides which chapters seem interesting and worth opening. In fact usually the majority of chapters of the result tree is not visited, and this user behaviour can be used to distinguish between potentially correct and presumably incorrect results of query. An evaluation can be done based on the observation of which part of the result tree was visited, which one was ignored and which additional concepts were visited that were not part of the original result tree. Thus we define the *precision* of a result set as the percentage of visited concepts in comparison to the overall size of the result set. The precision is a measure for the relevance of a result set, the higher the value, the more relevant is the returned result set. Further we define the *recall* of a result set as the percentage of the visited concepts that were in the result set in comparison to the overall number of visited concepts during a code retrieval process. The recall is a measure for the completeness of a result set, the higher the value, the more complete is the returned result set. Recall and precision are here no absolute measures, but measures relative to a given system context, which allow to judge the impact of modifications of this system. Comparing those measures immediately after the first query and after the last query for all queries of code retrieval process together shows whether the additional queries really led to new information, i.e. increased recall and at what cost, i.e. decreased precision.

ICD 10 prototype uses a variant of the stemmer for French medical term which was discussed in Section 2. Based on the data from

Table 2. Performance of code retrieval systems with and without a stemmer module for medical terms.

	No Stemmer	Stemmer
Precision of first Query	40%	39%
Precision all Queries together	36%	34%
Recall of first Query	59%	79%
Recall all Queries together	65%	88%

the log file the code retrieval processes were reconstructed and sent to another system, which uses no stemming at all. Table 2 shows the comparison of the two systems. The usefulness of the stemming system becomes evident by the fact that the recall of the system with the stemmer reaches already at 79% after the first query, which is 14% better than a system without stemmer achieves with all the queries of a code retrieval process together. In each of the two systems can be observed that the further queries lead to increased recall (6%-9%), at the cost of some precision (4%-5%), but the recall of the system with the stemmer is 20% higher after the first query and 23% higher for the overall code retrieval process. The differences in terms of precision are far smaller, the system with the stemmer returns results that contain 1% to 2% less of relevant entries than the system without a stemmer. That means for accepting 2% more of not relevant codes in the result set, it contains 23% more of the codes that can be considered relevant for the request.

6 CONCLUSION AND FUTURE WORK

The development and testing of these tools is being carried out in close contact with medical professionals that are providing us with valuable feedback. Apart from positive feedback from those users, it was possible to quantify the benefits of a domain specific stemming algorithm. While most search engines are reluctant with the use of stemming because of fear of a considerable loss of precision, it could be demonstrated in case of the ICD 10 ontology that the loss of precision is smaller by factor ten compared to the gain of recall of potentially relevant codes. Considering the fact, that the user rarely knows the exact name of a code that he is looking for, there will be always several potentially correct answers to his query. Instead of forcing the user to browse through long lists of results, the hierarchical structure of ontologies allows to structure the results in a way that in average only 34% of the results are visited and taken into consideration by the user. This percentage becomes as small as 9% for large result set with more than 100 entries. The system doesn't try to be more intelligent than its users and therefore does not impose presumably "correct" answers on them, but presents information successful in a way that supports their decision making.

Both, the ICD 10 and the TARMED Explorer are currently running as stand-alone applications that can also be integrated in bigger frameworks as lookup-tools. The TARMED Editor will be evolving towards a multi-user editing environment and there is research going on to use the TARMED Explorer in combination with a voice recognition system for formulating the queries offline in a dictaphone.

ACKNOWLEDGEMENTS

We would like to thank Mr. Jean-Claude Vergriete for providing us with extensive lists of medical word components and synonyms and we also would like to thank the users of our system for their valuable feedback.

Model-Based Failure Analysis with RODON

Karin Lunde¹ and Rüdiger Lunde¹ and Burkhard Münker²

Abstract. The model-based reasoning tool RODON supports engineers in their quest for reliable, well-designed technical products, by providing means to analyze system behavior, especially in case of failure, systematically. Based on a quantitative product model, it offers a wide range of analyses, including reliability analyses such as FMEA and FTA or the generation of diagnostic knowledge such as diagnostic decision trees. An object-oriented modeling language enhances the reusability of models and, together with an integrated design environment and extensive model libraries, considerably reduces the modeling effort. In this paper, we describe the modeling framework and the model analyses supported by RODON (considering as example the model of a comfort seat), and characterize the technology behind them. Finally, we discuss the experience gained during the development of RODON.

1 Introduction

During the life cycle of a technical product, various analysis tasks are necessary to ensure system safety and soundness of design, such as requirements analysis, design, reliability analysis, optimization and maintenance. Different teams specialized in certain phases of the development process have to work together in a highly distributed environment. The more people are involved, the more the exchange of knowledge becomes a bottleneck.

Model-based engineering aims to incorporate as much knowledge as possible in formalized, computer-interpretable models and to share those models between the different phases of the engineering process. The scope of those models is not fixed and can include very different aspects of structural and functional knowledge. To support knowledge reuse, domain specific, product specific, and task specific knowledge has to be separated. The goal of model-based engineering is to improve process efficiency as well as product quality by automation and to reduce errors caused by misinterpretations.

Since the introduction of CAD systems in the early 80s, the exchange of formalized structural product knowledge has continuously increased. Today, CAD models originating from the design phase are reused in almost all later phases, for example to export part specifications for subcontractors like wiring harness suppliers, or to support product management systems. There are also promising examples for the reuse of behavioral models, like model-based code generation for embedded control units (MATLAB tool suite) or failure and reliability analysis (MDS [9], AutoSteve[11], or AUTAS [10], to name only a few tools).

In this paper, we present the model-based reasoning tool RODON. It provides a wide range of analyses, with a focus on failure analysis

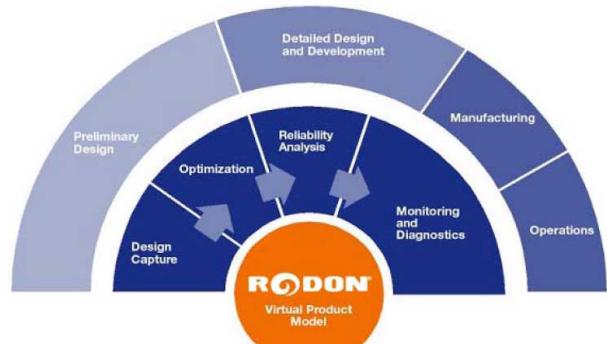

Figure 1. RODON's contribution to engineering tasks within the product life cycle

(see Figure 1). Based on a component-oriented, hierarchical model, which describes component behavior in terms of mathematical relations, RODON allows to

- simulate the behavior of the system in any state (which is part of the model);
- perform reliability analyses such as FMEA and FTA;
- compute optimal architectures for safety-critical applications;
- generate reliability block diagrams and failure trees;
- generate diagnostic knowledge such as diagnostic rules and diagnostic decision trees;
- perform interactive diagnoses with measurement proposal.

Since building and converting models between tools was identified as a major source of engineering effort, we attach great importance to the reusability of models. In the following, we describe the modeling framework and characterize shortly the algorithms which are at work behind the scenes to facilitate all those analyses. In Section 4, typical analyses are demonstrated considering as example a comfort seat model. A short discussion of lessons learned completes the paper.

2 Modeling in RODON

An object-oriented modeling language together with an integrated design environment and extensible hierarchical model libraries are the building blocks of a modeling environment which allows the engineer to create highly reusable and maintainable models with a moderate effort. In RODON, there are basically three modeling modes which differ widely in their degree of automation:

- The model topology can be imported automatically from CAD data, where component models are chosen from existing libraries.
- A model can be assembled graphically using existing model libraries (drag and drop).

¹ University of Applied Sciences Ulm, Germany, emails: k.lunde@hs-ulm.de, r.lunde@hs-ulm.de

² Sörman Information & Media AB, Heidenheim, Germany, email: burkhard.muenker@sorman.com

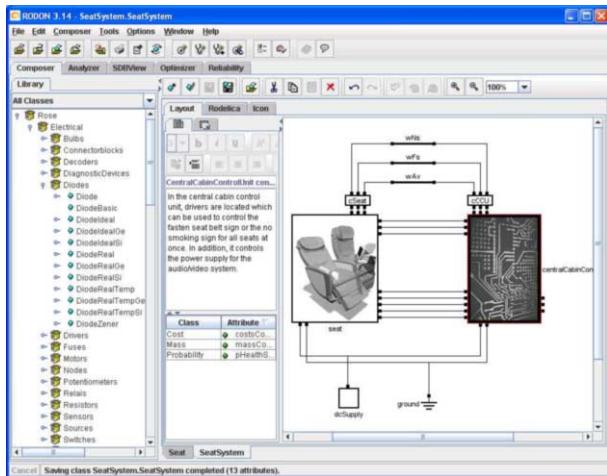

Figure 2. The model composer, at the left side the hierarchical library.

- A model can be built from scratch using the object-oriented modeling language Rodelica³.

In practice, these modeling approaches are frequently combined: The main structure of a model may be imported from a CAD tool, while some parts can be built re-using parameterizable library components, and company-specific parts have to be modeled by the engineer himself. The degree of possible automatization depends on how accurately the model structure matches the structure of the artifact. All models are organized within hierarchical libraries which can be extended continually by adding new models.

Object-oriented modeling Modeling in RODON is component-oriented, which means that the structure of the model reflects the structure of the artifact itself rather than the signal flow. In particular, this is essential for model-based diagnosis, where the engineer is interested in identifying the component whose failure caused the observed faulty system behavior. More important, a failure of one component can change the signal flow significantly, which restricts the use of a signal-flow-oriented model to certain behavior modes.

It is only a small step from a component-oriented to an object-oriented modeling paradigm. All essential properties of a component type are subsumed in a model class. It describes the interface of the component to other components, the substructure or the quantities which characterize its behavior, and their interactions in terms of constraints.

The concept of a model class is very general. Model classes represent components as well as connectors or physical quantities. They consist of attributes, behavior sections containing the constraints, and extends statements which declare base classes whose attributes and behavior are inherited. An attribute is defined by a name, which must be unique within the class, and a type, which is a model class (or an array of those). As primitives, Rodelica provides a set of built-in classes, e.g. Real or Interval. Besides, attributes and extends statements can contain parametrizations. Connections between the connectors of components are expressed by connect statements

³ Rodelica is a dialect of Modelica, which is a standardized object-oriented language to describe physical systems in a component-oriented and declarative way (see www.modelica.org). It differs mainly in the behavior representation, by using constraints rather than differential equations. This deviation from Modelica is due to the requirements of model-based diagnosis, where model behavior is often underdetermined (see [4]).

within the behavior section and translated into constraints at instantiation time.

The concept of inheritance greatly enhances the reusability and maintainability of model libraries: General knowledge can be encapsulated in more abstract base classes which are likely to be reused frequently. All changes which are made to a base class propagate automatically to all classes inheriting from it.

Uncertainty and constraints To solve diagnostic problems, explicit representation of uncertainty is needed. It may sometimes be hard even to predict a system's nominal behavior exactly. To scope all possible kinds of faulty behavior is in general infeasible. For some components, the number of all possible fault behaviors is infinite (consider e.g. a leak with arbitrary diameter in a pipe). And even if the number is finite, the number may be too high to be managed efficiently (e.g. shorted pins in a connector block).

Constraint techniques provide a convenient framework to represent this kind of behavioral knowledge. Arbitrary dependencies between values of different variables can be expressed by constraints which represent relations corresponding to the underlying physical laws. The representation is declarative. It abstracts from details how to perform simulations. The modeler does not need to direct relations by transforming equations into assignments or arrange sets of equations in a special order. It just suffices to formalize the relationships between the relevant variables. This abstraction makes it possible to arrange knowledge in a context-free component-oriented way. Especially the fact that constraint networks support reasoning about sets of possible values rather than exact values makes them well suited for diagnostic reasoning.

Constraint and data types The built-in classes can be understood as the data types provided by the modeling language. In RODON, the most important data types represent sets of integer numbers (built-in class Discrete), sets of boolean values (Boolean) or interval sets (Interval). Besides, the usual data types Integer, Real and String are available, as well as arrays and records. Several kinds of constraints are supported, providing the means to combine the quantitative and qualitative modeling approaches as appropriate:

- algebraic (in-)equalities,
- boolean relations (as formulas or truth tables),
- qualitative relations (tables),
- alternative behavior: conditional constraints and disjunctions,
- spline interpolation (for measured data or characteristics).

In some applications, it is adequate to use a directed modeling approach. For this reason, RODON supports assignments and algorithmic sections in models where values can be computed using elements known from programming languages, e.g. loops. Thus, the modeler can choose the modeling style and the level of abstraction which are particularly suitable for the task at hand with great flexibility.

An integrated design environment RODON's COMPOSER module supports the user in assembling, editing and debugging models. To the left, the library of the current project is shown. The user can choose between the compact tree view or a palette view, where the icons of selected library packages are listed. To the right, one or several class editors may be active (see Figure 2).

Each class editor features three main panels: the layout pane, the Rodelica pane, and the icon pane. In the layout pane, a model can be assembled graphically, by dragging classes from the library and

dropping them in the desired location on the canvas (thereby creating an attribute of the corresponding type), renaming and connecting them. A dialog assists the user in the parametrization, by showing the available parameters of the selected attribute and their admissible values. Besides, documentation texts can be assigned to the class as a whole and to each attribute. From the layout, a Rodelica text is generated, which can be viewed and edited after switching to the Rodelica pane. The Rodelica text and the layout view are synchronized — changes made in the Rodelica pane are visible after switching back to the layout pane. Finally, in the icon pane the user edits the external view at attributes which use the current class as their type, by assigning an icon and arranging connectors and labels around it. At any time, it can be checked whether the recent changes are syntactically correct and compatible with the project library.

3 Behind the scenes: The reasoning framework

The approach to model-based engineering followed by RODON is strongly inspired by the general diagnostic engine (GDE) [1] and its extensions for handling different behavioral modes [2] [13] and state transitions [14]. It is based on a reasoning framework which incorporates concepts from the classical approach to model-based diagnosis, such as component-oriented modeling, dependency tracking and conflict directed search for candidates. Reasoning is divided into two layers.

The first layer is the prediction layer. In this layer inferences are drawn to compute logical consequences based on a behavioral model and information about relevant system states (e.g. assumed fault mode assignments, symptoms, measurement results or top events). We describe technical systems as discrete-time systems. Constraints represent relations between different variables at the same point in time, and difference equations the evolution of state variable values from the current to the next point in time. During behavior prediction, two main analysis steps are performed in a loop.

Given value assignments of at least the dynamic state variables, the intra-state analysis tries to determine the values of all variables at a certain point in time. This step is an iterative domain reduction step. Based on the specified relations between the variables, the constraint solver successively prunes out those regions of the variable domains which do not occur in a solution.

The results of the intra-state analysis are fed into the inter-state analysis, which checks by evaluating the difference equations whether another state should be added to the current sequence, which value sets to assign to which state variable, and which time increment to use. By allowing both continuous and discrete time variables as state variables, events as well as continuous dynamic behavior can be simulated.

The second reasoning layer is the explanation layer. The methods applied here aim to find input parameter settings for the model such that it behaves consistently to some given external observations. In diagnosis, this includes at least assignment of a value to each fault mode variable. Additionally, a search in the possible space of other unknown inputs like switch states or hidden memory states can be included. Potential explanations are called *candidates*. The search for the most plausible candidates is determined by

- the definition of the candidate space, which is given by a set of variables and their possible values,
- the conflict information, which is obtained in the prediction layer by tracking the dependencies between the input parameters and their consequences during intra-state analysis, and additionally by

back-mapping [14] if a sequence of more than one state is analyzed, and

- some candidate orders defining minimality and plausibility.

Over the past years, this reasoning framework has been refined and extended in order to increase the reasoning efficiency without restricting the flexibility and expressiveness of the modeling paradigm. Most important are the following two modifications.

Inference completeness was improved by combining local consistency techniques with interval arithmetics, domain splitting and network decomposition (see [6]). The constraint solver extends the branch&prune algorithm (known from continuous constraint satisfaction problem solving, see [3]) by a network decomposition step and an interface to a reason maintenance system.

The reasoning efficiency was greatly improved by replacing the ATMS by a light-weight dependency tracking tool which we call the value manager (see [7]). In contrast to classical reason maintenance systems, the value manager actively controls resource consumption by applying data reduction techniques. Additionally, it incorporates strong focusing and data buffering.

A detailed account about the technology behind RODON can be found in [8].

4 Applications

4.1 Failure analysis of a comfort seat

In the following, we demonstrate several analyses provided by RODON by means of a simplified model of a comfort seat, like those in the first class of an aircraft. The seat model comprises an overhead unit featuring a reading light and visual signals, an audio/video unit, and three actuators to move the seat back horizontally and the foot rest both vertically and horizontally. Those elements are controlled by the operation unit which is situated in the arm rest. The seat control unit (SCU) contains drivers which process the incoming electric signals and drive the corresponding actuators or transmit messages via a bus to the central cabin control unit (CCU), as needed. The diagnostic trouble codes set by those drivers can be used by the service to locate faults.

In practice, the CCU controls all seats in the aircraft. From here, signals can be transmitted to all seats at once, e. g. to switch off the audio/video systems in case of a power drop. Each seat is connected to the CCU via a bus (modeled by electrical wires and connector blocks). The scope of the current model is restricted to only one seat and the CCU. Overall, the model consists of 183 components, 2540 variables and 2361 constraints.

Model-based diagnosis Consider a test of the comfort seat which involves checks of the three actuators, in the following order: Move the seat back forwards, then move the foot rest upwards, then move the foot rest inwards, and move the seat back backwards again.

When performing the test, it is observed that the seat back moves correctly, but the foot rest does not move at all. These observations, together with the switch positions in the four states of the test, are used as additional information for the diagnosis. Figure 3 shows the diagnosis: among all single faults there is only one candidate that can explain the system behavior in all four states, namely `seat.operationUnit.FootRestControl disconnected`; the next candidate is already a double fault. The dots at the end of the diagnosis denote the possibility of further double or higher order explanations. The diagnosis can be continued

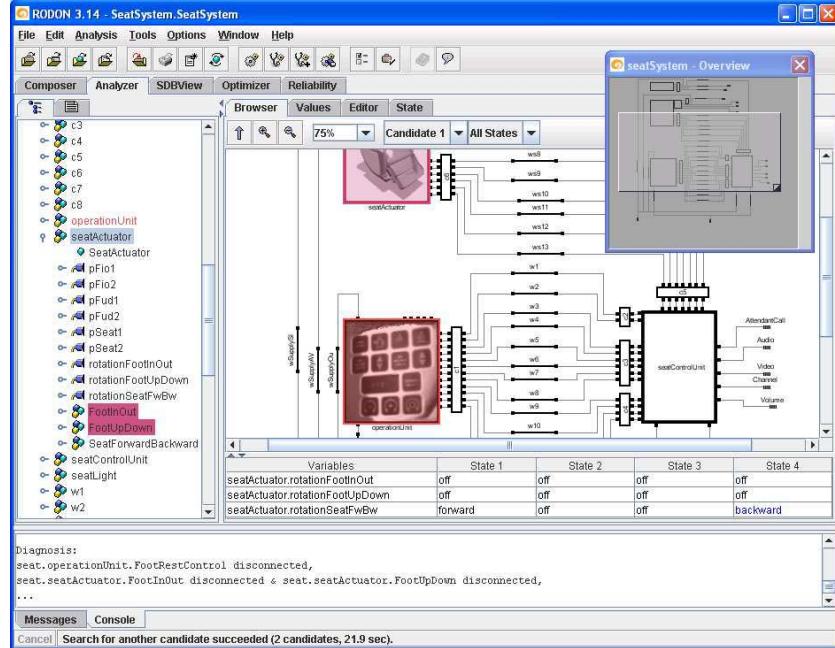

Figure 3. Model-based diagnosis of the seat system

upon request and would examine the candidates in the order of descending probability.

If the available information is insufficient to narrow down the possible explanations as far as in the last example, the tool is able to propose measurements whose results might help to eliminate candidates. Consider only the first two steps of the testing procedure above, with the same observation. Without the information about the outcome of the third test step, the model-based diagnosis finds alone 13 single faults which explain the malfunctioning foot rest. In such a situation, the interactive entropy-based measurement proposal may be used to restrict the set of candidates. The proposed measurements are listed in the order of their information gain, although the user is not bound to perform the measurements in that order.

Reliability analysis Comfort seats are not safety-critical systems, but frequent failures would annoy the passengers and are therefore to be avoided. A thorough reliability analysis in the design phase helps to reduce the probability of failures.

A common kind of reliability analysis is a failure mode and effects analysis (FMEA). RODON is able to generate the first columns of an FMEA table automatically. To this end, the user specifies which single faults and which operational states of the system are relevant for the analysis. The Cartesian product of all those operational states with the set of fault states (plus the state *System ok*) defines a so-called state space. An automatic simulation control module can then be used to perform simulations systematically for each state of the state space and to write the simulation results into a database, which we call state database (SDB). Finally, the desired table can be generated automatically, by evaluating and abstracting the SDB.

In Figure 4, a part of an automatically generated FMEA for the seat system is shown. The SDBVIEW module of RODON supports a great number of different views at the collected simulation results, among them a fault-oriented and an effects-oriented view. Customized table formats can be defined according to the requirements of the user.

4.2 Further applications

In addition to the systematic computation of an FMEA, the state database can be used to generate other knowledge representations, like diagnostic decision trees or diagnostic rules.

Diagnostic decision trees are used in the service bay to guide the mechanic through a failure analysis with minimal effort and costs. In a recent press release [12], Volkswagen confirmed that the RODON-generated test programs provide increased service quality concerning the maintenance of vehicle electronics.

Diagnostic rules represent a compact, compiled version of the model which can be evaluated efficiently. Therefore, diagnostic rules are well-suited for onboard diagnostics, where resources are usually scarce. For instance, the rules used in the onboard system's diagnostics (SD) of the Mercedes SL- and E-classes were generated by means of RODON.

For the reliability analysis of safety-critical systems, it is usually not enough to calculate the failure probabilities with respect to single faults (compare Figure 4). In such a case, RODON's special reliability module may be of use. For models which observe certain modeling conventions, it is able to compute minimal cut sets and failure probabilities for safety-critical functions algebraically. In addition, it generates the corresponding customary representations, namely reliability block diagrams and failure trees.

5 Conclusion

About seven years ago, RODON 3 started as a pure model-based diagnosis software but evolved gradually into a life-cycle support tool. The change in scope had mainly the following reasons, derived from our experience with various industrial customer projects:

- Besides the necessity to improve the diagnostic process with respect to flexibility and reliability, customer projects showed clearly that there is a growing need for automated diagnostic knowledge generation. Due to increasing system complexity, exploding variant diversity, and shortening product development

The screenshot shows the RODON 3.14 software interface with the title bar "RODON 3.14 - SeatSystem.SeatSystem". The menu bar includes File, Edit, Tools, Options, Window, Help, Composer, Analyzer, SDBView, Optimizer, and Reliability. The main window displays an FMEA table titled "FMEA (predicates) with rel. figu...". The table has columns for Fault, pHealthState, Effects, and Indications. The table lists several faults such as "cCCU disconnected", "cSeat disconnected", and various faults related to cabin control units and seat actuators. Each fault entry includes a probability value (e.g., 2.0001e-4t) and a list of effects and their corresponding indications.

Figure 4. Part of an FMEA of the comfort seat system.

To extend the FMEA table, the model has been enriched with probabilities, for all component fault modes in the model. During SDB generation, in every state a probability $pHealthState$ of the overall system is computed and written to the SDB, based upon the individual probabilities and with respect to the current fault state. As a consequence, this FMEA table provides, as an extra information (second column), a lower bound for the probability that a certain effect occurs.

cycles, diagnostic knowledge generation moves steadily from a practical experience-driven level towards a more theoretical level based on reasoning about construction data. For data processing and exchange, formal product description formats are needed, which cover structure as well as specified behavior. Component-oriented models like those used in model-based diagnosis are well suited for this purpose. To be able to serve as a vehicle for knowledge transfer, models must be generated in early stages of the product life cycle. But engineers which are involved in those early stages will spend time on modeling only if they benefit from this effort. This requires the modeling tool to provide additional functionality which helps them performing their own tasks.

- Modeling is always an investment since it consumes the expensive time of engineers. To maximize the return of invest, general reusable models should replace special purpose models in future, and be exploited wherever possible. Reliability analysis and diagnosis are related in many aspects. The needed product knowledge largely overlaps, and the level of abstraction in the knowledge representation is comparable. Additionally, common analysis algorithms can be used in both tasks. By extending the functionality of a model-based diagnostic tool to support reliability analysis, obvious synergy effects can be obtained.
- Compared to pure simulation approaches, our constraint-based approach with its ability to represent fuzziness and uncertainty explicitly gives the modeler more flexibility in his choice of abstraction level. This includes very high level abstractions, possibly qualitative ones, which are especially well-suited for very early stages of the product life cycle.

Our approach is well suited for realistic engineering applications (see also the examples in [5] and [8]). The main functional advantages in comparison to pure simulation approaches are the support of conflict-directed search strategies by dependency tracking, and the coverage of ranges of possible behaviors by set-valued reasoning about system behavior.

This additional functionality is not provided free of charge. For behavior prediction, pure simulation engines are significantly faster than the algorithms used within RODON. Although reason maintenance can compensate part of this difference, performance still remains a major issue when faced with the analysis of large systems.

Further improvements seem to be possible by combining numerical with algebraic methods. Especially in component-oriented models of electric circuits, a high amount of constraints consists of simple linear equations, which can easily be simplified by algebraic transformations. Therefore, the integration of such algebraic transformations into the reasoning framework seems to be a promising direction of further investigation.

A Learning Classifier Approach to Tomography

Kees Joost Batenburg¹

Abstract. Tomography is an important technique for noninvasive imaging: images of the interior of an object are computed from several scanned projections of the object, covering a range of angles. Traditionally, tomographic reconstruction algorithms have been based on techniques from analysis and linear algebra. In this paper we describe how a particular version of the tomographic reconstruction problem, known as *discrete tomography*, can be considered as a *classification problem*. By making this connection between two seemingly unrelated scientific areas, the full machinery of learning classifier theory can be used to solve tomographic problems.

The use of classifiers that can be trained from examples for tomography has two main advantages. First, prior knowledge concerning the images of interest can be learned automatically. Second, there are several types of classifiers that can perform the classification task very fast once trained. Real-time reconstruction is one of the main goals in tomographic imaging.

Tomography typically deals with huge amounts of high-dimensional data, which makes the corresponding classification task very hard. We describe several steps to reduce the dimensionality of the input data. For one type of classifier, the multilayer perceptron, we provide experimental evidence showing that it can indeed be used for efficient tomographic imaging.

1 INTRODUCTION

The field of tomography deals with the reconstruction of objects from their projections [4, 8]. In this paper we focus on *transmission tomography*, where projections are obtained by letting a beam (e.g., X-rays, electrons, neutrons) pass through the object of interest. Interaction of the beam with the object attenuates the beam, which is measured by a detector array after it has passed through the object. Figure 1 shows the basic idea of tomography. The attenuation of the beam along a certain line depends on the *materials* that the line passes through and the *lengths* of the corresponding line segments.

Since the start of its development in the 1970s, X-ray tomography has become a common tool in medical imaging for noninvasive scanning of patients. More recently, transmission tomography has been used extensively in electron microscopy for computing 3D reconstructions of samples [7]. Tomography is also used often in industry, for nondestructive testing of manufactured objects or reverse engineering.

Efficient algorithms are available for computing tomographic reconstructions. *Filtered backprojection* (FBP) is widely used, because of its simplicity and efficiency (see, e.g., Chapter 3 of [4]). The algorithm is based on the relation between the 2D Fourier transform of the unknown image and the 1D Fourier transforms of the measured

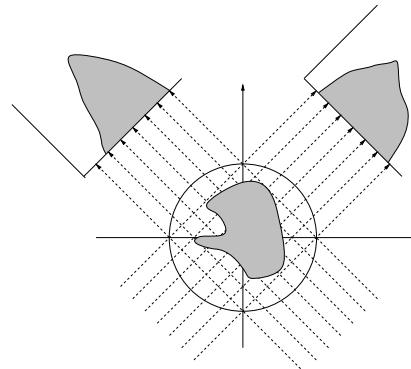

Figure 1. Basic idea of parallel beam transmission tomography.

projections. We refer to FBP and similar algorithms as *analytic reconstruction methods*, as the FBP algorithm is based on real analysis.

Another popular class of reconstruction algorithms uses methods from linear algebra to solve large, sparse systems of linear equations. If we represent the unknown image as an array of pixels then each measured line projection defines a linear equation on the values of these pixels, yielding a system of linear equations. Several iterative methods are available for solving this system, notably ART, SART and SIRT (cf. Chapter 7 of [4]). We refer to such methods as *algebraic reconstruction methods*.

Both analytic and algebraic reconstruction methods are *continuous* tomography algorithms, which means that the reconstructed image may exhibit a wide, continuous spectrum of gray values. Continuous reconstruction algorithms typically require a large number of projection angles to compute accurate reconstructions, i.e., more than 50. Reducing the number of projections is important, as it reduces the scanning time and – in the context of medical imaging – the radiation dose for the patient. One way to achieve this goal is to use additional application-specific prior knowledge in the reconstruction algorithm. It is desirable to automate the discovery of such prior knowledge, as the discovery process is usually difficult and time-consuming to do by hand.

The field of *discrete tomography* (DT) focuses on the reconstruction of images that consist of a small, discrete set of gray values that are known in advance [3]. Examples of such images can be found in semiconductor industry (semiconductor parts consist of few materials), medical imaging and crystallography. By assuming the discrete nature of the set of gray values it is often possible to vastly reduce the number of required projections. So far, most research in DT has been focused on the reconstruction of binary images (i.e., black-and-white). To reconstruct binary images from very few projections (i.e., less than 10), more prior knowledge has to be used, such as smoothness assumptions. At present, this knowledge is usually modeled by

¹ Leiden University and CWI, Amsterdam, The Netherlands, email: kbatenbu@math.leidenuniv.nl

hand.

The DT reconstruction problem can be considered as a classification task: there is a small number of classes (the gray values) and each pixel has to be assigned to one class, based on the projection data of the image. If a learning classifier can be trained for this task, using a set of application-specific training images, prior knowledge could be learned by the training algorithm instead of being modeled by hand. Another important benefit of using learning classifiers for DT is that the classification task can usually be performed extremely fast once the training phase is complete. This is particularly important for *real-time* imaging of dynamic processes [5]. Current DT algorithms typically take more than one minute to reconstruct a single slice of a 3D volume, which makes real-time imaging infeasible.

As an example, consider the problem of reconstructing a raw diamond slice from its projections (see Figure 2). A diamond consists of only one material, which leads to a binary classification task for the pixel values. The fact that the continuous reconstruction from Figure 2 is not completely binary, is the result of using too few projections and noise in the measured projection data.

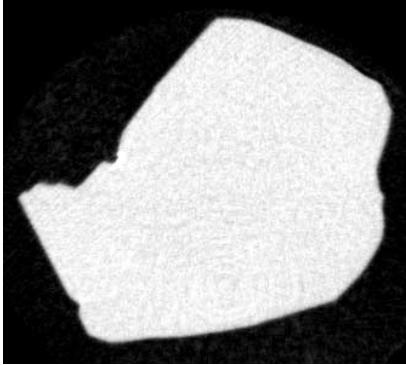

Figure 2. Slice of a raw diamond, reconstructed by continuous tomography from 125 projections; courtesy of DiamScan, Antwerp, Belgium.

Although the number of classes for the DT classification task is small, the dimension of the input space can be huge. Each point in the input space contains a set of measured line projections. If 10 projections are used, and each projection consists of 256 line projections, every input pattern for the classifier is a real-valued vector of 2560 elements. To make the problem even harder, the dependency of each pixel on the projection data is different, so it seems that a new classifier has to be learned for each pixel.

In the next sections we describe a series of steps that reduce the input data, making its size suitable for applying learning classifier approaches. We also show that by applying a suitable transformation to the input data, the same classifier can be used for all pixels, instead of having to learn a new one for each pixel. Not only does this transformation decrease the training time, but it also vastly decreases the number of training images that is required, as each pixel in a training image can now be used as a separate training example by the training algorithm. We present reconstruction results, using a multilayer perceptron as a classifier, which demonstrate that using a small set of training images already leads to good reconstruction results.

2 RECONSTRUCTION PROBLEM

Figure 3 shows the main setting of 2D parallel beam transmission tomography. The object of interest is contained within a circular

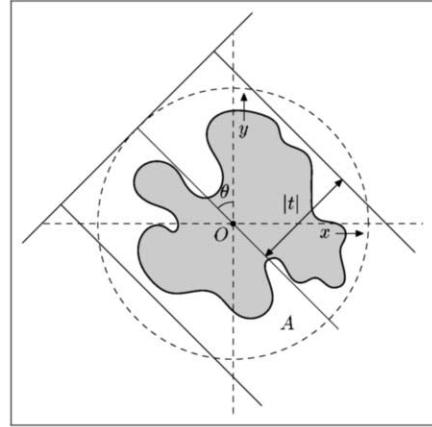

Figure 3. Schematic view of the experimental setup used in parallel beam tomography.

area A , the *imaging area*. A parallel source and detector array rotate around the object, measuring the projections from several angles. We assume that the object is *binary*, i.e., that there are only two gray values, for the interior and exterior of the object. In Section 5 we will discuss the generalization to more than two gray values.

The image of the unknown object that we want to reconstruct is considered as a mapping $f : A \rightarrow \{0, 1\}$. A value of 0 (black) denotes the exterior of the object and 1 (white) denotes the interior.

Projections are measured along lines $l_{\theta,t}$ of the form

$$l_{\theta,t} = \{(x, y) \in \mathbb{R}^2 : x \cos \theta + y \sin \theta = t\}.$$

The line $l_{\theta,t}$ makes an angle θ with the vertical axis and is at distance $|t|$ from the origin.

The *Radon transform* $P_\theta : \mathbb{R} \rightarrow \mathbb{R}$ for projection angle θ of the image f is defined as

$$P_{\theta,f}(t) = \int_{l_{\theta,t}} f(x, y) \, ds.$$

The function $P_{\theta,f}(t)$ measures the intersection length between $l_{\theta,t}$ and the interior of the object. It is also called the *projection* for angle θ and its values $P_{\theta,f}(t)$ are called *line projections*.

In practice, the function $P_f(\theta, \cdot)$ is usually not measured in single points t . Instead, the total projection in a strip covering a small t -interval (t_ℓ, t_r) , is measured as

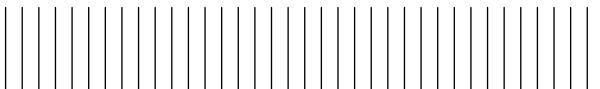

$$S_{\theta,f}(t_\ell, t_r) = \int_{t=t_\ell}^{t_r} P_f(\theta, t) \, dt.$$

The function $S_{\theta,f}(t_\ell, t_r)$ denotes the intersection area of the strip between l_{θ,t_ℓ} and l_{θ,t_r} with the unknown object. Typically, the value $S_{\theta,f}(t_\ell, t_r)$ is measured for consecutive strips of fixed width. In our approach we also need to evaluate $S_{\theta,f}(t_\ell, t_r)$ for other values of (t_ℓ, t_r) . These values are computed by linear interpolation of the measured projection data. The *tomographic reconstruction problem* deals with finding a function $f : A \rightarrow \{0, 1\}$ that adheres to a measured set of strip projections. Its solution is not necessarily unique. If the number of angles for which the projections are given is small there may be many, very different solutions. Therefore additional prior knowledge must be used in the reconstruction algorithm to obtain satisfactory results.

3 RECONSTRUCTING A SINGLE PIXEL

We now focus on the task of reconstructing a single pixel in a binary image from the given projection data. If the image has some local structure, such as smoothness, it may seem to be better to reconstruct all pixels simultaneously, as the gray value of a pixel depends on the gray values of its neighbours. However, the gray values of neighbouring pixels also depend on the projection data. Therefore, dependencies on neighbouring pixels can also be modeled as dependencies on the projection data.

In principle, it is possible to train a classifier by performing reinforcement learning directly on the measured projection data. Consider a typical discrete tomography problem, where 256 strip projections are measured from 20 angles. In that case the dimension of the input space for the classifier is over 5000, which makes the training task very difficult. Our approach to dealing with the high dimensionality is to perform a preprocessing step that maps the projection data to a lower dimensional space, while still capturing most of the important features. The intuitive reasoning behind this reduction is that the projection data for strips that go through a certain pixel are much more important to the value of this pixel than strips that are far away. To reconstruct a pixel, we use fine measurements near this pixel and coarse measurements further away. As an example, consider the case that we are only interested in reconstructing the central region of the imaging area. Figure 4a shows the strips as they are measured by the detector array. Since we only need a high quality reconstruction of the central region, we can use coarse strips outside this area, as in Figure 4b. By merging several consecutive detector values into a single ‘‘coarse’’ detector, the strip projections for the configuration in Figure 4b can be computed from the measured, fine strip projections. One may also wonder if we can leave the distant strip projections out completely, see Figure 4c. Figure 5 shows a binary phantom image (i.e., a test image) and three SIRT reconstructions from 30 projections, using the three strip configurations from Figure 4. On the right, a magnification of the central region is shown.

(a) Equally spaced fine strips.

(b) Fine strips covering the central region, exponentially increasing strip sizes outside

(c) Fine strips in the central region, no strips outside.

Figure 4. Three sets of detector strips that can be used to reconstruct the central region of the imaging area.

The reconstruction in Figure 5b was computed using all available strip projection data. The reconstructed image in Figure 5c, which was computed using very coarse projection data outside the central region, shows that the reconstruction quality of the central square remains almost the same. This suggests that to reconstruct pixels in the

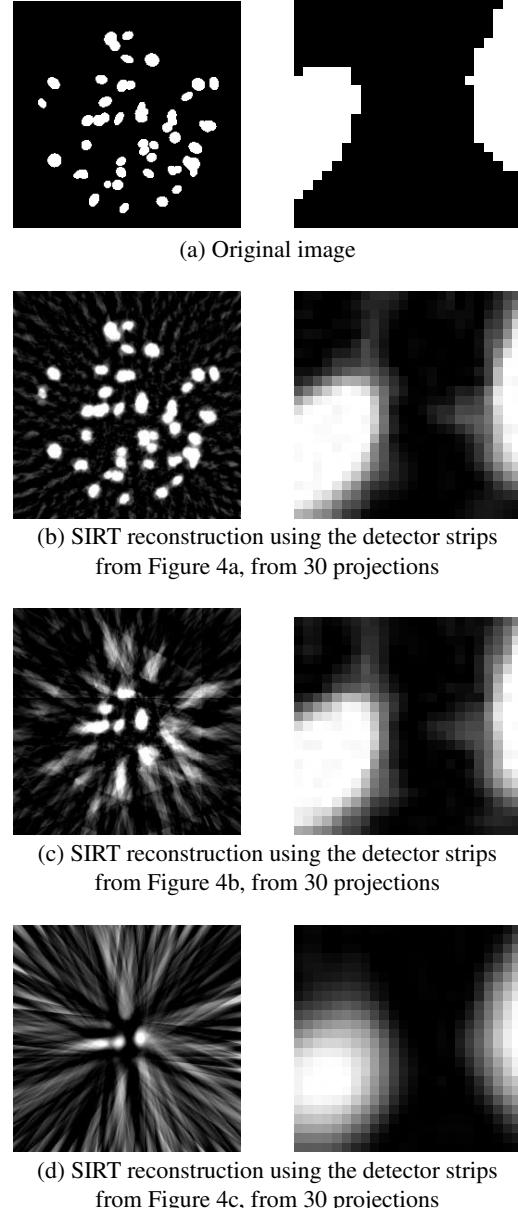

Figure 5. Left: A phantom image and three ART reconstructions, using the different sets of detectors strips from Figure 4. Right: Zoomed central region of the image on the left.

center of the image, knowing the most central part of each projection may already be sufficient. Figure 5d shows a SIRT reconstruction that was obtained by removing all strip projections outside the central region completely, corresponding to Figure 4c. We see that although the number of coarse strips in Figure 4b is fairly small, leaving them out of the reconstruction process completely results in an inferior reconstruction of the central square.

To reconstruct a single pixel instead of an entire region, we use even fewer strip projections. Starting from a fine strip that is centered on a given pixel p and the two direct neighbours of this strip, the width of the strips is doubled at each step further away from p . Using this exponential scheme, the number of strips for each projection angle is logarithmic in the number of detectors, vastly reducing

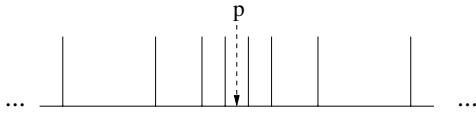

Figure 6. Starting from the projection of a pixel p , strips become exponentially wider as the distance from p increases.

the dimension of the input data for the classifier, see Figure 6. Note that the coarse detector strips do not correspond directly to physical detectors of the scanner. For each pixel, the strip projections for each of the corresponding coarse strips are *computed* from the measured projection data. By “compressing” the input data in this way, the number of inputs for the classification task is reduced from $O(dn)$ to $O(d \log n)$, where d denotes the number of projection angles and n denotes the number of detectors on the (physical) scanner. As we will see in Section 6, it is still possible to train a good classifier on the reduced input data.

4 FROM MANY CLASSIFIERS DOWN TO ONE

The main task for the classifier training algorithm consists of learning the mapping from the projection data to the value of a certain pixel. Clearly, the dependence of the pixel value on the projection data measured by the scanner is different for each pixel. However, after performing the compression step from the previous section, all input strip projections are *centered* around the position of the pixel. Therefore one would expect that a classifier that is trained for one pixel could also be used to compute the value of other pixels. The different dependencies on the measured strip projections are then addressed in the procedure that computes the input data for the classifier. The only remaining difference between the classification tasks for two different pixels is that the relative position of the imaging area A is different. If the set of training images contains some features that occur particularly often at specific positions in the image, the *position* of a pixel within the imaging area will be an important parameter in the classification task. To be able to model such location dependent information, two extra inputs are added to the set of input strip projection for the classifier, containing the x - and y -coordinate of the pixel. Figure 7 shows a schematic view of the resulting classification task.

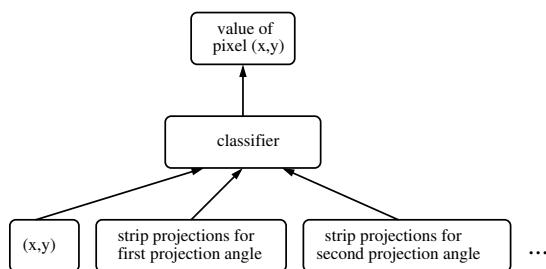

Figure 7. Schematic view of the classification task.

As the same classifier will be used to reconstruct each of the pixels, every training image (along with its projection data) can now be considered as an entire set of examples for the training algorithm: one for each pixel. In the experiments that are described in Section 6,

more than 10^7 examples are used to train the input-output relation. If a new image would be required for each new training example, the approach could not be used for practical applications at all, as it won't be possible to acquire so many scanner images. By using a single classifier for all pixels, each image that is acquired by the scanner yields thousands of training examples, which makes the approach practically feasible.

5 MORE THAN TWO GRAY VALUES

So far we have considered binary images, but the approach can also be used with more general images. For example, if all images in the training class contain three different gray values, the classifier may be trained to reconstruct the area covered by *one* of those gray values. The examples that are used by the training algorithm will still be binary images, that contain a 1 if a pixel has the desired gray value and a 0 otherwise. However, the projection data corresponds to the three-valued image. In that case, the classification that is learned by the training algorithm no longer corresponds to a conventional tomographic reconstruction. Using such a classifier, it may be possible to reconstruct an image of a single object in the tomographic scanner, while it is surrounded by various other objects. Doing this by conventional tomography algorithms would be an elaborate task: first the reconstruction that contains all objects has to be computed and subsequently the reconstruction has to be segmented as to separate the object of interest from the remaining part of the image. Section 6 presents several reconstruction results for images consisting of three gray values.

Clearly, our model can also be extended towards the full reconstruction of images that contain several gray values. The number of classes grows linearly with the number of gray values. The difficulty of the resulting training task is not only determined by the number of gray values and the types of images, but also by the difference between different gray values. Two gray values that have only a small difference will be difficult to distinguish.

6 RESULTS

Using compression of the input projection data of the classifier, as proposed in Section 3, reduces the input size significantly. Still, if more than just a few projection angles are used (i.e., more than 10) the input of the classifier may consist of more than 100 values. Tree-based classification models do not seem to be suitable for this task, as the number of features in the input space is too large. Both neural networks [1] and support vector machines [2] seem to be suitable for handling this large classification task. Efficient training algorithms are available that can deal with problems of this size. Neural networks for continuous tomography have already been proposed by several authors (see, e.g., [6]).

To demonstrate the feasibility of implementing tomographic reconstruction within a common learning classifier framework, we implemented a multilayer perceptron (MLP) with one hidden layer and backpropagation learning. All neuron activation functions are sigmoids. The network contains 50 hidden nodes and is trained for 200 epochs, each consisting of 250.000 training examples. Recall that a training example corresponds to a *pixel* of a *training image*, so each training image yields many different training examples. The MLP has one output, corresponding to the pixel value, which is thresholded at 0.5 to obtain a binary output. The training set consists of 1000 random binary images that have been formed by first drawing four white ellipses to create an “object” and subsequently draw-

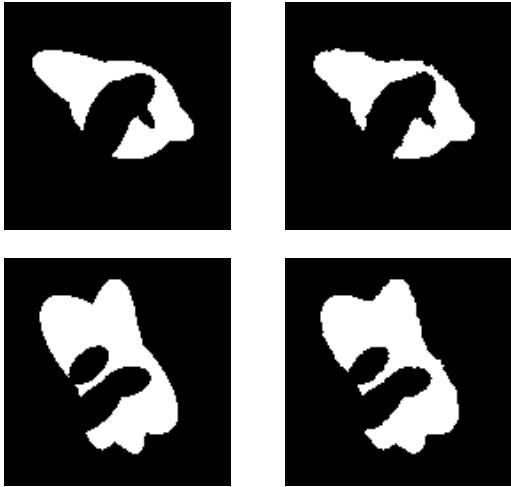

Figure 8. Left: two phantom images of size 128×128 . Right: reconstructions computed by the MLP classifier from 10 projections.

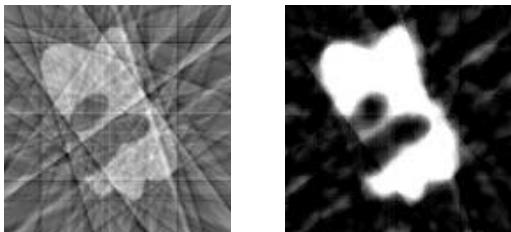

Figure 9. Left: Filtered Backprojection reconstruction of the top phantom in Figure 8 from 10 projections. Right: SIRT reconstruction from 10 projections.

ing three black ellipses inside the object to create various types of ‘holes’. The MLP was trained on images of size 128×128 . The total training time was around three hours. After training, the performance of the MLP was evaluated on a new set of 1000 random images that have a similar structure. Figure 8 shows two images from the test set and their reconstructions from 10 projections, equally spaced between 0 and 180 degrees. Averaged over all 1000 images in the test set, only 0.7% of all pixels are classified incorrectly by the MLP. Figure 9 shows reconstruction results from the same projection data by two continuous tomography algorithms. Filtered backprojection can be used in real-time, just as our MLP classifier, but it yields an inferior reconstruction. SIRT yields a much better reconstruction (though still not as good as the MLP), but on a standard 2.5GHz PC it takes about 20 seconds to run for a 128×128 image, compared to around 0.25s for the MLP (when used for all pixels in the image). By parallelisation of the MLP computations, even higher speeds are possible.

We also tested the MLP on a set of images that contain three pixel values (black, gray and white), training it to detect the presence of one of the pixel values (gray). Each image in the training and test sets consists of 10 ellipses that can be either gray or white, on a black background. Figure 10 demonstrates the performance of the trained network on a three-valued phantom image. Using 18 projections, the MLP is capable of detecting quite accurately where the gray pixels are directly from the projection data. For the test set of 1000 images, only 0.6% of all pixels are classified incorrectly by the MLP.

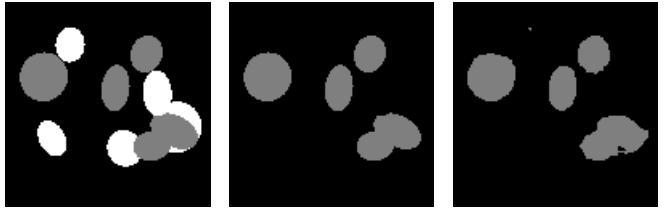

Figure 10. Left: Phantom image containing three gray levels. Middle: Gray part of the phantom image. Right: Reconstruction of the gray part, computed by the MLP from 18 projections of the three-valued phantom.

7 CONCLUSIONS

The goal of tomography is to reconstruct an object from its projections. If it is known beforehand that the object consists of only a few different materials (*discrete tomography*), the reconstruction problem can be considered as a *classification problem*. The dimension of the input space for the classifier is typically very large. We have described an approach for reducing the size of the input space in such a way that accurate classification is still possible using the reduced data. By defining all inputs *relative* to the position of a pixel, the same classifier can be used for all pixels in the image.

Our reconstruction results of an MLP classifier suggest that the reduced input data is indeed sufficient to perform accurate classification, at least for certain types of images. Once trained, the MLP can be used to compute new reconstructions very fast, and even more accurately than much slower algorithms from continuous tomography.

By training the classifier from a set of examples, prior knowledge of the set of images (besides the knowledge of the gray values) is learned automatically, instead of having to be modeled by hand.

Our approach is not limited to the reconstruction of binary images. In particular, it can be used to detect all pixels that have a certain gray value, directly from the projection data of an image that contains several gray values.

The experimental results were obtained using a training set of 1000 images. In many practical applications of tomography, 3D volumes are reconstructed that consist of several hundreds of stacked 2D slices. Therefore, a few 3D datasets would already be sufficient to perform training on real-world experimental data.

Depth Ordering and Figure-Ground Segregation in Monocular Images derived from Illusory Contour Perception

Marcus Hund and Bärbel Mertsching¹

Abstract. One of the elaborated tasks for the low level image processing stage of a vision system is the completion of cluttered or occluded object boundaries and the depth assignment of overlapped boundaries. We describe a novel method for depth ordering and figure-ground segregation from monocular depth cues, namely the arrangement of so-called illusory contours at junctions in the edge map of an image. Therefore, a computational approach to the perception of illusory contours, based on the tensor voting technique, is introduced. Furthermore, two simple rules for figure-ground segregation are presented that are capable of explaining a wide range of perceptual phenomena like the Kanizsa illusion. Finally, we present a diffusion approach to derive the depth ordering for the whole contour from the figure-ground segregation at key points.

1 Introduction

For technical as well as for biological vision systems, the completion of object boundaries that are interrupted due to occlusions or low luminance contrast is essential. This implies the distinction of completions of foreground object boundaries, called modal completions, and those of occluded background object boundaries, called amodal completions. The entirety of these completions are referred to as illusory contours. Illusory contours, also called virtual contours, are perceived contours that have no counterpart in the retinal image of the human vision system. Neurophysical studies have shown that the perception of illusory contours can be found in mammals, birds and insects [22]. The importance of illusory contours becomes obvious regarding the fact that the brains of these animals have developed independently throughout evolution. We can therefore assume that illusory contour perception is not just a malfunction of these visual processing systems, but instead is necessary for object border completion.

For the human vision system, illusory contours have been studied by Gestalt psychologists from the early 20th century on ([15], [3], [28]). Schuhmann was one of the first to mention this phenomenon in 1900 [27]. He described illusory contours as contours that are not "objectively present". In the following years the contributions to the field of illusory contour perception comprised the description of optical illusions based on contour perception rather than explaining these illusions.

Fig. 1(a) shows the Kanizsa triangle, an optical illusion which is the standard example for human mechanisms of illusory contour perception and for depth ordering derived from monocular inducers (see

also [13]). Even though there exists a multitude of correct scene interpretations leading to the same retinal image (Fig. 1(b)-(f)), the most often perceived depth ordering is the one shown in Fig. 1(b). Consequently, the aim of a computational approach to scene interpretation cannot be to find the correct depth ordering but to find the most probable scene interpretation.

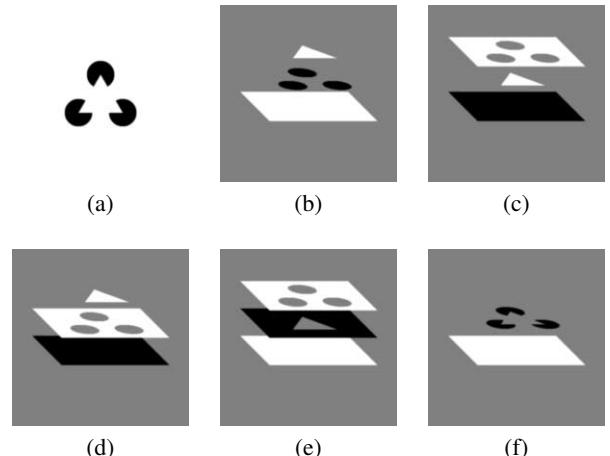

Figure 1. Some possible depth interpretations for the Kanizsa triangle shown in (a).

One possibility for figure-ground segregation is to consider contours that are interrupted by other contours. Such T-junctions can be interpreted as contours that are interrupted by a foreground object boundary and therefore belong to the background. But, as is stated in [10], where the figure-ground segregation was based on this principle, "such a simple mechanism can be fooled". For example, the stripes of a zebra produce T-junctions at the "object boundary", which would lead the mechanism to regard the zebra as the background. In such a case it is impossible to distinguish a hole from a textured object. In the following we will show that the ambiguities can be reduced if the possible completions of the interrupted contour are taken into account (compare Fig. 9).

2 Related Work

The majority of approaches or models dealing with the problem of spatial contour integration use some kind of bipole connection scheme ([7], [23]), as introduced by Grossberg and Mingolla [25].

¹ University of Paderborn, Germany, email: hund@get.uni-paderborn.de

This perceptual grouping kernel usually consists of two symmetric lobes encoding the connection strength and orientation. In [30], Williams and Thornber address the comparison of different methods of aggregating the contributions of neighboring sites of the grouping kernel. For a detailed overview of contour integration approaches, see [6] or [21]. In [21], emphasis is placed on models including illusory contour perception, namely the model of Heitger et al. ([9], [24]) and Neumann and coworkers [8] as a neurophysiological inspired computational model while the approach of Zweck and Williams [32] models the Brownian motion of a particle from source to sink.

The method proposed in this paper uses the tensor voting technique introduced by Medioni et al. [5]. Tensor voting was applied successfully to contour inference problems on synthetic and binary input images in [19]. In [16], this approach was extended to grayscale images as input, using gabor filtering as a preceding image processing step. In the tensor voting framework the grouping kernel, called stick voting field, is orientational, i.e. with angles from 0° to 180° and designed for contour inference. Considering illusory contour perception, the use of this stick voting field could make sense in the context of a unified treatment of all contour elements, but would lead to interference of contour elements, especially in the case of amodal completions behind a textured foreground. What is needed for illusory contours including amodal completions is a directional communication pattern (with angles from 0° to 360°), e.g. one lobe, which was already used in [18], but addressed to spontaneously splitting figures and binary input images.

Relatively little computational work has been done so far on figure-ground segregation derived from illusory contour cues. As mentioned above, Heitger et al. have implemented a merely rudimentary mechanism for figure-ground segregation [10]. In [14], the phenomena of unit formation and depth ordering are treated on a theoretical basis with focus on the neurophysiological view. Furthermore the "identity hypothesis" is proposed, stating that the mechanisms for modal and amodal completions are identical and that the depth ordering can be separated from the contour completion process. This view is challenged in [1], but the given arguments refer to examples using knowledge base or stereoscopic cues. Also no clues are given how the completion process takes place or how the depth ordering is realized. Regarding the monocular case in a low level processing step, we will give hints that, for this early stage, the depth ordering indeed can be realized with the contour completion being identical for modal and amodal completions. In this context unit formation has to be understood in the sense of contour formation.

3 Edge and Corner detection

As a preprocessing step we have developed a method for threshold-free edge detection and a subsequent corner detection. This is achieved by applying a recursive search to edge candidates. The edge candidates are local extrema and zero-crossings of the responses of several Gaussian-based filter banks. For an overview of edge detection algorithms, see [4] and [31].

The result of the recursive search is shown in Fig. 2(c), detected corners are shown superposed to the input image in Fig. 2(d). A comparison to other corner detectors is given in [20]. The used method for corner and edge detection is not an integral part of the proposed computational approach to illusory contour perception and can therefore be replaced by any other corner detector providing not only the corner positions but also the associated orientation angles. For a more detailed explanation of the used edge and corner detector, see [12].

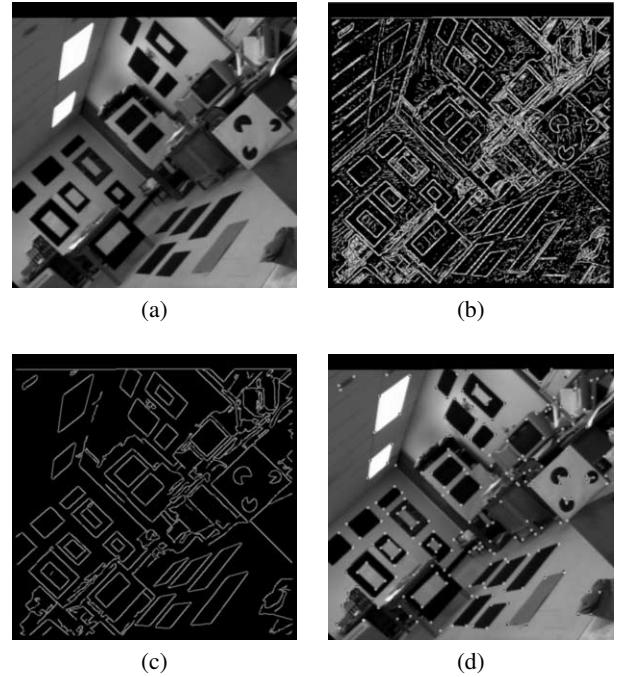

Figure 2. Lab scene: (a) Input image (b) Edge Candidates (c) Detected edges (d) Detected corners

4 Tensor Voting

In [19], Medioni, Lee and Tang describe a framework for feature inference from sparse and noisy data called tensor voting. The most important issue is the representation of edge elements as tensors. In the 2D-case, a tensor over \mathbb{R}^2 can be denoted by a symmetric 2×2 matrix T with two perpendicular eigenvectors \vec{e}_1, \vec{e}_2 and two corresponding real eigenvalues $\lambda_1 > \lambda_2$. A tensor can be visualized as an ellipse in 2-D with the major axis representing the estimated tangent direction \vec{e}_1 and its length λ_1 reflecting the saliency of this estimation. The length λ_2 assigned to the perpendicular eigenvector \vec{e}_2 encodes the orientation uncertainty. The definition of saliency measures is deducted from the following decomposition of a tensor into $T = \lambda_1 \vec{e}_1 \vec{e}_1^\top + \lambda_2 \vec{e}_2 \vec{e}_2^\top$ or equivalently $T = (\lambda_1 - \lambda_2) \vec{e}_1 \vec{e}_1^\top + \lambda_2 (\vec{e}_1 \vec{e}_1^\top + \vec{e}_2 \vec{e}_2^\top)$. Then, the weighting factor $(\lambda_1 - \lambda_2)$ represents an orientation in the direction of the eigenvector \vec{e}_1 and thus will be called *curve- or stick-saliency*. The second weight λ_2 is applied to a circle, hence it is called *junction- or ball-saliency* as its information about multiple orientations measures the confidence in the presence of a junction. Note that for junctions or corners neither the tensor representation suffices to encode the at least two different orientations nor is the ball saliency a trustable measure for junctions, since it is highly dependent on the orientations of incoming edges [17].

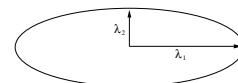

Figure 3. Visualization of a tensor as an ellipse

Grouping can now be formulated as the combination of elements according to their stick-saliency or ball-saliency. In stick-voting, for each oriented input token the grouping kernel called stick-voting-

field is aligned to the eigenvector \vec{e}_1 . In the following the input tokens consist of detected junctions and their associated directions. All fields are combined by tensor addition, i.e. addition of the matrices and spectral decomposition of the sum into eigenvectors and -values. The field is designed to create groupings with neighboring tokens which fulfill the minimal curvature constraint. Hence the orientation of each token of the voting field is defined to lie on a cocircular path. The strength is defined as follows:

Given a point P with an associated tangent direction and a point Q with the orientation difference θ between the tangent direction and the direct connection of P and Q . Let ℓ be the distance between P and Q . Then, with

$$r = \frac{\ell}{2\sin\theta} \quad \text{and} \quad s = \frac{\ell \cdot \theta}{\sin\theta} \quad ,$$

r is the radius of the tangent circle to P going through Q and s is the arc length distance along the circular path (radian).

Most approaches to spatial contour integration define the connection strength V for P and Q and therefore the shape of the bipole connection scheme via $V = V_d \cdot V_c$ with a distance term V_d and a curvature term V_c . In [9], Heitger et al. use

$$V_{d1} = e^{-\frac{\ell^2}{2\sigma^2}} \quad \text{and} \quad V_{c1} = \begin{cases} \cos^k(\frac{\pi/2}{\alpha} \cdot \theta) & \text{if } |\theta| < \alpha \\ 0 & \text{otherwise} \end{cases}$$

with $k = 2n$, $n \in \mathbb{N}$ and an opening angle $2\alpha = \pi$. Hansen and Neumann also use V_{d1} and V_{c1} , but with $k = 1$ and $\alpha = 10^\circ$ [7]. In [19], Medioni et al. define the proximity term V_{d2} and the curvature term V_{c2} as follows:

$$V_{d2} = e^{-\frac{s^2}{2\sigma^2}} \quad \text{and} \quad V_{c2} = e^{-\frac{c \cdot \rho^2}{\sigma^2}} \quad \text{with} \quad \rho = \frac{2\sin\theta}{\ell}$$

c is a positive constant and ρ is nothing else than the inverse radius of the osculating circle. This results in a curvature measure that is highly dependent on scale.

Figure 4. Stick saliency for the half lobe stick voting field with $V = V_{d2} \cdot V_{c1}$, $k = 1$ and $\alpha = 15^\circ$

To achieve a clear separation of distance along the circular path and its curvature, we choose V_{d2} and V_{c1} . The results presented in the next section are computed with a directional one-lobe voting field and $V = V_{d2} \cdot V_{c1}$, $k = 1$ and $\alpha = 15^\circ$, i.e. an opening angle of 30° .

Starting from junctions the illusory contour perception is now realized by letting the junctions cast Stick Voting Fields according to their associated orientations. By a maximum search along the voting field we try to find a connection to other junctions.

5 Illusory Contour Perception

Fig. 5(a) shows detected edges and corners and their associated orientations, (b) shows the stick saliences after tensor voting and (c) shows extracted illusory contours superposed to the previously detected contours. It is remarkable, that in Fig. 5(c) the amodal completions of the circles are not found. This is due to the acute connection angles as can be seen in Fig. 5(b).

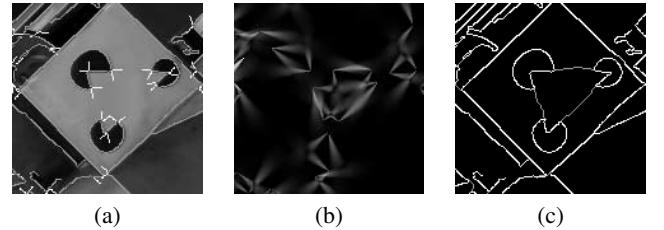

Figure 5. Illusory contour perception for the Kanizsa triangle in Fig. 2. For further description see text.

In Fig. 6, the rubber duck is partially occluded by a black cable. Note that there are some light reflections on the cable causing a foreground texture. For contour inference approaches, i.e. the application of bipole voting fields to all edgels, the voting fields cast by these foreground elements would interfere with the fields generated at the duck's object boundary and hence compromise the correct detection of amodal completions (Fig. 6(b)).

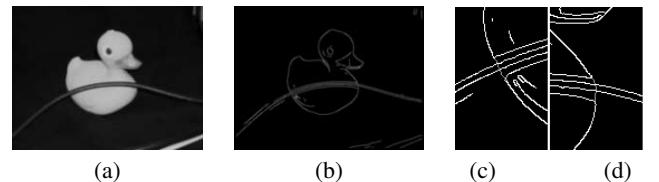

Figure 6. Rubber duck image: (a) input image, (b) illusory contours superposed to detected edges, (c) and (d) magnification of regions containing illusory contours

This illustrates that a unified treatment of edge segments and junctions would disturb the perception of amodal completions, at least for this low level image processing step. Anyhow just the two desired amodal completions of the duck's object boundary are marked as illusory contours, see Fig. 6(d) and (e), so the correct virtual contours are found.

6 Figure-Ground Segregation and Depth Ordering

The figure-ground segregation for the results shown in the next section is based on two simple rules for the crossing of two contours:

If a contour changes its state from real to illusory at a point of interest and if a crossing contour does not, then the first contour belongs to the background and the second contour belongs to an occluding foreground surface.

If a contour changes its state from real to illusory and if the illusory part lies within the bounded region of a closed crossing contour, then the first contour belongs to the background and the second contour is the closed boundary of an occluding object. If both contours are closed and both contours have illusory parts that lie within the bounded region of the other contour, no reasonable decision can be made. This would be the case of spontaneously splitting figures.

More complex graph based labeling schemes can be found in [29] and [26], but these two rules already suffice to interpret a variety of situations in an accurate way, e.g. the second rule is sufficient to describe the complex depth ordering in the Kanizsa triangle. While the

second rule describes a more complex scene understanding mechanism, the first rule is even simpler and just requires the treatment of local image structure.

To ensure that the depth assignment is continuous even for contours that bound surfaces that change from back- to foreground and vice versa, we realize the depth ordering with a diffusion process: Let x_n be the relative depth of a contour element with neighbors $x_{n+1}, x_{n+2}, x_{n-1}$ and x_{n-2} . Depth of a contour means the depth of the occluding surface if the contour marks the boundary of a surface. Given a smoothing factor a , the cost term

$$\begin{aligned} C = \frac{1}{2} \sum_n & a \cdot (((x_{n+1} - x_n) - (x_n - x_{n-1}))^2 \\ & + (x_n - x_{n+1})^2 + (x_n - x_{n-1})^2) \\ & + \begin{cases} (x_n - x_0)^2 & \text{if } x_n \text{ belongs to a junction} \\ 0 & \text{otherwise} \end{cases} \quad (1) \end{aligned}$$

enforces the smoothness of neighboring values as well as of the first derivative. Using the gradient descent method to minimize Equation (1) leads to

$$\begin{aligned} -\frac{\partial}{\partial x_n} C = & -a \cdot (6x_n - 4x_{n+1} - 4x_{n-1} + x_{n+2} + x_{n-2} \\ & + 4x_n - 2x_{n+1} - 2x_{n-1}) \\ & - \begin{cases} 2(x_n - x_0) & \text{if } x_n \text{ belongs to a junction} \\ 0 & \text{otherwise} \end{cases} \end{aligned}$$

Then, with λ being the step width, the update rule for x_n is given by

$$x_n^{(k+1)} = x_n^{(k)} - \lambda \cdot \frac{\partial}{\partial x_n} C \quad (2)$$

During the dynamic process we update the x_0 values at points of interest according to the figure-ground segregation described above.

7 Results

Fig. 7 illustrates the different processing steps to the given input images in 7(a). Fig. 7(b)-(e) shows detected edges and the possible orientations at junctions. In (c) the votes cast by these junctions are shown and in (d) the resulting illusory contours are superposed to the real contours.

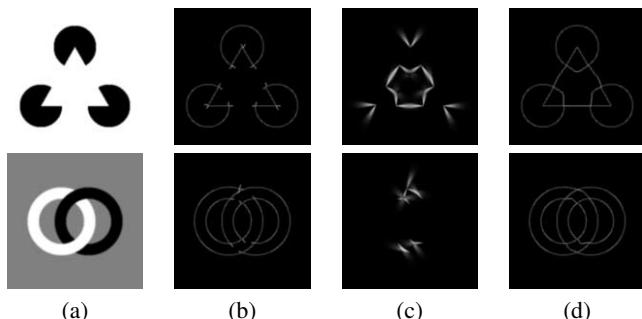

Figure 7. Kanizsa Triangle (top row) and Rings (bottom row): (a) Input Images , (b)-(e) Different processing steps. For further description see text.

In Fig. 8 and the bottom row of Fig. 9 the results for the figure-ground and depth ordering mechanisms are shown. The contour elements bounding a foreground surface are displayed lighter while edges being assigned a higher distance to the viewer are displayed darker.

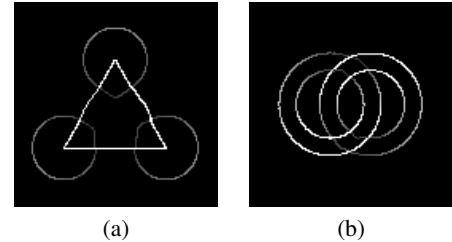

Figure 8. Depth ordering for the images in fig. 7(a)

Fig. 8(a) shows that the second rule presented in the previous section lets the mechanism interpret the depth ordering that is identical to human perception. In 8(b) the figure-ground segregation results from the first rule. As can be seen, eq. 2 ensures that even with key points changing from figure to ground a continuous depth signal can be produced.

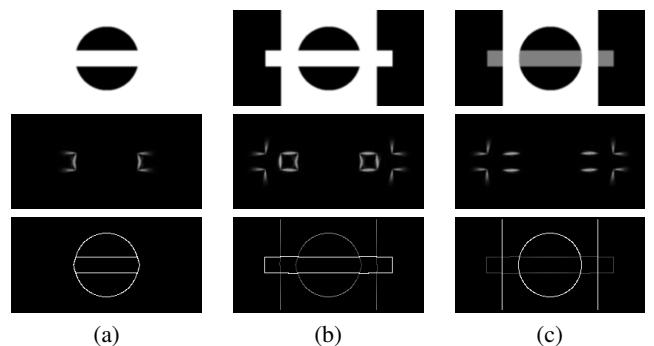

Figure 9. Top row: Input images for a circle with a bar, middle row: Voting fields cast by detected junctions, bottom row: Real and illusory contours with assigned depth values. For further description see text.

Fig. 9(a) shows the "zebra case". The constellation is highly ambiguous, since there is no cue to decide whether the white bar in the black circle is foreground, seen through a hole or part of the circle's surface texture. In Fig. 9(b) the last case, being part of the circle's surface, is eliminated by the fact that the bar is bounded by a closed contour. The second rule presented in the previous section enforces the perception of a bar in front of the circle, as can be seen in the bottom row, which correlates with the perception of the majority of observers. Also most observers perceive a white surface containing a hole in front of a grey bar in front of a black background in Fig. (9(c)). The bottom row shows that the first rule presented in the previous section leads exactly to this depth ordering.

8 Conclusion

A computational approach was presented for the depth ordering at surface boundaries in monocular images. The approach includes corner- and edge detection, illusory contour perception, figure-ground segregation at junctions and depth ordering for real and completed contours. The illusory contour perception is based on the Tensor Voting framework, for what we constructed a new communication pattern that allows a clear distinction between the distance along a circular path and its curvature. The figure-ground segregation is done by the application of two simple rules, one regarding local image content and one placing emphasis on closed contours. Furthermore we invented a diffusion process, in which the figure-ground

segregation at key points is carried to the rest of the contour. It was shown that this proceeding even works with two surfaces occluding one another. Consequently, this approach allows an assumption about an object's relative position in space, not just a distinction between figure and ground. The promising results presented for these mechanisms may be considered as an evidence for Kellmanns "identity hypothesis" [14], but on the other hand, regarding a larger scale, it seems clear that contour perception is also influenced by top down processes driven by knowledge base.

9 Future work

Obviously, binocular depth cues belong to the most significant inducers for depth perception. Our future work will include a fusion of work we have done on stereoscopic algorithms ([2],[11]) with the mechanisms presented here. On the one hand, the depth ordering presented here can be used as an input to stereoscopic disparity estimation, on the other hand the results of a stereoscopic algorithm can be feeded back to the figure-ground segregation step. Furthermore, all this can be realized without any knowledge about the objects in the world that is observed.

Graph Neural Networks for Object Localization

Gabriele Monfardini and Vincenzo Di Massa and Franco Scarselli and Marco Gori¹

Abstract. Graph Neural Networks (GNNs) are a recently proposed connectionist model that extends previous neural methods to structured domains. GNNs can be applied on datasets that contain very general types of graphs and, under mild hypotheses, they have been proven to be universal approximators on graphical domains. Whereas most of the common approaches to graphs processing are based on a preliminary phase that maps each graph onto a simpler data type, like a vector or a sequence of reals, GNNs have the ability to directly process input graphs, thus embedding their connectivity into the processing scheme. In this paper, the main theoretical properties of GNNs are briefly reviewed and they are proposed as a tool for object localization. An experimentation has been carried out on the task of locating the face of a popular Walt Disney character in comic covers. In the dataset the character is shown in a number of different poses, often in cluttered backgrounds, and in high variety of colors. The proposed learning framework provides a way to deal with complex data arising from image segmentation process, without exploiting any prior knowledge on the dataset. The results are very encouraging, prove the viability of the method and the effectiveness of the structural representation of images.

1 Introduction

Object localization [4, 3], image classification [7], natural language processing [14, 6], bioinformatic [2], Web page scoring, social networks analysis [16] and relational learning are examples of machine learning applications where the information of interest are encoded into the relationships between a set of basic entities. In those domains, data is suitably represented as sequences, trees, and, more generally, directed or undirected graphs. In fact, nodes can be naturally used to denote concepts with edges specifying their relationships. For instance, an image can be represented by a Region Adjacency Graph (RAG), where the nodes denote the homogeneous regions of the image and the edges represent their adjacency relationship (Fig. 1).

In those applications, the goal consists of designing a function τ that maps a graph G and one of its nodes n to a vector of reals $\tau(G, n)$. For example, the localization of an object in a image can be implemented by a function τ that classifies the nodes of the RAG according to whether the corresponding region belongs to the object or not. In the case of Fig. 1, where the object to be localized is the plane, $\tau(G, n)$ might be 1 for the black nodes, which correspond to the parts of the plane, and -1 otherwise.

Traditional methods usually deal with graphs using a preprocessing procedure that transforms the graphs into simpler representations, as vectors or sequences of reals, which are then elaborated with

common machine learning techniques. However, valuable information may be lost during the preprocessing and, as a consequence, the application may suffer from a poor performance and generalization.

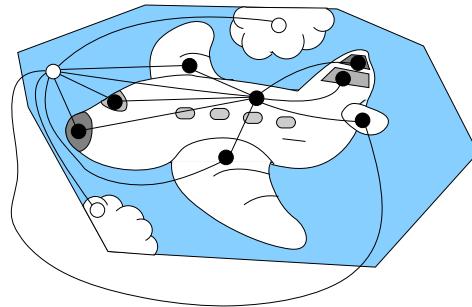

Figure 1. An image and its graphical representation by a RAG. Black nodes are associated to the parts of the plane, white nodes to the background.

Recently, a new connectionist model, called Graph Neural Network (GNN) model, has been proposed to better exploit the graphical representation of data [9, 20]. In GNNs, the preprocessing procedure is not required since the relationships between the basic entities of the input domain are directly embedded into the processing scheme of the model. It has been proved that, under mild hypotheses, GNNs are universal approximators on graphical domains, i.e. the can approximate any function $\tau(G, n)$.

GNNs extend the previous connectionist methods for structured domains [11] like Recursive Neural Networks (RNNs) [21, 8], and SOM for structured domains (SOM-SD) [10]. Actually, whereas RNNs and SOM-SD were limited by the fact that they can be applied only on a restricted class of structures, i.e. the directed acyclic graphs, GNNs can virtually elaborate any type of graphs, including cyclic and acyclic, directed and undirected ones. Moreover, the original RNN model produces one output for each graph and can be applied only on those problems where $\tau(G, n)$ does not depend on the node n . Thus, for example, RNNs are suitable for image classification, but not for object localization².

However GNNs had not been widely validated experimentally since now and it was unknown whether they could be applied with success on practical problems. In this paper, the results on an object localization problem are presented. The task consists of locating the face of a popular Walt Disney character in comic covers. Each cover was segmented and represented by a RAG, with labeled nodes and edges.

¹ Università degli Studi di Siena, Dip. Ingegneria dell'Informazione, Italy,
 email: {monfardini,dimassa,franco,marco}@dii.unisi.it

² More precisely, object localization in images can be carried out even by RNNs, but, in this case, the input RAGs must undergo a preprocessing step that transforms RAGs to direct acyclic graphs [4] (see Sect. 3).

In comic covers the character is shown in a number of different poses, often in cluttered backgrounds, and in high variety of colors. The proposed learning framework provides a way to deal with complex data arising from image segmentation process, without exploiting any prior knowledge on the dataset.

Moreover, common approaches to object localization are usually based on a window which is moved over the image [23, 22]. At each step of such a procedure, a classification technique is used to verify whether the window currently contains the target object. On the other hand, GNNs process the whole image representation once and for all, exploiting the graphical structure encoded naturally in the RAG.

The paper is organized as follows. In the next section, the GNN model and its main properties are reviewed. Section 3 illustrates the object localization problem and shows the results obtained by GNNs. Finally, the conclusions are drawn in Sect. 4.

2 Graph Neural Networks

In the following, a *graph* G is a pair (N, E) , where N is a set of *nodes* (or vertices), and E is a set of *edges* (or arcs) between nodes: $E \subseteq \{(u, v) | u, v \in N\}$. If the graph is *directed*, each edge (u, v) has a direction, i.e. a head and a tail, whereas, in *undirected* graphs, the ordering between u and v is not defined, i.e. $(u, v) = (v, u)$. Nodes and edges may be labeled and labels are represented by l_n and $l_{(u,v)}$, respectively. By convention, the symbol l with no further specifications defines all the labels of the graph, while operator $| \cdot |$ denotes the cardinality or the absolute value of its argument, according to whether it is applied to a set or to a number. A graph is called *acyclic* if there is no path, i.e. a sequence of connected edges, that starts and ends in the same node, otherwise it is *cyclic*. Finally, the nodes adjacent to some node n (or neighbors of n) are those connected to it by an edge and are represented by $\text{ne}[n]$.

2.1 The GNN model

The GNN model has been conceived to approximate a target function τ that maps a graph G and one of its nodes n into an output vector $o_n = \tau(G, n)$. In categorization problems $o_n \in \mathbb{N}^m$, while in regression problems the outputs belong to \mathbb{R}^m .

In GNN framework, a node represents an object or a concept of the domain of interest. Each node can be described using a fixed-length vector of real numbers $x_n \in \mathbb{R}^s$ called *state*, where the dimension s is a predefined parameter of the model. In order to derive a flat but adaptive description of each node n in a distributed processing scheme, the state must be evaluated locally at each node. The goal here is to combine label symbolic information with subsymbolic contributions embedded in graph topology. Such a task is accomplished modeling x_n as the output of a parametric function f_w (called *state transition function*), that depends on the node label l_n and on the relationships between n and its neighbors

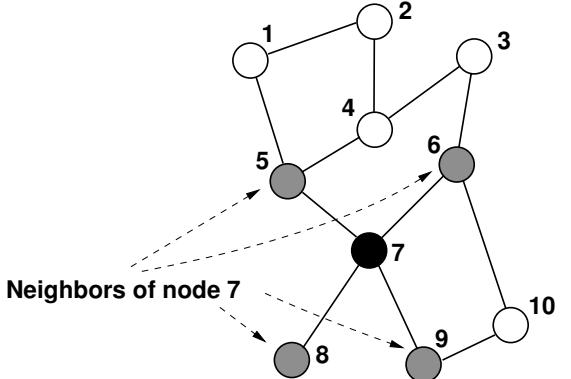

$$x_n = f_w(l_n, x_{\text{ne}[n]}, l_{\text{ne}[n]}, l_{(n, \text{ne}[n])}), \quad n \in N, \quad (1)$$

where $\text{ne}[n]$ is the set of neighbors of node n . Here, $x_{\text{ne}[n]}$ and $l_{\text{ne}[n]}$ are the states and the labels of the nodes in $\text{ne}[n]$, respectively, and $l_{(n, \text{ne}[n])}$ collects the labels of the edges connected to n (Fig. 2).

For each node n , the state x_n is also combined with node label l_n to produce an output vector o_n

$$o_n = g_w(x_n, l_n), \quad n \in N, \quad (2)$$

where g_w is another parametric function, called *output function*.

$$\begin{aligned} x_7 = f_w(l_7, x_5, x_6, x_8, x_9, l_5, l_6, l_8, l_9, \\ l_{(7,5)}, l_{(7,6)}, l_{(7,8)}, l_{(7,9)}) \end{aligned}$$

Figure 2. The state x_n depends on the information in its neighborhood.

In conclusion, Eqs. (1) and (2) define a method to compute an output $o_n = \varphi_w(G, n)$ for each node n of the graph G , taking into account the local descriptions and the relationships of all the nodes in G . The goal of the learning procedure is to adapt the parameters w so that φ_w approximates the data in the learning set $\mathcal{L} = \{(G_i, n_{i,j}, t_{n_{i,j}}) | 1 \leq i \leq p, 1 \leq j \leq q_i\}$, where each triple $(G_i, n_{i,j}, t_{n_{i,j}})$ denotes a graph G_i , one of its nodes $n_{i,j}$ and the desired output $t_{n_{i,j}}$. Moreover, p is the number of graphs in \mathcal{L} and q_i is the cardinality of the set of supervised nodes in graph G_i . In practice, the learning problem can be implemented as the minimization of the quadratic error function

$$e_w = \sum_{i=1}^p \sum_{j=1}^{q_i} (t_{n_{i,j}} - \varphi_w(G_i, n_{i,j}))^2. \quad (3)$$

Notice, however, that the following three issues must be solved in order to implement the proposed model.

1. How can the transition function f_w and the output function g_w be implemented?
2. The state x_n should be uniquely defined, but Eq. (1) provides a recursive specification of x_n . Thus, how can be ensured that Eq. (1) has a unique solution?
3. How can the parameters be adapted to minimize the error function?

In GNNs, both f_w and g_w can be implemented by two feedforward neural networks. However, the fact that f_w doesn't have a fixed number of input parameters, as different nodes have different numbers of neighbors (see Eq (1)), raises some practical problems. In fact, the network implementing f_w should be designed to accommodate the maximal number of input parameters, even if several of them may remain unused in most of the cases. A better solution consists of specializing Eq. (1)

$$x_n = \sum_{i=1}^{|\text{ne}[n]|} h_w(l_n, x_{\text{ne}_i[n]}, l_{\text{ne}_i[n]}, l_{(n, \text{ne}_i[n])}), \quad n \in N \quad (4)$$

where $\text{ne}_i[n]$ is the i -th neighbor of n , $|\text{ne}[n]|$ is the number of neighbors of n , and h_w is parametric function implemented by a feedfor-

ward neural network. Here, the idea is that \mathbf{x}_n can be evaluated as a sum of “contributions”, one for each of the neighbors of node n .

In order to solve the second issue, notice the set of Eqs. (1) can be also represented as

$$\begin{bmatrix} \mathbf{x}_1 \\ \mathbf{x}_2 \\ \vdots \\ \mathbf{x}_N \end{bmatrix} = \begin{bmatrix} f_w(l_1, \mathbf{x}_{ne[1]}, l_{ne[1]}, l_{(1,ne[1])}) \\ f_w(l_2, \mathbf{x}_{ne[2]}, l_{ne[2]}, l_{(2,ne[2])}) \\ \vdots \\ f_w(l_N, \mathbf{x}_{ne[N]}, l_{ne[N]}, l_{(N,ne[N])}) \end{bmatrix}$$

where N is the cardinality $|N|$ of node set N . Introducing a vectorial function \mathbf{F}_w obtained stacking together the instances of the transition function f_w , collecting all the states in the symbol \mathbf{x} and all the labels in the symbol \mathbf{l} , the previous equation can be rewritten as

$$\mathbf{x} = \mathbf{F}_w(\mathbf{x}, \mathbf{l}). \quad (5)$$

By Banach Theorem, if \mathbf{F}_w is a contraction mapping³, then Eq. (5) has a unique solution [13]. Thus, the second issue can be solved by designing f_w such that the global function \mathbf{F}_w results to be a *contraction mapping* w.r.t. the state \mathbf{x} .

In practice, this goal can be achieved by adding a penalty term to the error function

$$e_w = \sum_{i=1}^p \sum_{j=1}^{q_i} (\mathbf{t}_{n_{i,j}} - \varphi_w(\mathbf{G}_i, n_{i,j}))^2 + \beta L \left(\left\| \frac{\partial \mathbf{F}_w}{\partial \mathbf{x}} \right\| \right),$$

where $L(y) = (y - \mu)^2$, if $y > \mu$, and $L(y) = 0$ otherwise [20]. Moreover, the real number β balances the importance of the penalty term and the error on patterns, the parameter $\mu \in (0, 1)$ defines a desired upper bound on the contraction constant of \mathbf{F}_w , and $\left\| \frac{\partial \mathbf{F}_w}{\partial \mathbf{x}} \right\|$ denotes the norm of the Jacobian of \mathbf{F}_w .

Next section answers briefly to the last issue, discussing the learning algorithm used to adapt model parameters. More details can be found in [20].

2.2 The learning algorithm

The functions h_w and g_w may be implemented by a variety of feedforward neural network architectures. In our experiments, they are designed as three layered (i.e. with one hidden layer) feedforward neural networks. According to Banach fixed point theorem, if ρ is a generic contraction mapping, then the dynamical system $\mathbf{x}(t+1) = \rho(\mathbf{x}(t))$, where $\mathbf{x}(t)$ denotes the t -th iterate of \mathbf{x} , converges exponentially fast to the solution of the equation $\mathbf{x} = \rho(\mathbf{x})$ for any initial state $\mathbf{x}(0)$. Thus Eq. (5) can be solved simply by iteration. Then, fixed point states are used by function g_w to evaluate the outputs \mathbf{o}_n (Eq. (2)), while the weight updating is accomplished deriving the error according to Eq. (3) and employing a gradient descent strategy as in traditional backpropagation algorithm.

The main difference with respect to the traditional backpropagation is due to the fact that fixed point states depend on the parameters of f_w through the iteration procedure. For this reason the error should be backpropagated from one iteration to the previous, accumulating the gradient until convergence. The adopted gradient computation is not completely new: it combines the backpropagation through structure algorithm, designed to train Recursive Neural Networks [21, 8], and the recurrent backpropagation algorithm [1, 18].

³ A generic function $\rho : \mathbb{R}^n \rightarrow \mathbb{R}^n$ is a contraction mapping w.r.t. a vector norm $\|\cdot\|$, if it exists a real number μ , $0 \leq \mu < 1$, such that for any $\mathbf{x}_1, \mathbf{x}_2 \in \mathbb{R}^n$, $\|\rho(\mathbf{x}_1) - \rho(\mathbf{x}_2)\| \leq \mu \|\mathbf{x}_1 - \mathbf{x}_2\|$.

When the gradient is available, the weights can be updated using resilient backpropagation [19], a well-known variant of standard backpropagation that speeds up the convergence.

3 Application to object localization

In order to test the performance of the Graph Neural Network model, an object localization problem was designed. It consists of finding the face and the hat of a famous Walt Disney character, Uncle Scrooge, in a set of cartoon covers taken from two different Italian publications. The full dataset comprises 319 images, all of which show the character in various sizes and poses. Some pictures have multiple copies of the face, with or without the hat, whereas other images also show the faces of other Walt Disney characters, that are quite difficult to distinguish from Uncle Scrooge, f.i. Donald Duck, or other ducks. A training set, a validation set and a test set have been built randomly using, respectively, 127, 64 and 125 images from the dataset.

Images were encoded into Region Adjacency Graphs (RAGs). RAGs [17] are a classical image representation, where nodes stand for homogeneous regions and edges encode the relationship “is adjacent to” (Fig. 1). Since adjacency is a symmetric relationship, the obtained graphs are undirected. Previous attempts to elaborate RAGs with Recursive Neural Networks [4, 3], showed encouraging results, even if RAGs had to be transformed into acyclic graphs, because of the limitations of Recursive Neural Networks. On the contrary, GNNs are able to directly process undirected graphs, so no preprocessing was needed.

The RAGs have labels on both nodes and edges: node labels contain features of the corresponding image regions, while edge labels store information on adjacent regions pairs⁴ (Fig. 3). Tab. 1 lists all the features in detail. Each node n also has a manually assigned tar-

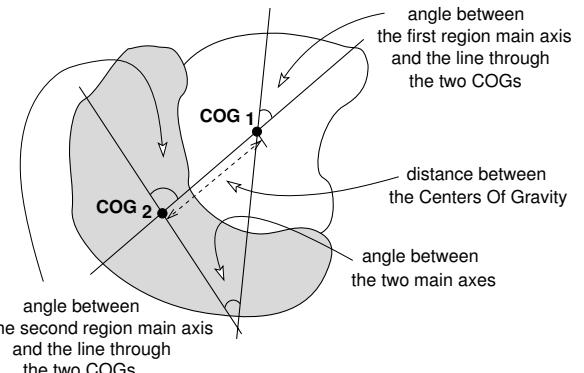

Figure 3. The geometric features stored in each edge label. COG is an abbreviation for “center of gravity”.

get t_n which is positive for regions belonging to Uncle Scrooge’s face or hat and negative elsewhere. The targets were assigned using a graphical interface that shows the segmented image and allows to select the regions that compose each object.

In order to obtain the homogeneous regions a segmentation procedure composed by three steps was adopted. In the first, each image was filtered using the Mean Shift algorithm [5], that acts like a low-pass filter in a mixed 5D feature space composed by the tristimulus

⁴ The used features have been computed using the LTI-Lib library [15], developed by the Chair of Technical Computer Science, RWTH-Aachen University, and released under the GNU Lesser General Public License.

Table 1. Features contained in node and edge labels

Label type	Feat. type	Description
Node label	color	average color
		area
		perimeter
	geometric	coordinates of the center of gravity (COG)
		coordinates of the bounding box
		$compactness: 4 * \pi * area / (perim.)^2$
		$eccentricity$
		main axis orientation
		inertia parallel. and orthog. to main axis
	moments	Several central moments m_{xy} of various orders w.r.t. x and y : $m_{02}, m_{03}, m_{11}, m_{12}, m_{20}, m_{21}, m_{30}$
		RGB-color distance between the average colors of the two regions
Edge label	geometric	distance between the two COGs
		angle between the main axes
		angle between the main axis of the first region and the line through the COGs
		angle between the main axis of the second region and the line through the two COGs

values in CIE-Luv color space and the bidimensional image coordinates (x, y). The main advantage of this technique is that it is especially designed to preserve gradient discontinuities. Thus smallest textures, often oversegmented by techniques employing only color information, are heavily smoothed, while significant edges remain almost crisp, easing region boundaries detection. This filtering step plays a key role in removing the noise introduced by image digitalization and JPEG compression⁵.

Then, a k-means [12] color quantization procedure was adopted to locate an initial large number of homogeneously colored regions. Finally, pairs of adjacent regions were recursively merged, using a heuristic function that evaluated similarities in order to choose the best pair. Such a procedure was repeated until the desired final number of regions was achieved. The optimal number of regions was automatically defined using a function that estimates the image complexity through the average value of the luminance gradient.

Several tests were performed using GNNs with three different architectures. More precisely, the state dimensions s and the number of hidden units r in the neural networks that implement the functions f_w and g_w were varied⁶. In the first GNN architecture, $s = 3$ and $r = 3$ hold, in the second architecture $s = 5$ and $r = 5$, and in third architecture $s = 10$ and $r = 10$.

To evaluate the importance of the subsymbolic information and the effectiveness of the structural representation of objects, the GNN model was compared with a three layered feedforward neural networks (MLP), that solved the problem using only the node labels as input patterns. Since the MLPs cannot exploit the graph connectivity, while GNNs can, the performance difference is mostly due to the subsymbolic information embedded in RAG topology.

Table 2 shows the accuracies obtained by the various architectures measured by the percentage of the correctly classified regions.

⁵ Mean Shift algorithm was implemented using the LTI-Lib library [15].

⁶ For sake of simplicity, in all the experiments the two neural network were three layered feedforward networks with the same number r of hidden neurons.

Table 2. Percent of correctly predicted regions in the positive examples (Object), in the negative (Non-obj.), and on average (Total)

Model	Configuration	Object	Non-obj.	Total
MLP	10 hidden u.	84.39%	68.91%	70.44%
	20 hidden u.	85.15%	69.45%	70.90%
	30 hidden u.	84.96%	69.27%	70.73%
GNN	state dimension = 3 3 hidden u. in funct. f 3 hidden u. in funct. g	78.90%	75.97%	74.72%
	state dimension = 5 5 hidden u. in funct. f 5 hidden u. in funct. g	77.29%	78.00%	77.93%
	state dimension = 10 10 hidden u. in funct. f 10 hidden u. in funct. g	78.81%	78.54%	78.56%

MLPs reached very high accuracies on the class of positive examples and quite low accuracies on the other nodes, while GNNs behaved similarly on the two classes. The reason is that the positive regions have features that belong to a restricted set, while the features of the negative regions have a wider range. Thus, false positives are more frequent than false negatives in MLPs. On the other hands, GNN are able to exploit also the information given the regions adjacent to the possible face, that usually represents the clothes or the hat. Such an information allows to largely decrease the number of false positives. Notice that the unbalanced results obtained by MLPs has a negative impact on the total accuracy of the MLPs w.r.t. the results achieved by GNNs, as clearly shown in Tab. 2. The error function considers both the positive and the negative examples, thus the training tried to force the MLPs to increase the performance on the negative examples, eventually decreasing the accuracy on the positive examples, but such a goal cannot be reached because of the task difficulty.

Since the dimension of the regions greatly varies in the dataset and larger regions are more important than smaller regions in object localization applications, the obtained networks were also evaluated on the base of the number of pixels that have been correctly classified. Table 3 shows the achieved results with accuracy defined as the ratio between the correctly predicted pixels and the total number of pixels of the image.

Table 3. Percent of correctly predicted pixels in the positive examples (Object), in the negative (Non-obj.), and on average (Total)

Model	Configuration	Object	Non-obj.	Total
MLP	10 hidden u.	83.72%	82.68%	82.73%
	20 hidden u.	86.76%	84.07%	84.20%
	30 hidden u.	83.92%	84.55%	84.52%
GNN	state dimension = 3 3 hidden u. in funct. f 3 hidden u. in funct. g	76.49%	87.91%	87.38%
	state dimension = 5 5 hidden u. in funct. f 5 hidden u. in funct. g	75.70%	88.92%	88.30%
	state dimension = 10 10 hidden u. in funct. f 10 hidden u. in funct. g	73.91%	88.56%	87.88%

Comparing the results of Tab. 2 and Tab. 3, we notice that all neural models better classify the largest regions w.r.t. the smallest ones. In fact, it can be shown that the mean size of the mistaken regions is about a half of the mean size of the correctly predicted ones, in all tests and with all architectures. This behavior is probably due to the fact that geometric features are likely to be progressively less significant when the regions become too small.

Finally, the correctly processed images were counted. In this case, an image was defined as correctly processed if the number of correctly classified pixels exceeded a given threshold. Table 4 shows the achieved accuracies using a 80% threshold and a 90% threshold. The

Table 4. Percent of images where the total pixel-based accuracy exceeded 80% and 90%

Model	Configuration	Acc. \geq 80%	Acc. \geq 90%
MLP	10 hidden u.	75.59%	17.32%
	20 hidden u.	76.38%	19.69%
	30 hidden u.	78.74%	20.47%
GNN	state dimension = 3 3 hidden u. in funct. f 3 hidden u. in funct. g	83.46%	41.73%
	state dimension = 5 5 hidden u. in funct. f 5 hidden u. in funct. g	90.55%	51.18%
	state dimension = 10 10 hidden u. in funct. f 10 hidden u. in funct. g	82.68%	52.76%

results show that GNNs outperform MLPs because the structural information make GNNs less prone to spurious features. In fact, sets of adjacent positive regions reinforce themselves mutually, and the same happens for each cluster of negative regions.

Finally it is worthy to remark that GNNs succeeded in correctly classifying over the ninety percent of the pixels for more than a half of the images. Since the faced problem was particularly difficult, those results are encouraging and prove that the application of the GNN model on structural domains is viable.

4 Conclusions

This paper has presented the preliminary results obtained by the application of the Graph Neural Network model to an object localization task. The results were encouraging and have shown that the model can really combine the symbolic and the subsymbolic information stored in structured data. Future matter of research includes a more systematic experimentation of the GNN model on object localization problems and the application of the model to other tasks where the information is naturally represented by graphs as relational learning problems and social network applications.

Situation Assessment for Sensor-Based Recovery Planning

Abdelbaki Bouguerra and Lars Karlsson and Alessandro Saffiotti¹

Abstract. We present an approach for recovery from perceptual failures, or more precisely anchoring failures. Anchoring is the problem of connecting symbols representing objects to sensor data corresponding to the same objects. The approach is based on using planning, but our focus is not on the plan generation per se. We focus on the very important aspect of situation assessment and how it is carried out for recovering from anchoring failures. The proposed approach uses background knowledge to create hypotheses about world states and handles uncertainty in terms of probabilistic belief states. This work is relevant both from the perspective of developing the anchoring framework, and as a study in plan-based recovery from epistemic failures in mobile robots. Experiments on a mobile robot are shown to validate the applicability of the proposed approach.

1 Introduction

Mobile robots and other autonomous systems acting in the real world face the problem of uncertainty, and uncertainty can cause even the best laid plans to fail. Therefore, the ability to recover from failures is vital for such systems. AI planning is one of the tools used to recover from failures. Recovery is viewed as a planning task where the initial state of the planner is the unexpected state encountered by the agent, and the goal is to reach a nominal state where the plan can be continued. Most robotic systems employing planning [9, 1] focus largely on generation and repair of plans. However, having a good planner is not sufficient, as a planner fed with the wrong initial state will produce an inadequate plan. Consequently, a functionality for situation assessment is also needed. By situation assessment we mean the process of identifying what went wrong, and the creation of a description that reflects what is known about the real world state.

In this paper, we study the problem of situation assessment for recovering from anchoring failures in mobile robotics using sensor-based planning [3]. Anchoring is the problem of establishing the correspondence between a symbol and a percept. A type of anchoring failure is when one cannot determine which percept corresponds to a given symbol due to ambiguity: there are several plausible percepts. This requires the robot to generate a description of the current situation and generate a plan that disambiguates that situation. However, the approach in [3] does not quantify uncertainty, so there is no way to distinguish between more likely and less likely candidates. All candidates are considered equally important.

The main contribution of this paper is an approach for automatic situation assessment for recovery planning in terms of probabilistic belief states. The recovery module can assign probabilities to what

perceived object should be anchored to the given symbol, and it can generate plans that disambiguate the current situation with a threshold probability instead of plans that always have to succeed. Finally, it can choose to anchor an object to a symbol with a degree of certainty; absolute certainty is not required. In fact there are situations where certain relevant properties of an object cannot be determined, and absolute certainty about which is the correct object is not attainable. Besides, the robot might have only a limited amount of time for planning. The approach in [3] did not permit this.

Besides probabilities, there are two other contributions relative to [3]. The first one is the use of background knowledge to fill in missing information about perceived objects in terms of conditional probabilities. The second is the handling of new candidate objects that are perceived at run-time. We do so by making a closed world assumption during plan generation (by considering only those relevant objects perceived so far), and we use a monitor process to check that the closed world assumption is not violated. When it is violated, a new plan that takes the new objects into account is generated.

This work is relevant both from the perspective of developing the anchoring framework, and as a case study in the more general problem of sensor-based recovery.

This paper is organized as follows: in the next section we review the concept of perceptual anchoring and the problem of ambiguity. In section 3, we present our method for automatically recovering from ambiguous anchoring situations; this is the central part of the paper. Section 4 presents 3 different experiments intended to test our approach, and section 5 provides some discussion.

2 Overview of Perceptual Anchoring

Anchoring is the process of establishing and maintaining the correspondence between the perceptual data and symbolic abstract representation that refer to the same physical object [4]. Intelligent embedded systems using symbolic representations, such as mobile robots, need to perform some form of anchoring in order to achieve their tasks. Consider a mobile robot, equipped with a vision system and a symbolic AI planner, trying to find dangerous gas bottles in a building at fire. In order to execute the ‘GoNear (bottle1)’ action, where the symbol ‘bottle1’ refers to an object described as ‘a green gas bottle’, the robot must make sure that the vision percept it is approaching is the one of the object whose identity is ‘bottle1’.

The symbolic description of an object with symbol o is denoted $Desc(o)$. A percept π consists of information about an object derived from sensor data (e.g. a video image), such as estimates of shape, color and other properties. These estimates are often uncertain; for instance, the vision module we use assigns degrees to the values of properties and to the classification of objects.

¹ Center for Applied Autonomous Sensor Systems - AASS;
Örebro University; Sweden; Web: <http://www.aass.oru.se>; Email: {abdelbaki.bouguerra,lars.karlsson}@tech.oru.se; asaffio@aass.oru.se

In order to decide which percept π to anchor to a given symbol o , one needs to match $Desc(o)$ against the properties of π . The result is either *no* match, a *partial* or a *complete* match [5]. A percept π is said to be completely matching o if all the properties of $Desc(o)$ match those of π , and partially matching if it at least a property of the description $Desc(o)$ cannot be determined to match its counterpart in π due to uncertainty.

Another important distinction is whether a symbol o is making a definite reference, to exactly one object in the world ("the red ball"), or an indefinite reference, to any matching object ("a red ball").

2.1 Relational properties

There are situations when it is relevant to describe objects not just in terms of their properties but also their relations to other objects. An example is "the green garbage can that is near the red ball and the blue box". We consider the object that needs to be anchored, in the example "the green can", as the *primary object* and the other objects related to it, in the example "the red ball" and "the blue box", as *secondary objects* [3]. In this paper we use in particular binary relations and we allow for descriptions with several nested relations.

Definition 1 Let O denote the set of object symbols. A relational description of an object $o \in O$ having m binary relations ($R_{k;1 \leq k \leq m}$) with m secondary objects ($o_k;1 \leq k \leq m$) is denoted $Rel_{desc}(o)$ and it is defined recursively as:

$$Rel_{desc}(o) =_{def} Desc(o) \bigcup_{1 \leq k \leq m} \{R_k(o, o_k)\} \cup Rel_{desc}(o_k)$$

Anchoring a symbol with a relational description, involves considering the secondary objects too. They become new objects to anchor. In practice, we always limit the depth of the relational description.

Example: In a world configuration there are three objects $O = \{o_1, o_2, o_3\}$ such that o_1 is a red ball, o_2 is a blue box, and o_3 is a cup whose color is green. We have also observed that o_1 is *near* o_2 , and o_3 is *on* o_2 . The relational description of o_1 is given by:

$$\begin{aligned} Rel_{desc}(o_1) = & \{(shape\ o_1 = ball), (color\ o_1 = red)\} \cup \\ & \{(near\ o_1\ o_2), (shape\ o_2 = box), (color\ o_2 = blue)\} \cup \\ & \{(on\ o_3\ o_2), (shape\ o_3 = cup), (color\ o_3 = green)\} \end{aligned}$$

2.2 Anchoring with Ambiguities

There are situations where the anchoring module cannot create or maintain an anchor for a specific symbol from its percepts because of the presence of ambiguity, i.e. it cannot determine what anchoring candidate to choose. In order to detect and resolve ambiguities, we need to consider what candidates there are to anchor the given symbol, as well as the symbols of related objects.

Definition 2 A relational anchoring candidate for an object o having m binary relations ($R_{k;1 \leq k \leq m}$) with m secondary objects ($o_k;1 \leq k \leq m$) is represented by a list $(\pi_0, (\pi_{1,1} \dots), (\pi_{2,1} \dots), \dots, (\pi_{m,1} \dots))$ such that π_0 is a candidate percept for the primary object o , and for each secondary object o_k , a (possibly empty) list $(\pi_{k,1} \dots)$ of all candidate percepts satisfying $Rel_{desc}(o_k)$ and relation $R_k(o, o_k)$.

Notice that the same definition applies recursively to relational anchoring candidates for secondary objects. In fact, a relational anchoring candidate can be easily represented using an *and-or* tree where

the *and* nodes represent the relations and the *or* nodes represent the candidate percepts satisfying the relation of the parent node.

A relational anchoring candidate is *completely matching* if π_0 completely matches $Desc(o)$ (the primary object), and for each secondary object o_k there is only one (definite case) or at least one (indefinite case) candidate percept $\pi_{k,j}$ completely matching $Desc(o_k)$. The definite/indefinite distinction here refers to whether the secondary object symbol is definite/indefinite.

A relational anchoring candidate is *partially matching* if for some o_k there is no completely matching percept $\pi_{k,l}$. A special case is when there is no $\pi_{k,l}$ at all, i.e. the candidate list for o_k is empty.

Once each relational candidate for the desired object (primary) has been classified this way, the entire situation is handled. The anchoring module detects the presence of ambiguity on the basis of the number of complete and partial anchoring candidates, and whether the description is definite or indefinite [3]. In short, the definite case is ambiguous unless there is exactly one candidate, and it is completely matching (more than one complete match is considered a conflict). The indefinite case is ambiguous if there is no completely matching candidate. In case of ambiguity the recovery module is invoked to find a plan to acquire additional information about primary and/or secondary candidate objects if necessary.

Example The robot is presented with the symbolic description " $g1$ is a garbage can near a red ball with a mark" and given the task to go near $g1$. To do this, the robot needs to anchor the symbol $g1$. Consider a situation where a garbage can π_0 and a red ball $\pi_{1,1}$ are perceived, but no mark is visible. We have a situation where we have a singleton set $\{(\pi_0, (\pi_{1,1}))\}$ of relational candidates. There is one fully matching percept for the primary object, and one partial match for the secondary object: the mark was not observed. Consequently the entire relational candidate is a partial match, giving rise to ambiguity. Thus, to be sure that the observed garbage can is the requested one, the red ball has to be checked for marks from other viewpoints.

3 Recovering from Anchoring Failures

A recovery situation in anchoring typically occurs when the robot is executing some higher-level plan and encounters an ambiguous situation. Such a situation is handled in six steps:

1. Detection: the problematic situation is detected, and the top-level plan is halted.
2. Situation Assessment: the recovery module analyzes the problematic situation. If the situation is found to be recoverable, i.e. due to uncertain perceptual information (see [3] for more details), it formulates a belief state consisting of a set of possible worlds with probabilities. This step is achieved by considering the properties of the requested object and of the perceived objects to generate different hypotheses for which of the perceived objects corresponds to the requested one.
3. Planning: the planner is called to achieve the goal of disambiguating the situation and anchoring the requested object.
4. Plan Execution: the plan is executed, and either the requested object is found and identified and can be anchored, or it is established that it cannot be identified.
5. Monitoring: if during the execution of the recovery plan, new perceived objects are encountered that completely or partially match the primary or a secondary object, then go back to step 2.
6. Resume: if recovery was successful, the top-level plan is resumed.

The authors in [3] describe how the recovery module builds the initial belief state, that encodes the different hypotheses of anchoring

the desired object to one of the perceived candidates. In summary, it constructs one hypothesis, for each relational anchoring candidate, consisting of a positive (completely matching) description of the chosen candidates, and negative (non-matching) descriptions of the remaining candidates. Hypotheses with zero or two or more candidates may also be generated. These different hypotheses are then combined in a disjunction to generate a (crisp) belief state.

When we introduce probabilities, we need to be able to handle dependencies between different candidates in a graceful manner, in particular when the same percept appears more than once. Consequently, we have taken a reversed approach: instead of starting from the different candidates, we simply start from what is known about the different perceived objects, and generate a belief state from that. While doing this, we can also use background knowledge to fill in missing information about percepts. Next, we go through the possible worlds in the belief state and classify them according to what relational anchoring candidate they agree with (if any).

3.1 Background knowledge

Ambiguous situations typically involve partial matches of some perceived objects. This occurs when a certain property or relation is observed with uncertainty, or neither it nor its opposite was observed at all. Situation assessment involves considering how probable it is that those properties hold. There are two sources from which this information can be obtained.

First, the vision system (and other sensing systems) can provide us with matching degrees, which can serve as weights when assigning a probability distribution to a property or relation. For instance, if it could not be determined whether a perceived object π_1 was red or orange but red is matching better than orange, we might assert in our planner language (color pi-1 = (red 0.6) (orange 0.4)), which means $P(\text{color}(\pi_1) = \text{red}) = 0.6$ and $P(\text{color}(\pi_1) = \text{orange}) = 0.4$.

Second, we can use background knowledge expressed as conditional probabilities. This background knowledge is encoded as probabilistic assertion rules that can specify conditional and prior probability distributions over the values of uncertain properties of perceived objects. Probabilistic assertion rules are a part of a language used for the forward-searching planners [8, 2] to describe the results of the application of an action in a belief state. These action results may involve conditional probabilistic effects, and hence the same representation can also be used to encode background knowledge.

Example: The following rule describes the conditional probability of a perceived object $?o$ containing (has) a substance (milk, tea or nothing) given its shape (cup, bowl, or something else).

```
(forall (?o) (perc ?o)
  (cond
    ((shape ?o = cup)
     (has ?o = (milk 0.4) (Tea 0.4) (nothing 0.2)))
    ((shape ?o = bowl)
     (has ?o = (milk 0.2) (Tea 0.3) (nothing 0.5)))
    ((true) (has ?o = (Tea 0.1) (nothing 0.9))))
```

This rule can be used when we see an object but do not know what it contains. For instance, percepts that have the shape of a cup are believed to contain either milk, or tea (with 0.4 probability), or nothing (with 0.2 probability). Notice how conditional probabilities are defined using the `cond` form which specifies conditional outcomes. It works like a LISP `cond` where each clause consists of a test (which may refer to uncertain properties) followed by a consequent formula.

The `forall` assertion formula allows to iterate over elements of a certain type (here `perc` for percept), to execute an assertion formula (here the `cond` form).

Assertion formulas are applied to belief states, and belief states are probability distributions over sets of possible worlds (crisp states). The assertion formula is applied to each possible world in the belief state, resulting in new possible worlds. These new possible worlds and their probabilities constitute the new belief state(s). Note that the belief state explicitly represents a joint probability distribution over the uncertain properties and relations in the situation.

3.2 Situation Assessment

Once the recovery module is notified of the failure to anchor an object o due to ambiguity, it starts a situation assessment process aiming at creating a belief state representing the different states the world may actually be in, given present uncertainties. The situation assessment process takes a set of relational anchoring candidates as input, and is performed in four steps.

1) Initialization: a number of properties not related to the anchoring candidates are assessed, such as the position of the robot and the topology of the room.

2) Description generation: the descriptions $Desc(\pi_j)$ and $R_k(\pi_j, \pi_k)$ are computed for all the perceived objects π_j in the relational anchoring candidates. The properties and relations that are considered are those appearing in $Rel_{desc}(o)$ for the object o such that π_j is a candidate object for o . Uncertain properties are estimated in the manner described in section 3.1, by using matching degrees and background knowledge. The result of the first step is a belief state representing a joint probability distribution over all uncertain properties and relations of the perceived objects in the candidates.

3) Classification: the possible worlds of the belief state are partitioned into three different sets for the definite case and two sets for the indefinite case. For the definite case, one partition contains the possible worlds where there is a unique matching candidate. A second partition contains those worlds where there is a conflict due to the presence of more than one matching candidate, and a third set includes worlds where there is no matching candidate. Partitioning relies on the evaluation of three existential formulas derived from $Rel_{desc}(o)$. Those formulas test if there is exactly one, two or more, and no relational anchoring candidate that matches $Rel_{desc}(o)$, respectively. In these formulas, the object names in $Rel_{desc}(o)$ are replaced by existentially quantified variables.

When the recovery module deals with an indefinite case, the partitioning yields only the set where there is no matching candidate and the set where there is at least a matching candidate (in the indefinite case there is no situation of conflict).

Sometimes, one might want to provide more weight to the possible worlds where there is exactly one anchoring candidate that matches. After all, if the robot was ordered to go to "the container with milk" it might be reasonable to consider it likely that there is exactly one such object. Hence, at this step one may discount the probability of the possible worlds with none or too many matching candidates using a discount factor α and then renormalize the probability distribution of the possible worlds to sum to one.

4) Labeling: The formula $(\text{anchor } o \ \pi)$ is added to each possible world where percept π is a fully matching candidate, and the formula $(\text{anchor } o \ \text{null})$ to the set of non-matching worlds (and conflict worlds for the definite case) to ascertain that the desired object o is not possible to anchor. The percepts π are those binding the variables in the existential formulas in step 3.

Example Assume that the plan executor could not anchor object $C1$ described as the container with milk which is near the fridge, because there are two perceived container objects π_c and π_b near the fridge π_f : π_c is a green cup and π_b is a blue bowl. Let's also assume that the recovery module uses the probabilistic conditional rule from section 3.1.

In step one, it is asserted that the robot is at the entrance of the coffee room and so on.

There are two relational candidates: $(\pi_c(\pi_f))$ and $(\pi_b(\pi_f))$. Step 2 consists of computing the description of all the perceived objects appearing in the relational candidates and relations among them to build an initial belief state for the subsequent steps.

The descriptions we obtain are a set Rel of two relations $\{(near \pi_c \pi_f), (near \pi_b \pi_f)\}$, and the following descriptions of the different perceived objects:

$$\begin{aligned} Desc(\pi_c) &= \{(perc \pi_c), (shape \pi_c = cup), (color \pi_c = green)\} \\ Desc(\pi_b) &= \{(perc \pi_b), (shape \pi_b = bowl), (color \pi_b = red)\} \\ Desc(\pi_f) &= \{(perc \pi_f), (shape \pi_f = fridge)\} \end{aligned}$$

We assert these descriptions, apply the background knowledge in section 3.1 and obtain a belief state bs with four possible worlds w_1, \dots, w_4 such that:

$$\begin{aligned} w_1 &= \{(has \pi_c = milk), (has \pi_b = (Tea 3/8)(nothing 5/8))\} \\ w_2 &= \{(has \pi_c = milk), (has \pi_b = milk)\} \\ w_3 &= \{(has \pi_c = (Tea 4/6)(nothing 2/6)), \\ &\quad (has \pi_b = (Tea 3/8)(nothing 5/8))\} \\ w_4 &= \{(has \pi_c = (Tea 4/6)(nothing 2/6)), (has \pi_b = milk)\} \end{aligned}$$

In addition, they all contain $Rel \cup Desc(\pi_c) \cup Desc(\pi_b) \cup Desc(\pi_f)$. The probability distribution over the possible worlds is:

$$\begin{aligned} p(w_1) &= 0.4 \cdot 0.8 = 0.32; p(w_2) = 0.4 \cdot 0.2 = 0.08 \\ p(w_3) &= 0.6 \cdot 0.8 = 0.48; p(w_4) = 0.6 \cdot 0.2 = 0.12 \end{aligned}$$

We compute $p(w_1)$ as the joint probability of π_c containing milk and π_b not containing milk, and so on.

In step 3, the situation assessment module classifies the worlds according to the number of matching candidates. In worlds w_1 and w_4 there is one and only one matching candidate. In world w_2 , there are two matching candidates, therefore we have a conflict. Finally in world w_3 there is no candidate object matching $Rel_{desc}(c1)$ i.e. the test formula for no matching candidates, $\neg \exists x_1, x_2 ((has x_1 = milk) \wedge (near x_1 x_2) \wedge (shape x_2 = fridge))$, holds in w_3 .

In step 4, the situation assessment module adds $(anchor c_1 \pi_c)$ to w_1 , $(anchor c_1 \pi_b)$ to w_4 , $(anchor c_1 \text{null})$ to both w_2 and w_3 .

3.3 Planning and Monitoring

3.3.1 Planning and Execution

Once the recovery module has created the belief state encoding the possible worlds, it passes it to the planner together with the goal of finding an anchor to the requested object. We use probabilistic conditional planners for stochastic partially observable domains with actions and sensing modeled in a POMDP-equivalent manner [8, 2].

The generated plans incorporate motion actions and sensing actions aiming at collecting more information about the unknown properties of the perceived objects. They are guaranteed to solve the planning problem (if it is solvable) with a certain probability of success.

The anchoring plan is then sent to the plan execution and monitoring module. Fig. 1 shows the global architecture of our mobile robot. The recovery module is part of the block labeled Executor/Monitor.

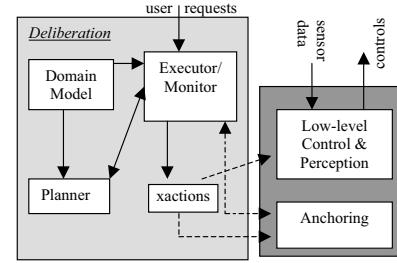

Figure 1. Plan execution and monitoring architecture

The actions such as $(smell \pi_c)$ and $(move-to pos2)$ are translated into executable perceptual and movement tasks ($xactions$ in the figure) that are sent to the low-level control architecture for execution. The anchoring module provides the plan executor/monitor with the results of perceptual task, which allow the latter to keep an updated belief state and to monitor how the plan progresses. The domain model module in the figure stores planning domains (actions, axioms and predicates) as well as the different conditional rules for building the background knowledge.

3.3.2 Closed World Assumption Monitoring

The recovery plans are generated under the assumption that all relevant candidates have been observed, with the exception of the explicit “missing objects” used when there is no candidate at all. However, there may be additional candidate objects that are not visible from the initial position of the robot, but become visible as the robot moves around while executing its recovery plan. The anchoring system regularly checks for the appearance of new percepts matching the description of the requested object. If such a percept is detected, the assumption of knowing all relevant objects has been violated, and the current recovery plan is considered obsolete. Hence, a new initial belief state is produced, taking into account the previous perceived objects and the information we have gained of those, as well as the new perceived object, and a new recovery plan is generated. This new plan replaces the old one.

Replanning for new candidate objects is not only used for the unexpected discovery of a new object: it is also instrumental in the case where the robot was explicitly searching for a candidate, and found a partially matching one. In such a situation, one cannot jump to the conclusion that the correct object has been found, but must plan to find more information about the object in question (together with the other remaining candidate objects).

4 Experiments

In [3] it has been experimentally demonstrated that the ability to recover from anchoring failures can improve the robustness of the behaviors of a mobile robot. Here, we intend to demonstrate how our approach can handle three different scenarios where probabilities are required. Our experiments are intended to show the feasibility of our approach; not to evaluate its performance. The experiments were run on a Magellan Pro Research Robot equipped with a CCD camera. The recovery planning time was always less than two seconds.

Scenario 1 serves to demonstrate that we can handle cases where there is no recovery plan that is certain to succeed. Our robot is to approach a marked gas bottle (indefinite reference). From its initial position, it

perceives two gas bottles π_1 and π_2 , but no mark is perceived on them. The mark may be on one of four sides of each gas bottle. However, the presence of obstacles prevents observing them from all sides. The situation assessment produced a belief state consisting of four possible worlds w_1, \dots, w_4 with a uniform probability i.e. $p(w_i) = 1/4; 1 \leq i \leq 4$. Each world reflects if π_1 or π_2 is having a mark, and if it had a mark, on which side it is. A plan was generated in which the robot is to move to the different accessible positions to look for a mark on the perceived gas bottles. When observation actions are performed, the probabilities of the possible worlds are updated accordingly. For instance, if no mark is seen on one side of π_1 , the probability that π_1 is a match decreases. In one of the runs, the robot had not found a mark after observing π_1 from three sides, and π_2 from two sides. At this stage, the anchoring module decided to anchor the more likely candidate π_2 but with a low degree of certainty. The scenario was also run successfully under different configurations (in terms of the locations of the gas bottles, whether they were marked, and observability of the marks on them).

Scenario 2 concerns run-time handling of new objects. Again, our robot is to approach a gas bottle with a mark upon it (indefinite reference). This time, only one gas bottle π_1 is initially perceived. The situation assessment produced a belief state with two uniformly distributed possible worlds w_1 (π_1 is marked), and w_2 (π_1 is not marked). In this scenario, all sides are observable, therefore in w_1 there is a probability distribution for which side, of the gas bottle, has the mark. When the recovery plan is executed, and the robot has moved to a different position, it detects a second gas bottle initially occluded by the first one. The situation is reassessed (to include the new perceived gas bottle) and a new recovery plan is produced that includes actions to check both the old and the new gas bottle. Also, this scenario was successfully run under different configurations (which of the bottles was marked, and which side of the bottle the mark was on).

Scenario 3 involves using background knowledge to resolve an ambiguous situation, where planning time is very short. The robot has to achieve the same task as before, but in addition there is the background knowledge that 90% of brown gas bottles have a mark, and only 20% of green ones have a mark. From its initial position, the robot perceives two gas bottles: one green and one brown. Using the background knowledge, the situation assessment procedure notices that the brown gas bottle has a higher chance of matching the description and decides to anchor it directly.

5 Discussion and Conclusions

We have presented a probabilistic approach to recovering from ambiguous anchoring situations, i.e. when one cannot determine which percept corresponds to a given symbol. The only previous approach [3] was non-probabilistic, and could not distinguish between more likely and less likely candidates, nor could it handle cases where the ambiguous situation could only partially be resolved.

Our approach (just like the previous one) builds on the steps detection, situation assessment, plan generation and execution. In addition, we have added monitoring for the appearance of new relevant objects. We have focused on the assessment step, where we have introduced the possibility to use matching degrees for percepts as well as background knowledge specifying conditional probabilities to determine the probability distributions for uncertain or unknown properties and relations.

The background knowledge is specified in terms of assertion formulas in the language of our planners. That has the advantage that they can be applied directly to the belief states that are to be used by

the planners, but they do not offer a compact representation of uncertainty. Therefore, we are presently considering other representations for our situation assessment steps. Probabilistic relational models (PRMs) [6] generalize Bayesian Networks to represent first order knowledge i.e. knowledge involving classes of objects where some attributes in a specific class are uncertain and may depend on attributes of the same class or another one. Relational Bayesian Networks [7] are also a tool that uses Bayesian Networks to represent objects explicitly and relations among them. Finally, the Bayesian language BLOG [10] is a tool that can be used to create first order probabilistic models involving unknown number of objects. BLOG deals with possible worlds of different numbers of objects and uncertainty about their attributes. That might offer a way to reason and plan explicitly about unobserved but possibly present objects. However, we have favored handling that problem by interleaving planning and execution, a desirable characteristic for acting under uncertainty due to lack of information [11].

The particular problem we have addressed in this paper concerns the important problem of anchoring: if a mobile robot with symbolic cognitive layer is to interact with different objects in its environment, it will frequently need to anchor those objects. A robust anchoring mechanism is then a prerequisite for robust behaviors. But the problem is also interesting as a case of what can be called epistemic recovery: if the plans of a robot or other agent is stalled due to lack of information, how can that be handled? We believe our work has demonstrated the usefulness of probabilistic sensor-based planning, and the important role of situation assessment in such unexpected situations.

Learning Behaviors Models for Robot Execution Control

Infantes Guillaume and Ingrand Félix and Ghallab Malik¹

Abstract. Robust execution of robotic tasks is a difficult problem. In many situations, these tasks involve complex behaviors combining different functionalities (e.g. perception, localization, motion planning and motion execution). These behaviors are often programmed with a strong focus on the robustness of the behavior itself, not on the definition of a “high level” model to be used by a task planner and an execution controller. We propose to learn behaviors models as structured stochastic processes: Dynamic Bayesian Network. Indeed, the DBN formalism allows us to learn and control behaviors with controllable parameters. We experimented our approach on a real robot, where we learned over a large number of runs the model of a complex navigation task using a modified version of Expectation Maximization for DBN. The resulting DBN is then used to control the robot navigation behavior and we show that for some given objectives (e.g. avoid failure, optimize speed), the learned DBN driven controller performs much better than the programmed controller. We also show a way to achieve efficient incremental learning of the DBN. We believe that the proposed approach remains generic and can be used to learn complex behaviors other than navigation and for other autonomous systems.

1 Introduction and Motivations

Tasks execution on autonomous robots is a very complex process: exploration rovers are expected to plan and properly execute their science observation missions; museum guide robots have to robustly execute their tour plans for visitors interested in a given subject; service robots must plan and execute daily activities for the elderly people they assist etc. The building blocks of these plans, i.e. the tasks and actions, can be quite complex. We refer to them as behaviors. These behaviors usually have an intrinsic complexity (e.g. navigation for a museum guide robot involve localization, perception, motion planning, etc.). Moreover, often no explicit model exists of how it performs in various environments. Last, even if a deterministic model of these behavior exists, it may not be appropriate to handle the intrinsic non-determinism of the environment and of the behavior execution outcomes. As a result, one has to cope with a planning problem where one must plan actions execution with poor model, or even, in some situation, with no model at all.

Some approaches [2] try to model actions deterministically, and apply a probabilistic bias afterward. This kind of approach may not be relevant for intrinsically stochastic systems, which are more common in real-world domain. Bayesian Networks [19] give to the authors of [9] the ability to model the actions and predict the effects of a manipulation task of a robot. But while this kind of model captures the stochastic nature of the system, it does not take into account its long-term dynamics.

Systems may be modeled as a Hidden Markov Model (HMM) [20]. In these models, the internal state is *hidden* to the observer, who

can only see the *observation*, that represent effects of the system on the environment. These stochastic models have proved quite adapted in domains such as speech recognition [20], modeling human activity [16], probabilistic plan recognition [5] and learning topological and metric maps [14]. In [10], the authors present an approach to models robot actions using HMM. Indeed, the resulting HMM actions can be used to recognize or to plan the modeled actions.

Yet, this representation does not allow the finer control of the action execution. An aspect of complex actions we want to address is that some of these activities may be controllable. Finding the proper parameter values with respect to the current environment and goal can be quite a challenge if again no model of the underlying action is available. Hence we would like to learn action models rich enough to allow us to use them to perform any of recognition, planning, control or supervision of the action. We propose to learn action models as highly structured stochastic processes: Dynamic Bayesian Network (DBN) [8].

We detail how such a model can be obtained from a number of real-world runs. We then show how it can be used to control the action itself while executing. We also sketch how this could be embedded in a more general controller able to supervise the action execution (to avoid failure) and to decide when the model has to be refined for new situations arising. The paper is organized as follow. The next section presents a complex robot behavior to model and to adapt. We then present how we can learn such a structured stochastic model. The following section presents how we can use the learned model, followed by a section on results obtained on a real robot (i.e. the learning phase as well as controlling the robot using the learned model). We then conclude the paper with a discussion on the current work as well as some perspectives we are currently pursuing.

2 Modeling and Adapting Robot Behavior

To conduct our experiments, we modeled a robotic navigation task, based on ND² reactive obstacle avoidance [17]. A schematic view of this navigation modality can be seen on figure 1(a). The laser range finder gives a set of points representing obstacles in front of the robot. These points are used to build a local map around the robot by the *aspect* module. ND uses the current position of the robot to compute the local goal in the robot’s coordinate system. Then with this local goal and the map around the robot, it computes a speed reference that tends to move the robot towards the goal position while avoiding obstacles. This modality is used on our B21R robot (figure 1(b)).

² Note that despite the fact that ND was partially developed in our lab (over a number of years), it is so intrinsically complex, and so “difficult” to tune, that no model exists which could help us supervise, control and plan its execution.

2.1 Structure of a Navigation Task

A navigation controller can be seen as a “black box” taking a relative goal position and some data about the environment as inputs and giving as output a speed reference for the robot to execute. We can model this by having an internal hidden state of the robot, with hidden variables. The control parameters of the navigation are observable and have an influence on the internal state. It changes the environment, because the environment is measured through the sensors of the robot: if the robot goes into a dead-end, the environment will seem very cluttered. The general structure can be seen on figure 2.

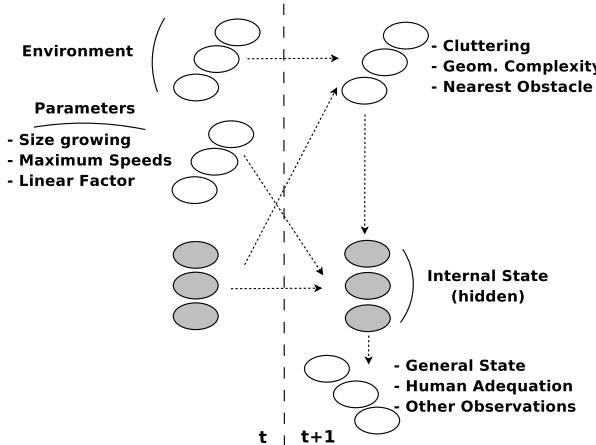

Figure 2. Abstract DBN structure for a navigation task

Choosing the variables is highly dependent on the process to model. The control parameters are given by the navigation controller, but we must choose wisely environment variables that represent important parameters for decisions made by the control process. In our reactive navigation task, the cluttering of the environment is to be taken into account, so is the closest obstacle, which has much influence on the future sight of the robot. On the other hand, we avoid including the position of the robot, so that the model can be used in places different from the one where the learning was performed.

The effects of the navigation task we need to recognize are the *fail* and *success* states, but we also aim at controlling more precisely the behavior in a qualitative way: some behaviors are successful, but not optimal. We also include as many variables as we can that could give us a hint on the internal state, for the learning process to be more

effective. Finally, we could also model resource usage.

2.2 Instantiation

For our navigation task, the control parameters are: the two **size growing** parameters of the robot: one surface represents the robot (where obstacles are totally forbidden); and a larger security area where there should be as few obstacles as possible; the **maximum linear and angular speeds** allowed; a **linearity factor** between the two speeds given by the motion generator controller.³

The environment variables chosen are: the **cluttering** of the environment, defined as a weighted sum of distances to nearest obstacles around the robot; the **angle of the nearest obstacle**; the **distance to the nearest obstacle**; the global **number of segments** in the scene and the number of possible ways to go (**valleys**) built by ND.

The output observable variables are: the current **linear and angular speeds** of the robot; its current **linear and angular accelerations**; the **variation of the distance to the goal** (estimated as an euclidean distance); the **achieved ratio** of the mission; the **current strategy** chosen by ND; the **general state** in *begin, end, fail, normal*; the **human adequacy** of the behavior⁴.

All the variables are discretized (into clusters from 3 to 6 values). The number of different potentially possible observations is more than 15×10^9 . This indicates that even with a very large number of runs, all possible observations will never be seen, leading to many non-informative transition probabilities into the DBN. We will show later how to deal with such a sparse DBN for decision making.

3 DBN Learning

To learn a DBN, we use an adaptation of the classical Expectation-Maximization (EM) algorithm defined for Hidden Markov Models [20]. The adaptations to make this algorithm tractable for DBN are not straightforward: we need to maintain an approximated “belief state”, i.e. a probabilistic hypothesis over the possible assignment of the values of the variables because they are strongly correlated. We choose to approximate this belief state as a particle filter, with a variable number of particles.

3.1 Parameters Learning

A DBN λ is defined by a set of variables (hidden or observable), a set of possible values for each variable, and a set of probabilistic causal links between the variables [8]. An evidence O is as a sequence of observations (i.e. instantiations of all observable variables of λ).

A good model λ with respect to O gives a high $P(O|\lambda)$ (likelihood of the evidence). In the DBN framework, λ may be adapted to the evidence either by modifying its structure or the probabilities attached to the causal links in a given structure. The EM algorithm can deal with hidden variables, but not with structure of the model.

In the HMM case, EM first compute probabilities of being in every hidden state, then every transition probability and every probability of seeing each observation from each hidden state, this for every time step. This is often referred as the Expectation step. For a DBN, the hidden state becomes an instantiation of the corresponding variables, and so does an observation. The state has to be approximated

³ The linear and angular speeds are mutually constrained by a polynomial function that influences the type of trajectory produced.

⁴ Some behaviors leads to success, but may be considered as too aggressive for humans around the robot, or on the contrary too shy, and thus to slow. Its value has to be given by the operator during the learning phase.

as a *belief state*, i.e. a set of weighted hypotheses over all possible instances. Furthermore, the observable variables are not decoupled from the hidden ones, so we compute an observation probability not only from hidden variables, but from the whole belief state. Then we can update the transition probabilities to maximize $P(O|\lambda)$. Then we go again into Expectation and Maximization steps. This algorithm is proved to reach a local maximum of $P(O|\lambda)$.

Choosing a good representation for the belief state is critical for the algorithm to behave correctly. A flat representation over the variables would lose all the correlations among them, being a very bad approximation. On the other side, maintaining an exact belief state implies keeping all correlations over time, and thus is exponentially complex over the length of the evidence [4]. Approximating the belief state with a particle filter seems to be a good trade-off. But while the size of the hypothesis state is very large, we choose to have a variable number of particles, because the probability of seeing the observations knowing the belief state might become very low. We maintain this probability by changing the number of particles in order to have always the same probability of seeing the observation [15].

3.2 Structure Learning

The EM algorithm updates only the transitions probabilities, without changing the structure of the DBN. An algorithm has been proposed [11] to add inside the loop some structural changes. The main issue is to evaluate the new model efficiently knowing the current one. Furthermore, this algorithm acts only as a local search into the structure space, so the optimal structure may not be reached. The GES algorithm [6] has been proposed to find an optimal structure of a Bayesian network. However, this technique relies upon sufficient statistical knowledge of the process, which is not our case due to the very large size of the observation space. In our case, the global structure is known. In order to decrease the size of the DBN and speed up the learning process, we plan to use these techniques only on the hidden variables of the process (and on the links toward the observable variables). For now, we use the structure described in section 5.1.

3.3 Incremental Learning

An open issue for learning stochastic models is the possibility to add knowledge into a previously learned model. This is difficult because the learning phase is a local search, and the algorithm must take into account all observations with the same weight.

We propose the following algorithm: we first learn λ_1 upon a training sequence $(O_1..O_i)$. Then we learn λ_2 over $(O_j..O_n)$, taking λ_1 as a start point for the local search of λ_2 ⁵. When its done, we simply sum λ_1 and λ_2 . For this merging to work, it must be applied after each iteration of EM, i.e. the merged DBN must be used for Maximization and not only for Expectation. We think this is because the role of the hidden variables may be changed otherwise, loosing the “meaning” of them. If the merging is done only between the different phases, the newly learned DBN optimizes itself only in the space of the current trunk of observations and goes somewhat “too far” from the previous one. In this case, the sum of the two DBNs does not reflect the reality of the space of the sum of the observations. This will be investigated in future work.

⁵ Note that λ_1 was learned from a random starting point. Thus the next phases of the learning should be better than the first, because the start point is not random, but somewhat represents a part of the dynamic of the system.

4 Adaptation of the Behavior

One possible use of the model presented in section 2.1 is to find optimal values for the ND motion generator controller, depending on the environment. ND is usually used with a fixed set of parameters, that are not optimal in every situation. We aim at having a fine-grained adaption of the parameters of the controller, modeled as a DBN, to optimize the navigation itself.

We need to introduce utilities into some of our variables with respect to an optimality criterion. We need to give high rewards to variable values that will lead to a desired behavior and penalties to values that will lead to a bad one. Typically, we need to avoid the *fail* value of the **general state** variable, while we want to reach the *end* value.

We also introduce a secondary criterion on the **human adequacy** of the navigation behavior. Between two successful behaviors, we prefer a behavior where the *normal* value of the **human adequacy** appears often, and try to avoid the *aggressive* and *shy* values of this variable. All these utilities will be given as scalar values, so we need to give greater values to the **general state** variable, and smaller ones to the secondary criterion, to avoid the case where the robot could collect reward by having a proper behavior with respect to humans, yet fail, thinking it is better to be gentle than to achieve its task.

4.1 Decision

In this application, the temporal aspect is primordial. The command process works at a frequency of 2.5 Hertz. The behavior adapter has a frequency of 1.66 Hz to collect the observations, but we do not need it to change the parameters at such a high frequency. Typically the parameters changes should occur at most at 0.5 Hertz, or less. Otherwise, the system could demonstrate a very unstable behavior.

So the problem we face is quite different from a classical Dynamic Decision Network [23] resolution, where a decision is taken after each observation, and the result is a decision tree which associates to each observation sequence an optimal decision sequence. Furthermore, the branching factor for a decision tree would be too high. We need a radically different strategy: we consider that when we take a decision, it will remain the same for a given amount of time. So we independently evaluate every decision towards a given horizon, and choose the best one.

The DBN we build includes a model of the evolution of the environment, thus we can accurately predict what will happen in the future. Starting from a belief state for the current time step (i.e. a probabilistic hypothesis on the current state of the system, including hidden variables), we can infer from the DBN the future belief states for each set of parameters and deduce the corresponding utilities.

The belief state is represented as a particle filter, each particle represents a weighted hypothesis on the values of the variables. When inferring the particles over time, we can compute the expected utility by simply summing utilities encountered by particles. This can be done for a few steps forward (which leads to imprecise expectations), or until all particles reach a final state (defined by the *end* and *fail* values of **general state**). The size of the estimation of the belief state (i.e. the number of particles used) is therefore a critical bottleneck for real-time decision making; to solve this issue, we sample the belief state to focus only on the few most probable hypothesis.

4.2 Meta Decision

We introduce a confidence factor in every transition probability. This confidence factor is the number of updates of a transition probability

during the learning phase. This helps us to differentiate an equiprobability due to a never seen transition into the data set from an informative one. When inferring particles to predict expected utilities of the decisions, we also collect the confidence factors of the transitions the particles used. If a particle comes with a high confidence factor, this means that this particle re-played in a learned set, whereas if the confidence factor is low, the particle went through never learned transitions. Thus the decision has to be taken in a two dimensional space: *utility* \times *confidence*. If we prefer to take a decision with high confidence, this will lead to re-play a previously learned observation, and the robot will preferably exploit its model. On the contrary, if we choose a decision with a low confidence factor, this will lead go through never learned transitions of our model, making the robot more “exploratory” of its capabilities, with a higher risk of failure. We encounter here the classic learning agent “exploration versus exploitation” trade-off, in an original fashion.

5 Results

5.1 Navigation Behavior Learning

The model management is implemented into a real-world robotic architecture [1], on a B21R robot. The monitoring of raw data is done at a frequency of 2.5 Hertz. The scalar raw data are clustered using k-means clustering [13] in order to obtain a few clusters.

The a priori adjacency structure of the graph is the following:

- in the same time step, every environment variable is linked to every hidden variable, every hidden variable is connected to every other hidden one, and finally every hidden variable is connect to every post-control observable variable;
- from step t to step $t + 1$, every observable variable is linked to itself, every control variable is linked to every hidden variable, and every hidden variable is connected to itself.

We did about 120 navigations of the robot into different environments, choosing randomly the control parameters at random frequencies; for a total of a few hundred meters of motion into cluttered environments, with people around the robot. The operator was asked to give the value of the **human adequacy** (into *good*, *aggressive*, and *shy*). He also has a *fail* button to stop navigations before dangerous failure like collisions. A failure case was automatically detected when the robot did not move during a given amount of time. The number of observations collected is about 7,000. Yet, it does not cover the total observation space at all. The learning of the DBN takes several minutes per iteration of Expectation-Maximization. The learned DBN stabilizes after less than 10 iterations. As EM is a local search, we use a “conservative” DBN as a starting point, meaning that with this DBN the probability that the variables change their value is low (about 10%).

To evaluate the quality of the learned DBN, we learn the DBN on all observations but one, and try to predict this observation. This is done by inferring a particle filter on the DBN, choosing the most probable observation in this particle filter, and comparing this predicted observation to the actual one. The global observation is seldom exactly the same, but is generally very close, that means that in most cases the particle filter predicts well most of the observable variables. An overview of recognition results is shown on table 3. We can notice that the recognition results are significantly better than a random prediction. Furthermore, if some aspects of the internal mechanisms of ND have not been well modeled (as the strategy choice, or number of valleys build) because of the lack of the environment variables that uses ND “for real”, the general behavior and the human adequacy are

well predicted. And these are the variables we use in particular for control.

variable	random guess	dbn
cluttering	33.3	87.3
angle of obstacle	25.0	86.4
dist. to obstacle	25.0	88.5
# segments	33.3	81.6
# valleys	33.3	79.9
v	33.3	90.8
w	25.0	79.0
dv	33.3	91.9
dw	33.3	92.2
Δ dist. to goal	33.3	77.8
% mission	33.3	97.1
strategy	20.0	84.8
general	25.0	96.4
adequacy	33.3	92.5
average	29.0	87.6

Figure 3. Table of well-guessed one-step predictions (%)

Using more hidden variables gives better results, meaning that 2 hidden variables with an arity of 2 is not enough. But using more hidden variables makes the learning process much longer because of the “complete” structure we use. Here we consider 49 causal links, while with 3 variables it comes up to 73. We intend to decrease this amount of links using structure learning in future work.

5.2 Control

The decision level of the behavior adapter was implemented using OpenPRS [12]. The current belief state is maintained along the navigation, and when a choice is to be made, it is sampled in order to limit the size of the particle filter for prediction.

In our control experiments, the choices were made at a fixed period of 2 seconds, changing reactive obstacle avoidance parameters dynamically during navigation, without stopping the robot motion. Therefore, the navigation behaves better than with default static hand-tuned parameters usually used on this robot, and much better than with random parameters. Typically, during the learning phase with random parameters, 1 run out of 3 ends on a failure state due to collisions or to blocked situations, while with the behavior adapter, the failures happen only once out of 10 experiments. This happens while using a parameter set never tried during the learning phase⁶. Also, in the learning phase, we label as *good* the parameters producing very high accelerations when the robots enters an open area. We give rewards to this value for decision making, and this behavior is clearly noticeable in these experiments, while it is not with the default hand-tuned parameters. This gives us quicker navigation for open areas than with default parameters. The average speedup of the navigation will be quantified in a future work.

Collecting observations can be made in the same time than active behavior adapting; the next step is to decide when the robot should use computed behavior or behaviors that extend the variety of the set of collected observations.

⁶ This is due to a confidence factor allowing learning more than using the model.

5.3 Incremental Learning

To evaluate the incremental learning algorithm, we learned a DBN in five phases as explained in section 3.3. Each phase uses 20% of the total observation. On figure 4, the phases are numbered on the X-axis. The Y-axis represents the log-likelihood obtained. The upper line shows the log-likelihood obtained with a single phase of learning (upon all observations). While the summed DBN does not behave as well as the one learned in a single phase, the difference is very small.

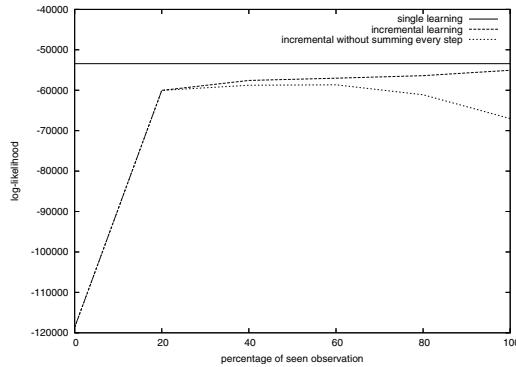

Figure 4. Incremental learning likelihoods

6 Conclusion and Discussion

We have presented an innovative approach to learn DBN models of complex robot behaviors. In our context, where we want to learn a model where controllable variables remain observable, DBN are preferable to HMM. We developed a modified version of EM for DBN. We presented our behavior controller, and how it can be used to learn the model and then use it online. The approach has been implemented and successfully tested on a robotic platform. We showed that, for a fairly complex navigation task, we were able to learn a model which, when used to dynamically set the controllable parameters (according to given objectives), performs much better than the default set, or a random set.

This work is closely related to [16], where the authors tries to model human activities with hierarchical DBN. Our approach tries to deal with more variables, and with sparse data sets. Furthermore, we propose a direct way to use our model not only for diagnosis, but to control the process itself. In [18], the authors learn to recognize robotic behaviors that fits with human judgment, but the emphasis is more on “how to built variables that make a intuitive sense” than on use of this kind of model. The proposed approache is a more classical planning one [21]. We propose an efficient way for mixing learning and decisions making. Our approach is in the same spirit than [3], where the authors model the system as neural nets or with tree induction, then take decision based on a MDP, for robotic autonomous navigation. We propose a more integrated approach, where the decision-taking mechanism is much closer from the model itself. Furthermore, it allows taking into account hidden variables, i.e. a more complex structure of the model itself. We propose a way to build a model using more features than the one proposed. In [22] the authors present an original way of optimizing tasks execution. High-level tasks are built with a number of parameters that must be optimized for smooth execution. Performance models are learned for the parameter sets as tree rules, but much of the work is hand-made. Our approach is automated, and the models we build are more expressive (while harshly

human-readable), due to the presence of hidden variables. Furthermore, the models we built are fully probabilistic, while this is not the case in this work. Both approaches show very high computational cost when different complex tasks have to be mixed.

In the long run, we keep in mind that these learned behaviors should not only be used to control the robot execution (to avoid failure and to optimize the execution), but can also be taken into account by a high level planner able to choose among a set of such behaviors.

Despite our application to a navigation task of a museum guide robot, we believe that the approach remains applicable to other behaviors and could be used for other autonomous systems.

Plan-Based Configuration of a Group of Robots

Robert Lundh and **Lars Karlsson** and **Alessandro Saffiotti**¹

Abstract. We consider groups of autonomous robots in which robots can help each other by offering information-producing functionalities. A functional *configuration* is a way to allocate and connect functionalities among robots. In general, different configurations can be used to solve the same task, depending on the current situation. In this paper, we define the idea of functional configuration, and we propose a plan-based approach to automatically generate a preferred configuration for a given task, environment, and set of resources. To illustrate these ideas, we show a simple experiment in which two robots mutually help each-other to cross a door.

1 Introduction

Consider the situation shown in Figure 1, in which a mobile robot, named Pippi, has the task to push a box across a door. In order to perform this task, Pippi needs to know the position and orientation of the door relative to itself at every time during execution. It can do so by using its sensors, e.g., a camera, to detect the edges of the door and measure their distance and bearing. While pushing the box, however, the camera may be covered by the box. Pippi can still rely on the previously observed position, and update this position using odometry while it moves. Unfortunately, odometry will be especially unreliable during the push operation due to slippage of the wheels. There is, however, another solution: a second robot, called Emil, could observe the scene from an external point of view in order to compute the position of the door relative to Pippi, and communicate this information to Pippi.

The above scenario illustrates a simple instance of the general approach that we suggest in this paper: to let robots help each other by borrowing functionalities from one another. In the above example, Pippi needs a functionality to measure the relative position and orientation of the door in order to perform its task: it has the options to either compute this information using its own sensors, or to borrow this functionality from Emil.

More generally, we consider a society of autonomous robotic systems embedded in a common environment [5]. Each robot in the society includes a number of *functionalities*: for instance, functionalities for image understanding, localization, planning, and so on. We do not assume that the robots are homogeneous: they may have different sensing, acting, and reasoning capacities, and some of them may be as simple as a fixed camera monitoring the environment. The key point here is that each robot may also use functionalities from other robots in order to compensate for the ones that it is lacking, or to improve its own. In the situation shown in Figure 1, Pippi borrows from Emil a perceptual functionality for measuring the relative position between the door and itself.

¹ Center for Applied Autonomous Sensor Systems, Örebro University, Sweden. email: {robert.lundh, lars.karlsson, alessandro.saffiotti}@aass.oru.se

We informally call *configuration* any way to allocate and connect the functionalities of a distributed multi-robot system. Often, the same task can be performed by using different configurations. For example, in our scenario, Pippi can perform its door-crossing task by connecting its own door-crossing functionality to either (1) its own perception functionality, (2) a perception functionality borrowed from Emil, or (3) a perception functionality borrowed from a camera placed over the door. Having the possibility to use different configurations to perform the same task opens the way to improve the flexibility, reliability, and adaptivity of a society of robotic agents. Ideally, we would like to automatically select, at any given moment, the best available configuration, and to change it when the situation has changed.

In this context, our overall research objective is threefold:

1. To formally define the concept of functional *configuration* of a robot society.
2. To study how to *automatically generate* a configuration of a robot society for a given task, environment, and set of resources.
3. To study when and how to *change* this configuration in response to changes in the environment, task, or resources.

In this paper, we focus on the first two objectives above: the third objective will be the subject of future work. More specifically, we define a concept of configuration which is adequate from the purpose of automatically reasoning about configurations, and show how to use AI planning techniques to generate a configuration that solves a given task. We also describe an experimental system where these ideas are

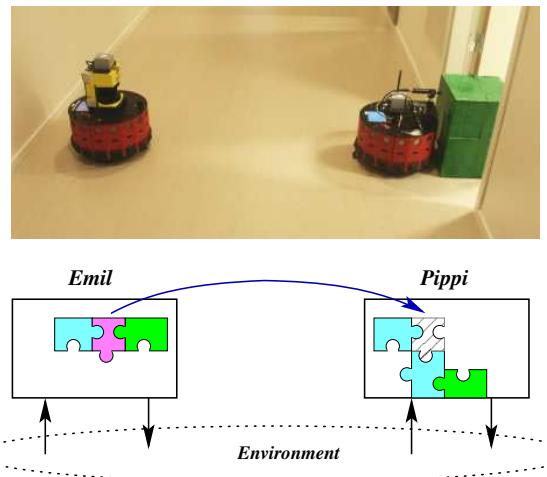

Figure 1. Top: Emil helps Pippi to push the box through the door by measuring their relative position. Bottom: the corresponding configuration in which Emil is providing a missing perceptual functionality to Pippi.

implemented, and show an example of it in which two iRobot Magellan Pro robots mutually help each other to cross a door.

2 Functional configurations

The first goal in our research program is to develop a definition of configuration that is adequate for the three objectives presented in the introduction. In general, a configuration of a team of robots may include interconnected functionalities of two types: functionalities that change the internal state by providing or processing information, and functionalities that change the state of the environment. (Some functionalities can have both aspects.)

To define our notion of configurations, a clarification of the three concepts of functionality, resource and channel is in order.

2.1 Preliminaries

We assume that the world can be in a number of different states. The set of all potential world states is denoted S . There is a number of robots r_1, \dots, r_n . The properties of the robots, such as what sensors they are equipped with and their current positions, are considered to be part of the current world state s_0 . There are also a number of communication media CM , such as radio, network, internal message queues, which can be used to transfer information between and within robots. A medium may have restrictions on band width.

2.2 Functionality

A *functionality* is an operator that uses information (provided by other functionalities) to produce additional information. A functionality is denoted by

$$f = \langle r, Id, I, O, \Phi, Pr, Po, Freq, Cost \rangle$$

Each instance of a functionality is located at a specific robot or other type of agent r and has a specific identifier Id .² The remaining fields of the functionality tuple represents:

- $I = \{i_1, i_2, \dots, i_n\}$ is a specification of inputs, where $i_k = \langle descr, dom \rangle$. The descriptor (*descr*) gives the state variable of the input data, and the domain (*dom*) specifies to which set the data must belongs.
- $O = \{o_1, o_2, \dots, o_m\}$ is a specification of outputs, where $o_k = \langle descr, dom \rangle$. The descriptor (*descr*) gives the state variable of the output data, and the domain (*dom*) specifies to which set the data must belongs.
- $\Phi : dom(I) \rightarrow dom(O)$ specifies the relations between inputs and outputs.
- $Pr : S \rightarrow \{T, F\}$ specifies the causal preconditions of the functionality. Pr specifies in what states $s \in S$ the functionality can be used.
- $Po : S \times dom(I) \rightarrow S$ specifies the causal postconditions. It is a function that, given the input to the functionality, transforms the world state s before the functionality was executed into the world state s' after the functionality has been executed.
- $Freq$ specifies how often the functionality is to be executed.
- $Cost$ specifies how expensive the functionality is, e.g. in terms of time, processor utilization, energy, etc.

² When referring to a specific element in a functionality or other entity represented as a tuple, we will be using a functional notation, e.g. $r(f)$ is the r field in the tuple of f .

A typical functionality could be the measure door operation mentioned in the introductory example. This functionality takes an image from a camera as an input and measures the position and orientation of a door in the image. To produce the output, the position and the orientation of the door, this functionality has a precondition that needs to be satisfied. The precondition is that the door must be visible in the (input) image.

2.3 Resource

A *resource* is a special case of a functionality. There are two different types of resources: sensing resources and action resources. A *sensing resource* has $I = \emptyset$, i.e., no input from other functionalities, and is typically a sensor that gives information about the current state of the surrounding environment or the physical state of the robot. An example of a sensing resource is a camera, which produces images as output as long as the preconditions (e.g. camera is on) are fulfilled.

An *action resource* has $O = \emptyset$ (i.e., gives no output to other functionalities) and Po is not the identity function. An action resource is typically some actuator (e.g., a manipulator).

2.4 Channel

A *channel* $Ch = \langle f_{send}, o, f_{rec}, i, medium \rangle$ transfers data from an output o of a functionality f_{send} to an input i of another functionality f_{rec} . It can be on different media.

2.5 Configuration

A *configuration* C is tuple $\langle F, Ch \rangle$, where F is a set of functionalities and Ch is a set of channels that connect functionalities to each other. Each channel connects the output of one functionality to the input of another functionality.

In the context of a specific world state s , a configuration is *admissible* if the following conditions are satisfied:

$$\forall f \in F \forall i \in I_f \exists ch \in Ch = \langle f_{send}, o, f_{rec}, i, m \rangle \text{ such that } descr(o) = descr(i), dom(o) = dom(i), \text{ and } Freq(f_{send}(ch)) \geq Freq(f_{rec}(ch))$$

That is, each input of each functionality is connected via an adequate channel to an output of another functionality with a compatible specification (information admissibility).

$$\forall f \in F : Pr_f(s) = T$$

That is, all preconditions of all functionalities hold in the current world state (causal admissibility).

$$\forall m \in CM : bandwidth(m) \geq \sum_{\{ch | medium(ch)=m\}} size(domain(i(ch))) \cdot Freq(f_{rec}(ch))$$

That is the combined requirements of the channels can be satisfied (communication admissibility).

Another issue is schedulability: whether the different functionalities can produce and communicate their outputs in a timely manner. However, that is a complex issue that cannot be detailed in the scope of this paper.

A configuration also has a cost. This can be based on functionality costs, communication cost, etc, but also on performance accuracy and reliability of the configuration. Currently, we compute the cost as a weighted sum of the number of components used (robots involved, functionalities, global and local channels).

2.6 Examples

To illustrate the above concepts, we consider a concrete example inspired by the scenario in the introduction. A robot is assigned the task of pushing a box from one room to another one by crossing a door between the two rooms. The “cross-door” action requires information about position and orientation of the door with respect to the robot performing the action. There are two indoor robots (including the one crossing the door) each one equipped with a camera and a compass. The door to cross is equipped with a wide-angle camera.

Fig. 2 illustrates four different (admissible) configurations that provide the information required by the action “cross-door”, which include the functionalities above.

The first configuration involves only the robot performing the action. The robot is equipped with an elevated panoramic camera that makes it possible to view the door even when pushing the box. The camera produces information to a functionality that measures the position and orientation of the door relative to the robot.

The second configuration in Fig. 2 shows the other extreme, when all information is provided by the door that the robot is crossing and the robot is not contributing with any information. The door is equipped with a camera and functionalities that can measure the position and orientation of the robot relative to the door. This information is transformed into position and orientation of door with respect to the robot before it is delivered to robot A.

In the third configuration in Fig. 2, robot A (the robot performing the “cross-door” action) contributes with a compass, and the second robot (*B*) contributes with a compass and a camera. The camera provides information to two functionalities: one that measures the position and orientation of the door, and another one that measures the position of robot A. All these measurements are computed relative to robot B. In order to compute the position and orientation of the door relative to robot A, we need to use a coordinate transformation. This in turn requires that we know, not only the relative position, but also the orientation of robot A relative to B. The later can be obtained by comparing the absolute orientations of the two robots, measured by their two on-board compasses.

The fourth configuration in Figure 2 is similar to the third one, except that the orientation of robot A relative to B is obtained in another way, i.e., no compasses are used. Both robots are equipped with cameras and have a functionality that can measure the bearing to an object. When the robots look at each other, each robot can measure the bearing to the other one. By comparing these two measurements, we obtain the orientation of robot A relative to robot B.

3 Configuration generation

Our second objective is to generate configurations automatically. This process requires a declarative description of:

- the functionalities and methods for connecting them,
- the current world state,
- the goal for what the configuration should produce.

The world state, as already mentioned, declares the available robots and their physical capabilities, as well as the state of the surrounding environment. It is encoded as a set of clauses, such as `robot(r1)`, `door(d1)`, `visible(r1, door1)`. The goal for the configuration generation process is to produce a desired information output. For example, in the cross-door example, the information goal is the position and orientation of the door that is required as input by the cross-door behavior.

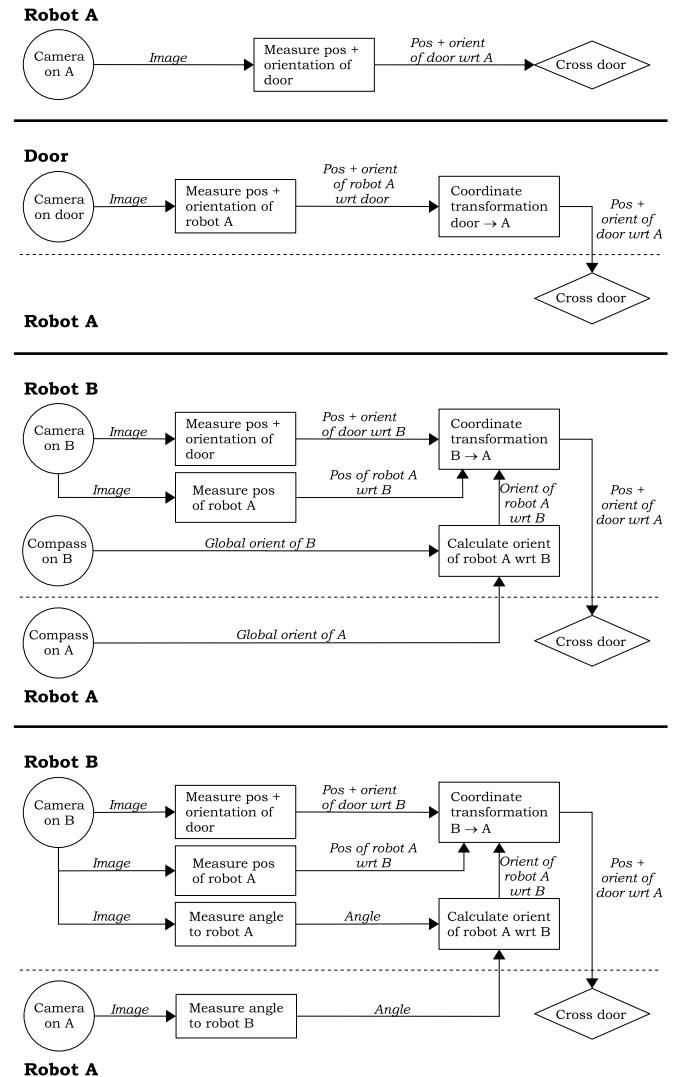

Figure 2. Four different configurations that provide the position and orientation of a given door with respect to robot A. (See text.)

The description of available functionalities is realized using operator schemas similar to those of AI action planners. One functionality operator schema from the scenario in the previous section, `measure-door`, is shown in the upper half of Figure 3.

The name field correspond to the *Id* component of a functionality, and the *r* parameter in the name is *r* in the functionality. The fields *input* and *output* correspond to *I* and *O*, and *precond* and *postcond* encode the *Pr* and *Po* components. In the `measure-door` example we have an image taken by the camera of *r* as input and from that we are able to compute the position and orientation of the door *d* relative to *r* as output. The precondition for `measure-door` is that the door *d* is fully visible in the input image. Note that the Φ function is not part of the operator schema; it corresponds to the actual code for executing the functionality.

In order to combine functionalities to form admissible configurations that solve specific tasks, we have chosen to use techniques inspired by hierarchical planning, in particular the SHOP planner [3]. Configuration planning differs from action planning in that the

```

(functionality
  name: measure-door(r, d)
  input: (image(r, d), image)
  output: (pos(r, d), real-coordinates)
           (orient(r, d), radians)
  precond: visible(r, d)
  postcond:
)

(config-method
  name: get-door-info(r, d)
  precond: (camera(r), in(r, room),
            in(d, room), robot(r), door(d))
  in: -
  out: f2: pos(r, d)
       f2: orient(r, d)
  channels: (f1, f2, image(r, d))
  body:
    f1: camera(r, d)
    f2: measure-door(r, d)
)

```

Figure 3. A functionality operator schema, and a method schema for combining functionalities.

functionalities, unlike the actions in a plan, are not temporally and causally related to each other, but related by the information flow as defined by the channels. Functionalities are executed in parallel, and a functionality becomes active when the input data is present. In order to achieve the data flow between functionalities, a mechanism that creates channels between functionalities is required. Such connections are not required for action planning, and obviously, no existing planning technique facilitate such a mechanism. Therefore we need to outline how the planner works.

Our configuration planner allows us to define methods that describe alternative ways to combine functionalities (or other methods) for specific purposes, e.g. combining the camera functionality and the measure-door functionality above with a channel on the same robot in order to obtain door measurements of a specific door.

The lower half of Figure 3 shows an example of a method schema that does exactly that. There is a channel inside the method connecting two functionalities (labeled f_1 and f_2). The descriptor of the channel ($image(r, d)$) tells which specific input and output of the functionalities should be connected. In addition, the outputs ($pos(r, d)$, $orient(r, d)$) of f_2 is declared in the out field to be the output of the entire method. Thereby, any channel that in a method higher up in the hierarchy is connected to the output of $get-door-info$ will be connected to the output of $measure-door$.

The configuration planner takes as input a current causal state s , a method "stack" with initially one unexpanded method instance $l : m(c_1, c_2, \dots)$ representing the goal of the robot (l is a label), and a set of methods M and a set of functionality operators O . It also maintains an initially empty configuration description C and an initially empty sets of causal postconditions P . It works as follows:

1. Take the unexpanded method instance $l : m(c_1, c_2, \dots)$ at the top of the stack.
2. If $l : m(c_1, c_2, \dots)$ matches the name of a functionality operator O , check if that functionality already exists in the current configuration description C . If it does not, add it to C , and add the clauses in $postcond$ to P . If there is an $l' : m(c_1, c_2, \dots)$ reuse it and reconnect any channel from/to l from/to l' instead. Go back to 1.
3. If $l : m(c_1, c_2, \dots)$ matches a method schema in M , select an instantiated version of the method schema from M with preconditions which are applicable in s (this is a backtrack point). If there

is none, report failure and backtrack.

4. Expand the method schema as follows:

- (a) Instantiate the remaining fields of the selected method, and generate new unique labels instead of the general labels f_1, f_2 etc.
- (b) Add the channels of the method body (with new labels) to the current configuration C .
- (c) Add the method instances (with new labels) of the method body to the top of the stack.
- (d) Use the in and out fields of the method to reconnect any channels in C from the method instance being expanded (i.e. with label l) to the new method instances as labeled in the method body.

5. If the stack is empty, return C and P . Otherwise go back to 1.

Step 4 may need some more explanation. Assume we are expanding 15: $get-door-info(robot1, door4)$, and we have chosen the method in Figure 3. First, we need to replace r with $robot1$ and d with $door4$ everywhere in the schema, and $room$ is bound to the room of $robot1$ (step a). New labels, say 17 and 18, replace f_1 and f_2 (step a). The channel is added to C (step b) and the two functionalities are added to the top of the stack (step c). Finally, according to the out field, any existing channel in C with label 15 (i.e. $get-door-info$) for its out connection is reconnected to 18 (i.e. $measure-door$) (step d).

The first output from the planner is a configuration description C , which essentially consists of a set of functionality names with labels, e.g. 18: $measure-door(robot1, door4)$, and set of channels, e.g. (17, 18, $image(robot1, door4)$, $local(robot1)$).

The second output from the planner is the set of postconditions P , which can be used to update the current state, which then in turn can be used as input for generating the configuration following the current one (if any).

It is possible to accidentally specify methods that can result in configurations with cycles. However, these cycles can easily be detected and the faulty configurations can be excluded.

Generally, there are several configurations that can address a problem, but obviously, only one configuration per problem can be performed at the time. By trying different applicable method versions, guided by the cost of configurations, our planner generates the admissible configuration with the lowest cost first.

The planning takes place on the robot that has the information goal. The selected configuration description is then implemented in two steps. First, the different functionalities and channels are distributed according to their location parameter. Then each robot launches a process for executing its assigned functionalities and sets up its channels.

4 Experiments

We have implemented the approach described above, and we have conducted a series of experiments using real robots equipped with different sensors. We report here a representative experiment based on the third and fourth configurations in Figure 2. The platforms used were two Magellan Pro robots from iRobot, shown in Figure 1. Both robots are equipped with compasses and fixed color cameras. The environment consists of two rooms (R1 and R2) with a door connecting them. The door and the robots have been marked with uniform colors in order to simplify the vision task.

The following scenario describes how the two configurations were used, and demonstrates the importance of being able to reconfigure dynamically. Robot *A* and robot *B* are in room R1. Robot *A* wants to go from room R1 to room R2. Since the camera on *A* is fixed and it has a narrow field of view, the robot cannot see the edges of the door when it is close to it. Therefore, robot *A* is not able to perform the action on its own. Robot *B* is equipped with the same sensors as robot *A*, but since robot *B* is not crossing the door it is able to observe both the door and robot *A* from a distance during the whole procedure. We therefore configure our team according to the third configuration in Figure 2, and execute the task. Robot *A* continuously receives information about the position and orientation during the execution of “cross-door”.

When robot *A* enters room R1 it signals that the task is accomplished. This signal is received by robot *B* and the current configuration is played out. Next, robot *B* is assigned the task of going from room R1 to room R2. The same configuration as before is used to solve this task, but with the roles exchanged — i.e., robot *A* is now guiding robot *B*. This time, however, during the execution of the “cross-door” behavior a compass fails due to a disturbance in the magnetic field. This makes the current configuration not admissible, and a reconfiguration is necessary to proceed. The fourth configuration in Figure 2 is still admissible even with no compass, and we therefore use this one to carry out the remaining part of the task.

5 Discussion

We have presented a general approach to automatically synthesize a team configuration using knowledge-based techniques. Our approach combines resources and functionalities, residing in different robots, into a functional configuration, in which the robots cooperate to generate the information required to perform a certain task.

Even though the example that we use in this paper to describe our approach is simple, our system is able to generate configurations for more complex problems. For instance, we have also used our configuration planner to address two object transportation tasks. The first task is considering two robots carrying a bar. The second tasks involves three robots building a wall with several wall blocks. In this task, two robots are pushing a wall block together and a third robot is guiding them in order to get the block aligned with the rest of the wall. Both tasks require tight coordination between the involved robots.

An interesting point to note is the relation between our functional configurations and task allocation/assignment [1]. Task allocation typically deals with the question: “Who should do which task?”. That is enough for tasks that only require loose coordination. For tasks that require tight cooperation (that is, they cannot be neatly divided among robots or modules), we must address the additional question: “How to execute a task in a cooperative manner?”. Configuration generation answers this question and can be seen as a proceeding step to task allocation, done after a task is assigned to a robot.

A related problem is how to motivate the robots involved in a configuration to commit to it, and to stay committed during the entire execution. For example, in the experiment above, we must guarantee that the observing robot does not run away from the scene. For most tasks, robots are motivated by the individual or the team goals. However, if the task is beneficial only to another individual, as in the case of robots that help each other, it may be harder to motivate a commitment. Task assignment, commitment and functional configurations all address different aspects of the multi-robot cooperation problem. In our work, we concentrate on the last one.

Problems similar to the work on automatic generation of configurations have been studied in several different research areas, e.g. in program supervision [7], automatic web service composition [4], coalition formation [6], and single robot task performance [2]. However, in the field of cooperative robotics, few works address similar problems. Tang and Parker [8] present an approach called ASyMTRe. The principle of ASyMTRe is to connect different schemas (similar to instantiated functionalities) in a way such that a robot team is able to solve tightly-coupled tasks by information sharing. ASyMTRe uses a greedy algorithm that starts with handling the information needs for the less capable robots and continues in order to the most capable robots. For each robot that is handled, the algorithm tries to find the robots with least sensing capabilities and maximal utility to provide information.

In contrast to the ASyMTRe approach, the approach presented in this paper uses a hierarchical planner to automatically generate configurations. We expect that the use of a hierarchical planner will make it easier to deal with the problem of when and how to change (replan) a configuration. This problem is related to the third objective stated in the introduction: how to monitor the performance of a configuration while executing it. We also believe that the use of a hierarchical planner will be beneficial for the next important step, to consider sequences, or plans, of configurations, in order to address more complex tasks. Our current system only considers the generation of configurations for performing one step of a particular task, and cannot deal with situations requiring several steps. In our box pushing example, if a second box is blocking the door, a configuration for removing that box would have to precede the configuration for getting the first box through the door. We are investigating the extension of our planning techniques to generate plans involving sequences of configurations.

Agents with Anticipatory Behaviors: To be Cautious in a Risky Environment¹

Cristiano Castelfranchi, Rino Falcone and Michele Piunti²

Abstract. This work presents some anticipatory mechanisms in an agent architecture, modeling affective behaviours as effects of surprise. Through experiment discussion, the advantages of becoming cautious are presented and is shown how this approach increases not only opportunism and reactivity but also anticipatory capabilities for planning and reasoning. Cautious agents outcomes are analyzed in risky surroundings both on the basis of the environment features and of the internal model of caution. Expectation-driven and caution enabled agents are designed with the BDI paradigm.

1 CAUTIOUS AGENTS

This work is based on a general research framework whose objective is to claim how important is for an autonomous, cognitive system to exploit anticipatory behaviors, and in particular anticipatory representations of the world (predictions and expectations). Here we introduce anticipatory mechanisms in a BDI architecture, and model part of the short-term functions of surprise, in particular the advantages (in some kinds of environment) of becoming cautious. To have anticipatory representations, to experience surprise, and to exploit various functions of them will be crucial, not only for curiosity and exploration [5], but also for learning, attention, prudently adjusting behaviour, and for social relations: like trust [2], suspicion; coordination with the others and reliance; cooperation and competition etc. Without examining deep surprise sources and dynamics, we exploit some effects of surprise and their possible outcomes: in risky, unknown, harmful environments agent cautiousness can be a consequence of a kind of surprise that is due to -and a signal of- a mismatch between the agent expectation (internal state) and the actual perceived input (perceived data) [3]. Its internal signal alerts the agent and bring to mental and behavioural changes both with *Long term effects* like becoming more accurate and less self-confident in predictions, memorizing anticipatory signs of danger and different kinds of environment, learning more or less safe plans and purposive actions for a given goal in a certain condition and *Short term effects* like intention reconsideration, redirecting attention, searching for additional information, or becoming prudent. Hence, the anticipatory dimension of caution is strictly related to a form of expectation: like agents use and represent expectations to select best expected action from a set of available ones, so caution guides agent in the selection of less risky action between possible ones. Given this, it is possible to characterize agents with stable 'personalities' (a watchful and a rash

agent, with locked capabilities [7]) and to experiment their performances in more or less dangerous environment. Moreover it is possible to build an adaptive agent able to run-time adjust its "degree" of caution to different environments or situations. This approach enhances anticipatory competences and increases the opportunism and the reactivity of BDI-like [6], planning and deliberative agents [1]. We do assume that the relevance of this problem is not only for theoretical modeling and for playing, but that will soon become important in virtual worlds and in the physical one, both for software cognitive agents and for autonomous robots.

2 SCENARIO DESIGN

A test bed scenario is designed as a simulation where entities and environment are represented as autonomous agents and artefacts. Environment is a 2D land map where sets of walls and gates (that can be open or closed) delimit rooms, corridors and areas where entities are able to move. A set of special locations seat symbolic reference points: these location of interest (LOI) contain noticeable world objects as *Repository*, *House*, *Tree*; two kinds of *Food* objects appear with modifiable frequencies, near to House and Tree: they rise at fixed location with a modifiable "reward" value; Harmful *Frozen puddles*, are located across rooms; *Fires* entities behave according to a two state cycle periodic function: in each period their first shape is a "Smoke" premonitory state, then they become real dangerous "Fire". For each period, fires change their location with discrete movements. Environment holds regularities as delimited risky areas where rise of fires can be related with agent presence.

At an high level of abstraction, we consider agents as mobile entities with sensors, reasoning and effectors components, characterized by the following tuple of bounded dynamic resources:

$$Ag = \langle En, r, Sr, s \rangle \quad (1)$$

En indicating the instant amount of energy, *r* the range of vision where sensors can retrieve data, *Sr* the sensor sample rate, and *s* the agent instant speed. Agents burn energy according to a combination of previous resource allocation (e.g. the more speed and sensor-rate is high, the more agent will spend energy) and they hold structured data sets representing knowledge and internal state.

In a Goal oriented fashion, first order objective for entities is to collect food items in the repository to obtain rewards and recharge energy. The task is composed of a recursive workflow of actions: 1) Look for Food with (supposed) best reward. Because agents know that each class of food rises near a proper LOI, this introduces agent explicit quantitative expectations about the possible food presence (and value). Each *lookForFoodPlan* is associated to a specific LOI and constantly monitored by a *subjective expected utility* function,

² ISTC - Institute of Cognitive Sciences and Technologies - C.n.r. - National Research Council, Italy, email: {c.castelfranchi, r.falcone, michele.piunti}@istc.cnr.it

determined merging both expectations on food reward and presence (near the LOI). 2) Go to the identified food location and pick it up. After identifying a set of food items, agent add them to the belief base and head for the nearest one, observing topology constraints and bounds. 3) Transport Foods (one at a time) from the original location to the repository and deposit them. Agents use belief modules referring to paths (defined as lists of locations to pass through) in order to routinize crossing rooms and LOI. By releasing foods in the repository, they obtain a reward calculated on the basis of the original food reward decreased with a decay factor strictly depending on the transport time interval. Along the presented workflow, agents run up against fires or frozen puddles: in these cases agents present a general short term reaction: actions and speed are obligate to reduce, furthermore a greater amount of energy has to be spent.

Starting from a traditional approach to the BDI systems³, we developed an architecture dealing with 'the future', where intelligent agents build mental representations [4] for explicit expectations and risk avoidance. Stable 'personalities' have routinized intention-deliberation policies. To capture environment regularities (e.g. dangerous areas), watchful agents are enabled to choose those plans with the expected lower risk-value (and accordingly the higher safety) while rash agents prefer to choose the quickest and simplest ones. To deal with *adaptive* caution, an internal k-length buffer for registering events was constantly updated and monitored by adaptive agents: when the stored negative events exceed fixed threshold in a k-length history interval, they autonomously deliberate to increase the caution level. Adaptive agents shift among three kinds of more or less cautious behaviours (default, watchful and rash) adapting on the fly caution configurations to anticipate the dangerous risks of the crossing area. These caution competences can be reflected on the tuple of agent bounded resources (1), saying that an agent increasing caution level and becoming watchful has to reallocate resources: reducing speed s , increasing sensor rate Sr and increasing range of vision r . These adaptations heavily modify behaviour affecting the intentional stance and elicit trade-off in their performances. Note that relationships among different parameters characterizing these epistemic resources have to be analyzed with respect to the features of the different environments.

3 EXPERIMENTAL TEST

To measure agent effectiveness we considered environments with different levels of risk and evaluated agent energy in function of simulated time (fig. 1). **Experiment 1.** Safe environment (no Fires and

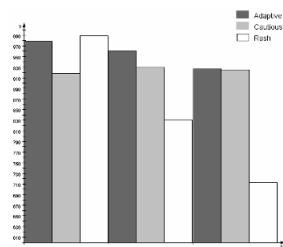

Figure 1. Adaptive, Cautious and Rash agent average energy comparison in safe, risky and unsafe environments.

no frozen puddles). We experience that to be cautious in safe worlds

³ System was built upon Jadex: see <http://vsis-www.informatik.uni-hamburg.de/projects/jadex/>.

is a drawback: best mean performances are those of the rash agent, because of his quickness and no resource consumption for useless and costly attention/caution capabilities (fig.1). **Experiment 2.** Risky environment (2 Fires and 2 frozen puddles). In the same time interval, adaptive agent outperforms the others: a stabilized cautious agent looks ahead and prevents accidents, while adaptive agent (with a modifiable caution) is able to minimize negative effects until its buffer reach the threshold to be watchful. On the contrary, rash agent is unable to react in safety mode because of its fixed low level of Caution. **Experiment 3.** Unsafe environment (4 Fires and 3 frozen puddles). It is interesting to note the different slopes of the functions (caused by the different energy consumption). Peaks indicate goal achievement while precipitous changes of slopes indicate unexpected accidents (agent near Fire or near a Frozen puddle) (fig. 2). Best energy performances come from adaptive agent that is able to optimize damages and resource consumption. Energy trend for the rash agents falls with deep peaks. Mean performances of cautious and adaptive agents are comparable (fig. 1): even if the adaptive agent continuously tries to modify its behaviours during the simulation (adapting it to the environment) at the end its global performances result comparable with the ones of the watchful agent that, in some sense, is "built" for well performing in a highly unsafe world.

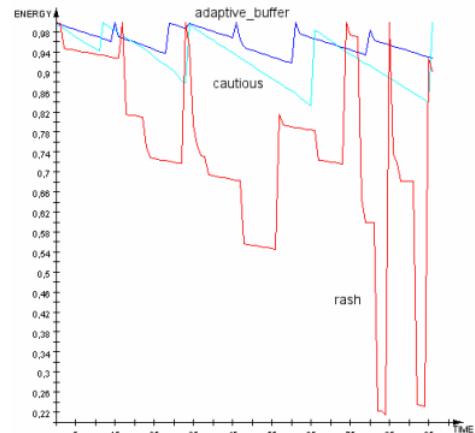

Figure 2. Agent comparison in unsafe environment shows best performance for adaptive agents.

AI and Music: Toward a Taxonomy of Problem Classes

Oliver Kramer¹ and Benno Stein² and Jürgen Wall³

Abstract. The application of Artificial Intelligence technology to the field of music has always been fascinating, from the first attempts in automating human problem solving behavior till this day. Human activities related to music vary in their complexity and in their amenability of becoming automated, and for both musicians and AI researchers various questions arise intuitively, e. g.: What are music-related activities or tasks that can be automated? How are they related to each other? Which problem solving methods have proven well? In which places does AI technology contribute?

Actually, the literature in the intersection of AI and music focuses on single problem classes and particular tasks only, and a comprehensive picture is not drawn. This paper, which outlines key ideas of our research in this field, provides a step toward closing this gap: it proposes a taxonomy of problem classes and tasks related to music, along with methods solving them.

Keywords AI and creativity, music, problem classes, taxonomy

1 INTRODUCTION

Music is an important part of almost every culture. Though music is an emotional thing and strongly connected to the human mind, a variety of tasks exists that—at least in part—can be automated, reaching from the analysis of acoustic data up to high level composition tasks like song arrangement. The identification and organization of such tasks within a taxonomy T of problem classes is of a high value:

- T may serve as a scheme for classifying existing problems and discovering unapparent similarities between them.
- Since T associates problems with methods solving them, a solution for a new but structurally similar task may be derived from existing solutions—where, at least, some proposition regarding its complexity can be stated.

Here we introduce such a taxonomy, from which Figure 1 captures the main aspects. The remainder of this section reports on existing classification work; Section 2 explains our classification paradigms, discusses music-related tasks under this perspective, and illustrates the research activities in the field of AI.

1.1 Existing Work

Roads identifies a set of general problem classes, covering the topics from composition to digital sound processing [7]. However, he neither defines relations between the problem classes nor unveils his classification paradigms. Similar shortcomings apply to the taxonomy of computer music by Pope [6]. Padadopoulos and Wiggins, as well as Tahiroglu, restrict their taxonomy to the classification of algorithmic composition systems along with the utilized computational

³ University of Paderborn, Germany. jwall@upb.de

methods [5, 8]. Ariza presents a survey of algorithmic composition tools and identifies seven primary descriptors [1].

Furthermore, schemes for special problem classes exist, such as the taxonomies for sound synthesis methods or for sequencer user interfaces by Duignan et al. [4]. Biles proposed a taxonomy for music and art systems that use evolutionary algorithms [2].

Our approach goes beyond existing work within two respects: it provides a framework that (i) is more generic, and (ii) makes the underlying classification paradigms explicit.

2 TAXONOMY OF PROBLEM CLASSES

The formation of our taxonomy is task-driven, i. e., the problem classes are formulated from a musician’s point of view. We identified three orthogonal paradigms that govern its structure and that proved to be qualified for classification purposes.

1. **Problem Type.** The most fundamental distinction follows Clancey’s ideas, where operations are grouped “[...] in terms of those that construct a system and those that interpret a system, corresponding to what is generally called synthesis and analysis.” [3]
2. **Modeling Level.** Defines the degree of abstraction; music becomes manifested both at a symbol level and a subsymbolic level. The transition between these levels is continuous and may form an additional level of sound:

Modeling level	Materialization	Human perception
symbolic	notes, accords	style, genre
sound	pitch, timbre	instrument, vocal tone
subsymbolic	amplitude, frequency	volume, sonority

3. **Arrangement Direction.** Explains music-related tasks as being of horizontal, vertical, or combined type:

Arrangement direction	Materialization	Musician’s viewpoint
horizontal	tone sequence	melody
combined	accord sequence	harmonizing
vertical	sound synthesis	instrumentation

Each task can be explained in the three dimensions. The composition of a melody theme, for example, is a horizontal, symbolic, synthesis task. By contrast, instrument identification is an analysis task that happens at the subsymbolic level.

2.1 Music Analysis

In the following, the analysis part of our taxonomy is presented, covering the fields of subsymbolic data analysis, i. e. the analysis of acoustic data, symbolic data analysis, and the connection between both, the so-called transcription.

Signal Analysis and Filter Theory Physical feature extraction pertains to both horizontal aspects along the time axis and vertical aspects like sound. Sound analysis basically exhibits vertical components, with the small exception of filter and amplifier envelopes

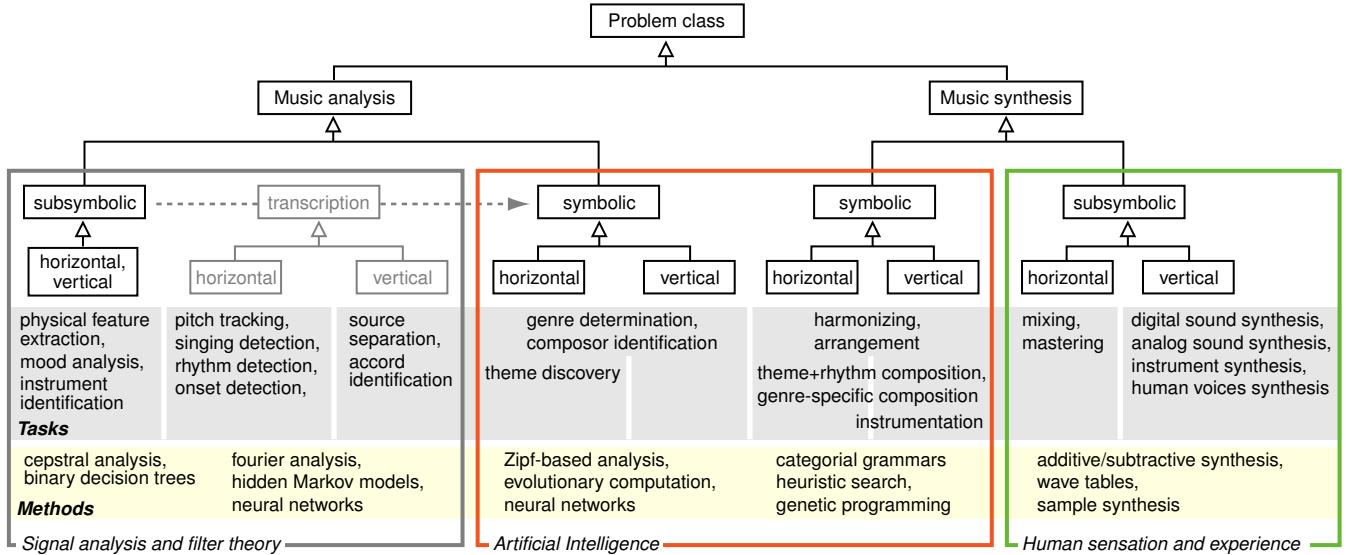

Figure 1. A taxonomy of problem classes in music. Note that the method section is not complete but shows representative methods.

or other parameter modulations. Further branches of subsymbolic music data analysis are mood and instrument classification. Transcription, which is the translation of acoustic information into notes, establishes an important field of operational tasks. It connects the subsymbolic with the symbolic classes as its methods work on acoustic data but make use of symbolic background knowledge. Except for source separation and accord detection the remaining tasks exhibit primarily horizontal dimensions.

Analysis by Artificial Intelligence The symbolic counterparts of both analysis and synthesis tasks are the challenging field for AI methods. A typical horizontal task is theme discovery, i.e., the identification of melodies and interludes. Other interesting problems are genre determination and note-based composer identification. Various AI methods are applied in this context, reaching from evolutionary methods to knowledge processing. Interestingly, the AI research activities in the synthesis field are prevalent compared to the activities in the analysis field (cf. Figure 2).

2.2 Music Synthesis

At the symbolic level the synthesis part of our taxonomy covers tasks from the field of song composition and arrangement. Here, AI methods demonstrate their power. The subsymbolic part of sound synthesis and instrumentation is only partly operational and comes within the limits of human sensation and experience.

Synthesis by Artificial Intelligence The automatic composition of songs is probably one of the most interesting AI applications. Again, we can distinguish between horizontal and vertical problems. Theme and rhythm composition is a genre-specific horizontal task. The tasks of harmonizing phrases and arranging a whole song exhibit both vertical and horizontal aspects, whereas the instrumentation task is rather vertical. The applied AI methods vary from categorical grammars to computational intelligence methods like genetic programming.

Human Sensation and Experience Horizontal aspects of the subsymbolic synthesis class concern mastering and mixing tasks; vertical aspects cover the task of sound synthesis. The latter ranges from natural sound synthesis of human voices and classical instruments to digital sound synthesis.

2.3 AI Research Activities

To get an overview of the research activities in the last forty years we have analyzed more than five hundred papers from the field of computer music. Figure 2 illustrates the activities for the symbolic problem classes. Observe that much more research took place in the synthesis branch compared to the analysis branch. Moreover, the distribution of the research activities for the different subproblems is quite interesting and may serve as a guide to future research.

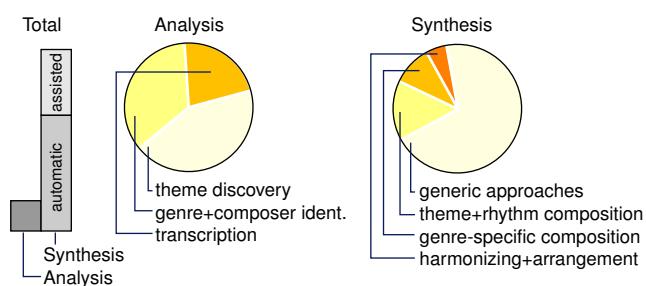

Figure 2. Distribution of research activities for AI and music. Basis for this investigation were 560 research papers, most of them published in the last twenty years. About 300 research papers fall into the area of symbolic problem classes (shown here), whereas 15% of them pertain to analysis tasks and 85% to synthesis tasks.

Using Emotions for Behaviour-Selection Learning

Maria Malfaz ¹ and Miguel A. Salichs ²

Abstract. Emotions play a very important role in human behaviour and social interaction. In this paper we present a control architecture which uses emotions in the behaviour selection process of autonomous and social agents. The state of the agent is determined by its internal state, defined by its dominant motivation, and its relation with the external objects including other agents. The behaviour selection is learned by the agent using standard and multiagent Q-learning algorithms. The considered emotions are fear, happiness and sadness. The role of these emotions in this architecture is different, while the learning algorithms use happiness/sadness of the agent as positive/negative reinforcement signals, the emotion fear is used to prevent the agent of choosing dangerous actions as well as a motivation.

1 INTRODUCTION

In previous works [7] an emotion-based architecture was proposed for an autonomous and social robot. The use of emotions in this architecture is oriented to the behavior selection process rather than the human-robot interaction issue. Several authors such as Canamero [3] and Gadanho [5] have used emotions to improve the adaptation of the robot to the environment and therefore the autonomy of the robot. Many others such as Breazeal [2], Fujita [4], Shibata et al [11] have implemented emotional models on robots to enhance the human-robot interaction. Their robots, Kismet and Leonardo, AIBO and Necoro, include the possibility of showing emotions, by facial and sometimes body expressions. We intend to make use of emotions in robots trying to imitate their purpose in nature, which includes, but is not limited to, interaction.

We think that the role that each emotion plays, and how the mechanisms associated to each one work are very specific. That means that each emotion must be incorporated to the robot in a particular way. In a recent paper [10] we have shown how some emotions such as happiness, sadness and fear are used to learn the right behaviour policy for each situation.

2 CONTROL ARCHITECTURE

The control architecture proposed here, see Fig. 1, has been designed for an autonomous robot. An autonomous agent/robot should be capable of determining its goals, and it must be capable of selecting the most suitable behaviour in order to reach them. Similarly to other authors [3], [2], [12], our agents autonomy relies on a motivational model.

² Carlos III University of Madrid, Spain, email: salichs@ing.uc3m.es

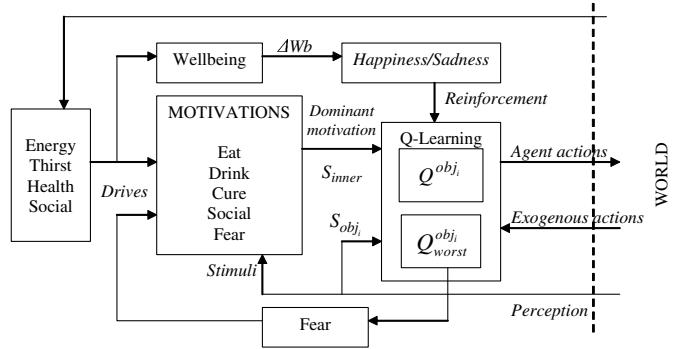

Figure 1. Control Architecture

2.1 Drives and Motivations

Motivations can be seen as homeostatic processes, which maintain a controlled physiological variable within a certain range. Homeostasis means maintaining a stable internal state [1]. The drives constitute urges to action based on bodily needs related to self-sufficiency and survival.

In order to model motivations, the hydraulic model of motivation described in [6] has been used as an inspiration. In this model, internal drive strength interacts with external stimulus strength. The intensity of motivations is a combination of the intensity of the related drive and the presence of the related external stimuli. The external stimuli are the different objects and agents that the player can find in the virtual world during the game. According to our model a motivation can obtain a high intensity due to two reasons: 1) the correspondent drive is the highest or 2) The correct stimulus is present. The dominant motivation will be the one with the highest intensity and the possibility of no dominant motivation exists.

2.2 Wellbeing

As it is shown in Fig. 1 the wellbeing of the agent is a function of the values of the drives. In [8] the wellbeing is defined in such a way that it is maximum when all the needs (drives) of the agent are satisfied. There exist some personality factors that weight the importance of the values of the drives on the wellbeing of the agent.

On the other hand, based on the definitions of the emotions given in [7], the emotions of happiness and sadness depends on the variation of the wellbeing of the agent. When the wellbeing of the agent is increased a certain amount, happiness arises, on the contrary, sadness is produced when the wellbeing decreases a certain amount.

2.3 Behaviour Selection

In this architecture the agent learns, using different reinforcement learning algorithms (RL), the best behaviour at each step using the emotions of happiness/sadness as the reward. This use of emotions as reinforcement has been proposed previously by Rolls [9]. Therefore, in this architecture behaviours are not selected to satisfy the goals determined by the dominant motivation but to optimize the wellbeing of the agent. This implies that the final goal of the agent is to reach Happiness and avoid Sadness.

In the proposed architecture the agent will use the Q-learning algorithm as the RL algorithm when the agent is not interacting with other players. In the case of social interaction, the agent uses a Q-multiagent RL algorithm.

The state of the agent is the aggregation of his inner state, the dominant motivation S_{inner} , and the states S_{obj} related to each of the external objects, including external agents, which can interact with him. For the RL algorithms the objects are considered as independent. This means that the state of the agent in relation with each object is $S \in S_{inner} \times S_{obj_1}$.

2.4 Fear

Fear is produced when the agent knows that something bad may happen. In this architecture there are two types of fear, one related to actions executed by the agent and the other related to exogenous actions carried out by other elements of the environment such as other agents.

2.4.1 To be afraid of executing risky actions

In order to avoid risky actions, the worst result experimented by the agent for each pair action-state is stored in a variable called $Q_{worst}^{obj_i}$. The effect of being afraid can be considered by following a policy that considers not only the average of the result obtained but also the worst one. We define a daring factor that measures the daring degree of the agent. By varying this parameter the agent gives more or less importance to the worst result obtained making the agent fearful or fearless respectively.

2.4.2 To be afraid of risky exogenous actions

When the agent may suffer some negative effects in a state as a consequence of exogenous events, feels fear. "Fear" is expressed as a drive D_{fear} . The fear drive is equally treated as the rest of drives, and its related motivation could be the dominant one. In this case, the agent will learn by itself what to do when it is afraid.

3 EXPERIMENTS

This control architecture has been tested on virtual MUD players (a text-based multi user game), who "live" in a virtual world. This game gave us the possibility of creating different 2-D environments to play in. This environment is fully described in [8].

The results obtained in [8] showed that using happiness and sadness as the reinforcement signal of the RL algorithms the agent learns the correct policy in order to survive in his virtual world. Moreover, the quality of life of the agent is quite good following the learned policy.

In recent experiments it has been proved that following a near fearless policy that consider the optimal policy as well as the worst

expected results in some degree, improves the performance of the agent.

4 CONCLUSIONS AND FUTURE WORKS

This control architecture implements emotions on the learning behaviour process of an artificial agent, obtaining quite good results in relation with the overall performance. The learning algorithms use happiness/sadness of the agent as positive/negative reinforcement signals. Fear is used to prevent the agent choosing dangerous actions or being in dangerous states where non-controlled exogenous events, produced by external objects or other agents, could danger him.

Using this control architecture the agent learns behavioural patterns, this means that the agent learns the sequence of behaviours to be executed in order to satisfy the drive related to the dominant motivation. The agent learns, for example, that he has to get food when he is hungry, even when this behaviour is was not previously linked with the "Eat" motivation.

The final goal of the project is to implement this architecture on a real personal robot. Meanwhile in the next future, another emotion is going to be implemented: Anger. This emotion will be produced when another active object, such as other agent, could reduce the expectancies of the wellbeing of the agent.

2. Constraints and Search

This page intentionally left blank

Efficient Handling of Complex Local Problems in Distributed Constraint Optimization ¹

David A. Burke and Kenneth N. Brown²

1 INTRODUCTION

Many distributed constraint optimisation algorithms require each agent to have a single variable. For agents with multiple variables, a standard approach is to compile the local problem down to a new variable whose domain is the set of all local solutions. We present two modifications to this method, which (i) reduce problem size by removing interchangeable and dominated local solutions, and (ii) speed up search by identifying values that are interchangeable with respect to specific agents. We show that the modifications give orders of magnitude improvement over the basic compilation.

2 BACKGROUND

A Distributed Constraint Optimisation Problem consists of a set of *agents*, $A = \{a_1, a_2, \dots, a_n\}$, and for each agent a_i , a set $X_i = \{x_{i1}, x_{i2}, \dots, x_{im_i}\}$ of *variables* it controls, such that $\forall i \neq j \ X_i \cap X_j = \emptyset$. Each variable x_{ij} has a corresponding domain D_{ij} . $X = \bigcup X_i$ is the set of all variables in the problem. $C = \{c_1, c_2, \dots, c_t\}$ is a set of *constraints*. Each c_k has a *scope* $s(c_k) \subseteq X$, and is a function $c_k : \prod_{ij: x_{ij} \in s(c_k)} D_{ij} \rightarrow \mathbb{N}$. The *agent scope*, $a(c_k)$, of c_k is the set of agents that c_k acts upon: $a(c_k) = \{a_i : X_i \cap s(c_k) \neq \emptyset\}$. An agent a_i is a *neighbour* of an agent a_j if $\exists c_k : a_i, a_j \in a(c_k)$. A *global assignment*, g , is the selection of one value for each variable in the problem: $g \in \prod_{ij} D_{ij}$. A *local assignment*, l_i , to an agent a_i , is an element of $\prod_j D_{ij}$. Let t be any assignment, and let Y be a set of variables, then $t|_Y$ is the projection of t over the variables in Y . The global objective function, F , assigns a cost to each global assignment: $F : \prod_{ij} D_{ij} \rightarrow \mathbb{N} :: g \mapsto \sum_k c_k(g|_{s(c_k)})$. An optimal solution is one which minimises F . The solution process, however, is restricted: each agent is responsible for the assignment of its own variables, and thus agents must communicate with each other, describing assignments and costs, in order to find a globally optimal solution.

Most DCOP algorithms assume that each agent controls only a single variable. This assumption is justified by two standard reformulations [2], by which any DCOP problem with complex local problems (i.e. multiple variables in each agent) can be transformed to give exactly one variable per agent: (i) *Compilation*: for each agent, define a variable whose

domain is the set of solutions to the original local problem; (ii) *Decomposition*: for each variable in each local problem, create a unique agent to manage it.

3 IMPROVING COMPIILATION

To apply the *basic compilation* method to a DCOP: (i) for each agent a_i , create a new variable z_i , whose domain $D_i = \prod_j D_{ij}$ is the set of all solutions to the agent's internal problem; (ii) for each agent a_i , add a unary constraint function f_i , where $\forall l \in D_i, f_i(l) = \sum_{j: s(c_j) \subseteq X_i} c_j(l|_{s(c_j)})$ (i.e. the cost is the sum of the costs from all constraints which act on a_i only); (iii) for each set of agents $A_j = \{a_{j1}, a_{j2}, \dots, a_{jp_j}\}$, let $R_j = \{c : a(c) = A_j\}$ be the set of constraints whose agent scope is A_j , and for each $R_j \neq \emptyset$, define a new constraint $C_j : D_{j1} \times D_{j2} \times \dots \times D_{jp_j} \rightarrow \mathbb{N} :: l \mapsto \sum_{c \in R_j} c(l|_{s(c)})$, equal to the sum of the constraints in R_j (i.e. construct constraints between the agents' new variables, that are defined by referring back to the original variables in the problem). In an optimisation problem, every set of assignments of values to variables is a valid solution giving a domain of size $|D_i| = \prod_j |D_{ij}|$ for each agent a_i . The solution space for the problem is $\prod_{i=1}^n |D_i|$.

For an agent with a complex local problem, only external variables (those that have constraints to other agents) can have a direct impact on other agents. We produce an *improved compilation* by recognising that any local solutions that have identical assignments to those external variables are equivalent with respect to the distributed problem. If there is more than one optimal local solution with the same assignments to external variables, the solutions are *fully interchangeable*, and so only one is required. Also, solutions with identically assigned external variables but with sub-optimally assigned other variables are *strictly dominated* and can be ignored. We refine the compilation so that we only find *one* optimal local solution for each combination of external variables. For each agent a_i , let $p_i = \{x_{ij} : \forall c \ x_{ij} \in s(c) \rightarrow s(c) \subseteq X_i\}$ be its *private* variables – variables which are not directly constrained by other agents' variables – and let $e_i = X_i \setminus p_i$ be its *external* variables – variables that do have direct constraints with other agents. For each a_i , create a new variable z'_i with domain $D'_i = \prod_{j: x_{ij} \in e_i} D_{ij}$, and add a function f'_i , where $\forall l \in D'_i, f'_i(l) = \min\{f_i(t) : t \in D_i, t|_{e_i} = l\}$. That is, D'_i contains all assignments to the external variables, and their cost is the minimum cost obtained when they are extended to a full local assignment for a_i . The new constraints are defined as in the basic compilation (for each $R_j \neq \emptyset$,

¹ This work is supported by SFI under Grant No. 03/CE3/I405. We thank the developers of ADOPT for making their code available, and BCRI at UCC for their computing resources.

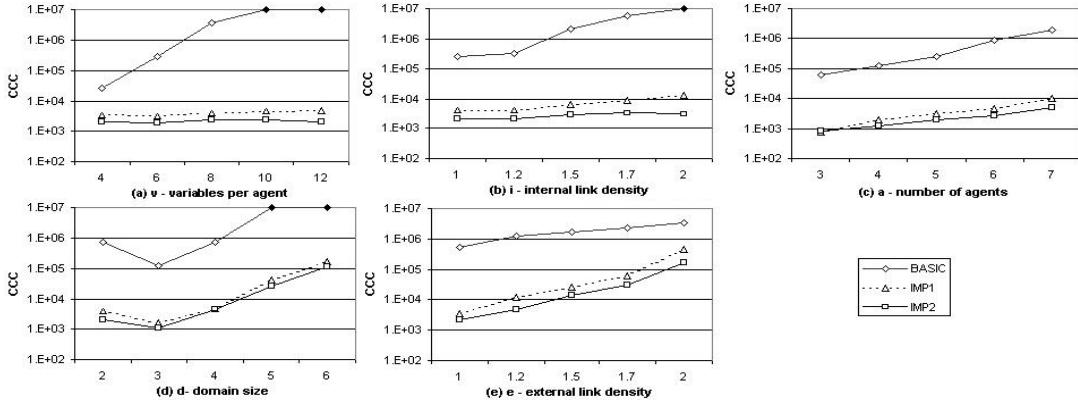

Figure 1. Concurrent Constraint Checks (cutoff = 10,000,000).

$C'_j : D'_{j1} \times D'_{j2} \times \dots \times D'_{jp_j} \rightarrow \mathbb{N} :: l \mapsto \sum_{c \in R_j} c(l_{\downarrow s(c)}))$, but will act on smaller sets of tuples. In our reduced compilation, the size of a domain is $|D'_i| = \prod_{j: x_{ij} \in e_i} |D_{ij}|$, which is a reduction over the basic compilation by a factor of $\prod_{j: x_{ij} \in p_i} |D_{ij}|$.

4 INTERCHANGEABILITY IN DCOP

We introduce the concept of sub-neighbourhood interchangeability and apply it to distributed search using compiled values. For each agent a_i and for a set of agents S , let $h_i^S = \{x_i : \exists c : x_{ij} \in S(c) \wedge a(c) \cap S \neq \emptyset\}$ be the set of original variables of a_i that are adjacent to original variables of the agents in S . Two compiled values, $l_a, l_b \in D_i$ are *sub-neighbourhood interchangeable* (SNI) with respect to the agents in S ($l_a \equiv_i^S l_b$), if both values represent identical assignments to the variables of h_i^S : $l_a \equiv_i^S l_b \leftrightarrow l_a \upharpoonright h_i^S = l_b \upharpoonright h_i^S$.

We apply SNI sets to the ADOPT algorithm [1]. In ADOPT, agents are prioritised into a tree. Agents send their values to all neighbours lower in the priority tree, and receive costs only from direct children. Considering each subtree separately, let S be the set of lower priority neighbours of a_i , lying in the subtree rooted by a_s . For each subtree, partition a_i 's values into SNI sets, such that $\Phi_i^S(x)$ is a function returning the SNI set to which x belongs: $\forall l_a, l_b \in D_i, l_a \equiv_i^S l_b \leftrightarrow \Phi_i^S(l_a) = \Phi_i^S(l_b)$. Then, ADOPT can be modified such that if a_i receives a cost ε from a_s with a compatible context, the costs of all values interchangeable with the current value x are updated: $\forall l \in \Phi_i^S(x), \text{cost}(l, a_s) \leftarrow \varepsilon$.

5 EXPERIMENTS

We compare the effect of the two modifications to the basic compilation on random binary graph colouring problems. The problems are characterised by a 5-tuple $\langle a, e, v, i, d \rangle$: a is the number of agents, e is the external link density (# inter-agent constraints = ea), v is the number of variables per agent, i is the internal link density (# intra-agent constraints = iv) and d is the domain size of each variable. Our base problem setting is $\langle 5, 1, 6, 1, 2 \rangle$. We then compare the algorithms varying v, i, a, d and e in turn, averaging over 20 test instances. Both the basic and reduced compilations are generated using Ilog JSolver. We implement the SNI sets in ADOPT and run it in

a simulated distributed environment: we use one machine but each agent runs asynchronously on its own thread.

The time required to compile agents into a single variable is always faster in the improved compilation – up to 2 orders of magnitude faster for some parameter settings. In the distributed search, we use the Concurrent Constraint Checks metric to measure performance. In Figure 1, plotted on a log scale, we compare the original compilation method *BASIC*, with our improved method *IMP1* and also *IMP2*, which uses both the improved compilation and SNI sets. The reduced domains resulting from our improved compilation, *IMP1*, give orders of magnitude improvements over the basic compilation for most parameter settings. In particular, as the number of variables in the local problem increases, the impact on our improved reformulation is minimal, while the basic reformulation quickly becomes very difficult to compute. Tests varying the internal link density, number of agents and domain size all demonstrate improvements of at least 2 orders of magnitude over *BASIC* (runs of *BASIC* that exceeded 10^7 CCC were cut off, and are shown shaded). *IMP2* also outperforms *IMP1* by on average 45%: using the SNI sets that occur in the compilation speeds up the distributed search.

6 CONCLUSION

A standard technique for handling complex local problems in DCOP is to convert multiple local variables to a single variable whose domain is the set of all local solutions. We have presented two advances on this method: we represent only one optimal local solution for each combination of external variables, discarding interchangeable and dominated solutions; and we identify values that are interchangeable with respect to neighbouring agents. We have evaluated the methods using the ADOPT algorithm, and they give orders of magnitude improvements over the basic compilation.

Visualization for Analyzing Trajectory-Based Metaheuristic Search Algorithms

Steven HALIM and Roland H.C. YAP¹ and Hoong Chuin LAU²

1 INTRODUCTION

Most combinatorial (optimization) problems are computationally intractable. We often have to be satisfied with *good* solutions and typically metaheuristic algorithms (such as various forms of local search, tabu search, etc) are used. Given the heuristic nature of such search algorithms, there are two important considerations in designing a metaheuristic algorithm:

- Choice of metaheuristics to employ, which may include problem specific tweaks;
- Selecting the appropriate parameters to drive the heuristics.

We call this problem of designing the appropriate metaheuristic problem for a combinatorial (optimization) problem, the *metaheuristic tuning problem* [1, 3, 7]. Anecdotal evidence suggests that tuning takes a major effort, i.e. [1] states that 90% of the design and testing time can be spent fine-tuning the algorithm.

Although it can be easy to come up with a variety of metaheuristics, tuning the metaheuristic implementation is not straightforward. Firstly, the metaheuristics may not be well understood. It might also be applied to problems which may not have been studied. Thus, it may not be clear how to perform tuning. Secondly, the space in which the tuning can operate on is very rich — there are many ways of combining different kinds of metaheuristics each with their own choice of strategies and variations. Furthermore, they each have their own parameters. In this paper, we take a broad view of the metaheuristic tuning problem and understand it to also encompass algorithm design and debugging.

Traditionally, the approach for to the tuning problem is either manual experimentation or more automated approaches such as finding the best parameter values [1], best configuration [3], or self-tuning algorithms [2]. In this paper, we take a different approach which takes a human/programmer perspective — how to aid human in solving the tuning problem. Like human-guided search [6], we believe that a cooperative paradigm with the human in the loop can be productive. The difference with human-guided search is that it is concerned with using the human to produce better solutions, while we want to use the human to produce better metaheuristic algorithms.

Ultimately, we would like a man-machine cooperation which can help the human to debug, analyze and improve a metaheuristic algorithm for particular problems. Some of the questions which we would like to help answer are:

1. Does the actual search behavior match how we think the algorithm should behave?

2. Are there signs of cycling behavior?
3. How does the metaheuristic algorithm make progress?
4. How effective the metaheuristic in conducting intensification and/or diversification?
5. How wide is the search coverage?
6. How far is the (greedy) initial solution to the best found solution?
7. Does the search quickly identify the region where the best solutions found reside or does it wander elsewhere?
8. How do the trajectories of two different metaheuristics compare?
9. What is the effect of modifying certain parameters, components or strategies with respect to the search behavior?

In this paper, we focus on the tuning problem for metaheuristic algorithms which are search trajectory based, such as iterated local search, simulated annealing, tabu search, etc. We believe that a good approach to get man-machine cooperation is with an interactive visualisation of the search trajectory. One way of understanding how a program works is with a debugger. We have built the analog of a debugger, the visualizer VIZ, for understanding search trajectories of metaheuristic algorithms. VIZ provides visualization and animation (forwards and backwards) in time. It has multiple visualizations: (i) problem independent visualization which allows it to be used on a broad range of metaheuristic algorithms in a generic way; and (ii) it can also make use of problem specific visualizations. Although VIZ is still in prototype stage, we believe that it is the first serious attempt at an interactive tool with emphasis on the human computer interaction aspects to help humans understand the dynamic behavior of metaheuristic algorithms and guide the tuning process.

2 SEARCH TRAJECTORY VISUALIZATION

Visualizing the search trajectory, i.e. local movement of the current solution along the search space is difficult because the problem is usually in very high dimensions and the search space is also extremely large. We are only aware of (very) few proposals for search trajectory visualization.

N-to-2 space mapping [4] gives a mapping from a higher dimensional problem space to 2-D for visualizing, e.g. coverage of search space. However, the proposed visualization is crowded and static.

In our earlier work, V-MDF [7], we proposed a visualization called the *distance radar*. A current set of elite solutions is chosen, called *anchor points*. The distance radar displays two graphs: the distance between the current solution in the search trajectory w.r.t the set of anchor points (one sorted by fitness and the other by recency). While V-MDF can help answering *some* of the questions about how the search trajectory is behaving, e.g. questions 1/2/4/7, the visualization is not very intuitive for answering questions 3/5/6/8/9. Another drawback is that the graphs can change simply because the elite set

¹ National University of Singapore, {stevenha,ryap}@comp.nus.edu.sg

² Singapore Management University, hclau@smu.edu.sg

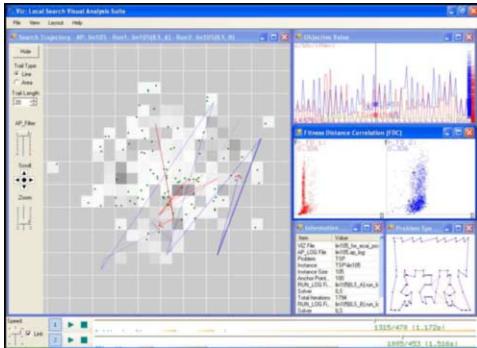

Figure 1. Screen shot of VIZ with multiple visualizations

changes with time. The visualization is less effective because the visualization is essentially one dimensional, graphs which show distance information.

With VIZ, we want to ensure that the visualization can be intuitive and exploit the fact that humans are good at recognizing visual patterns, in particular, not just in a static image but also how things change which exploits movement and temporal features. We make use of an abstract 2-D visualization where instead of trying to map the anchor points and points along the search trajectory from a high dimension to 2-D, we consider abstract points which are differentiated from each other using a distance metric. We do not have the space to discuss the visualization in detail — an example of a possible metric is the Hamming distance. These points can then be laid out in 2-D to approximate a visualization of the abstract points, we have used a spring model for the layout [5]. The search trajectory is then drawn interactively as a trail as shown in Fig. 1 and 2. The strength of this approach is that we now have a problem independent visualization which can be used with a suitably defined metric to demonstrate search trajectories.

3 THE VISUALIZER: VIZ

Fig. 1 shows VIZ's GUI. VIZ functions in interactive fashion as a kind of video player to play back an animation of the search trajectory drawn as a trail. The trail fades with time so that the animation does not clutter up the screen. Colors are used to compare two metaheuristic algorithms. Anchor points³ are landmarks to indicate the progress of the search trajectory in the abstract search space. Auxiliary visualizations are used to complement search trajectory visualization, e.g. time series of objective values, problem specific, etc. The animation of the geometric pattern of the trail, its relation to the anchor points, and auxiliary visualizations can be used to answer *all* the questions posed in Sec. 1.

Space doesn't permit more details, rather we use the following example which demonstrates how one can visualize the differences between two variants of Iterated Local Search (ILS) on TSP [9]. In TSP, it is conjectured that a heuristic algorithm should exploit the “Big Valley” property, a region in the TSP search space where most local optima (including the global optima) lie [8].

In this example, we want to know whether our algorithms make use of this property. We created two variants of the ILS algorithm which are run on the same TSP instance: ILS_A and ILS_B . The visualization of the search trajectories from ILS_A and ILS_B is shown in Fig. 1 (as a trail) and Fig. 2 (as region coverage). At a glance,

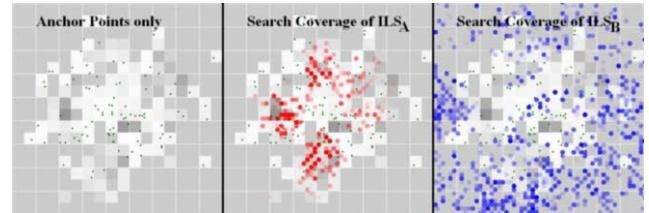

Figure 2. Search trajectory of ILS_A vs ILS_B on the same TSP instance

one can check the existence of the search intensification indicative of searching in a “Big Valley” by checking whether the search trajectory covers region with a cluster of many good anchor points (TSP local optima). Fig. 2 shows that the search trajectory for ILS_A is concentrated in the middle of the screen (indicative of a “Big Valley” region). On the other hand, after similar number of iterations, the coverage of ILS_B seems to be more diverse. ILS_B seems to spend most of its time exploring areas far from the cluster of good anchor points.

This gives a possible explanation of the algorithm behavior and suggests directions for tuning our algorithms. If our solution behaves like ILS_A , we know that we are on the right track, perhaps only few minor adjustments are needed. On the other hand, if it behaves like ILS_B , we may want to modify our ILS algorithm such that it is more focused.

4 CONCLUSION

We have presented a new approach for visualizing search trajectory and introduced the visualizer tool VIZ. This is not intended to replace the existing analysis tools, but rather it is meant to augment the existing tools to help the algorithm designer better understand the behavior of a trajectory based metaheuristic search algorithm and to debug and to tune the algorithm. A prototype of VIZ which is under continuous development is at: <http://www.comp.nus.edu.sg/~stevenha/viz>

³ These are slightly different from V-MDF, as anchor points in VIZ are now static: carefully chosen from the log files to achieve diversity and quality. The fitness of the anchor points is indicated via the contour map.

Bipolar preference problems

Stefano Bistarelli*, Maria Silvia Pini**, Francesca Rossi** and K. Brent Venable**¹

1 INTRODUCTION

Real-life problems present several kinds of preferences. In this paper we focus on problems with both positive and negative preferences, that we call *bipolar problems*. Although seemingly specular notions, these two kinds of preferences should be dealt differently to obtain the desired natural behaviour. In fact, assume, for example, to have a scenario with two objects A and B. If we like both A and B, i.e., if we give to A and B positive preferences, then the overall scenario should be more preferred than having just A or B alone, and so the combination of such a preferences should give an higher positive preference. Instead, if we dislike both A and B, i.e., if we give to A and B negative preferences, then the overall scenario should be less preferred than having just A or B alone and so the combination of such a negative preferences should give a lower negative preference. When dealing with both kinds of preferences, it is natural to express also indifference, which means that we express neither a positive nor a negative preference over an object. A desired behaviour of indifference is that, when combined with any preference, it should not influence the overall preference.

Finally, besides combining positive preferences among themselves, and also negative preferences among themselves, we also want to be able to combine positive with negative preferences, allowing compensation. For example, if we have a meal with meat (which we like very much) and wine (which we don't like), then what should be the preference of the meal? To know that, we should be able to compensate the positive preference given to meat with the negative preference given to wine.

In this paper we start from the soft constraint formalism [2] based on c-semirings, that models only negative preferences. We then extend it via a new mathematical structure, which allows to handle positive preferences as well and we address the issue of the compensation between positive and negative preferences, studying the properties of this operation. Parts of this paper have appeared in [3].

2 SOFT CONSTRAINT FORMALISM

A soft constraint [2] is a classical constraint [4] where each instantiation of its variables has an associated value from a (totally or partially ordered) set. This set has two operations, which makes it similar to a semiring, and is called a c-semiring. A c-semiring is a tuple $(A, +, \times, \mathbf{0}, \mathbf{1})$ where: A is a set and $\mathbf{0}, \mathbf{1} \in A$; $+$ is commutative, associative, idempotent, $\mathbf{0}$ is its unit element, and $\mathbf{1}$ is its absorbing element; \times is associative, commutative, distributes over $+$, $\mathbf{1}$ is its unit element and $\mathbf{0}$ is its absorbing element. Consider the relation \leq_S over A such that $a \leq_S b$ iff $a + b = b$. Then: \leq_S is a partial order; $+$

¹* : University of Pescara and CNR, Pisa, Italy. E-mail: bista@sci.unich.it and Stefano.Bistarelli@iit.cnr.it. ** : Department of Pure and Applied Mathematics, University of Padova, Italy. E-mail: {mpini,frossi,kvenable}@math.unipd.it.

and \times are monotone on \leq_S ; $\mathbf{0}$ is its minimum and $\mathbf{1}$ its maximum; (A, \leq_S) is a lattice and, $\forall a, b \in A, a + b = lub(a, b)$. Moreover, if \times is idempotent, then (A, \leq_S) is a distributive lattice and \times is its glb. Informally, the relation \leq_S gives us a way to compare (some of the) tuples of values and constraints. In fact, when we have $a \leq_S b$, we will say that b is better than a .

Given a c-semiring $S = (A, +, \times, \mathbf{0}, \mathbf{1})$, a finite set D (the domain of the variables), and an ordered set of variables V , a constraint is a pair $\langle def, con \rangle$ where $con \subseteq V$ and $def : D^{|con|} \rightarrow A$. Therefore, a constraint specifies a set of variables (the ones in con), and assigns to each tuple of values of D of these variables an element of A . A soft constraint satisfaction problem (SCSP) is just a set of soft constraints over a set of variables. For example, fuzzy CSPs [5] and weighted CSPs [2] are SCSPs that can be modeled by choosing resp. c-semirings $S_{FCSP} = ([0, 1], max, min, 0, 1)$ and $S_{WCSP} = (\mathbb{R}^+, min, sum, +\infty, 0)$.

3 NEGATIVE PREFERENCES

The structure we use to model negative preferences is exactly a c-semiring [2] as described in the previous section. In fact, in a c-semiring there is an element which acts as indifference, that is $\mathbf{1}$, since $\forall a \in A, a \times \mathbf{1} = a$, and the combination between negative preferences goes down in the ordering (in fact, $a \times b \leq a, b$), that is a desired property. This interpretation is very natural when considering, for example, the weighted c-semiring $(\mathbb{R}^+, min, +, +\infty, 0)$. In fact, in this case the real numbers are costs and thus negative preferences. The sum of different costs is worse in general w.r.t. the ordering induced by the additive operator (that is, min) of the c-semiring. From now on, we will use a standard c-semiring to model negative preferences, denoted as: $(N, +_n, \times_n, \perp_n, \top_n)$.

4 POSITIVE PREFERENCES

When dealing with positive preferences, we want two main properties to hold: combination should bring to better preferences, and indifference should be lower than all the other positive preferences. A positive preference structure is a tuple $(P, +_p, \times_p, \perp_p, \top_p)$ s.t. P is a set and $\top_p, \perp_p \in P$; $+_p$, the additive operator, is commutative, associative, idempotent, with \perp_p as its unit element ($\forall a \in P, a +_p \perp_p = a$) and \top_p as its absorbing element ($\forall a \in P, a +_p \top_p = \top_p$); \times_p , the multiplicative operator, is associative, commutative and distributes over $+_p$ ($a \times_p (b +_p c) = (a \times_p b) +_p (a \times_p c)$), with \perp_p as its unit element and \top_p as its absorbing element².

The additive operator of this structure has the same properties as the corresponding one in c-semirings, and thus it induces a partial order over P in the usual way: $a \leq_p b$ iff $a +_p b = b$. This allows to prove that $+_p$ is monotone ($\forall a, b, d \in P$ s.t. $a \leq_p b, a +_p d \leq_p b +_p d$).

² In fact, the absorbing nature of \top_p can be derived from the other properties.

$b \times_p d$) and that it is the least upper bound in the lattice (P, \leq_p) ($\forall a, b \in P, a \times_p b \geq_p a +_p b \geq_p a, b$).

On the other hand, \times_p has different properties w.r.t. \times_n : the best element in the ordering (\top_p) is now its absorbing element, while the worst element (\perp_p) is its unit element. \perp_p models indifference. These are exactly the desired properties for the combination and for indifference w.r.t. positive preferences. An example of a positive preference structure is $(\mathbb{R}^+, max, sum, 0, +\infty)$, where preferences are positive real numbers aggregated with *sum* and compared with *max*.

5 BIPOLAR PREFERENCE STRUCTURES

For handing both positive and negative preferences we propose to combine the two structures described in sections 4 and 3 in what we call a *bipolar preference structure*. A bipolar preference structure is a tuple $(N, P, +, \times, \perp, \square, \top)$ where, $(P, +|_P, \times|_P, \square, \top)$ is a positive preference structure; $(N, +|_N, \times|_N, \perp, \square)$ is a c-semiring; $+ : (N \cup P)^2 \rightarrow (N \cup P)$ is an operator s. t. $a_n + a_p = a_p$, $\forall a_n \in N$ and $a_p \in P$; it induces a partial ordering on $N \cup P$; $\forall a, b \in P \cup N, a \leq b$ iff $a + b = b$; $\times : (N \cup P)^2 \rightarrow (N \cup P)$ is a commutative and monotone ($\forall a, b, c \in N \cup P$, if $a \leq b$, then $a \times c \leq b \times c$) operator.

Bipolar preference structures generalize both c-semirings and positive structures. In fact, when $\square = \top$, we have a c-semiring and, when $\square = \perp$, we have a positive structure. Given the way the ordering is induced by $+$ on $N \cup P$, easily, we have $\perp \leq \square \leq \top$. Thus, there is a unique maximum element (that is, \top), a unique minimum element (that is, \perp); the element \square is smaller than any positive preference and greater than any negative preference, and it is used to model indifference.

A bipolar preference structure allows to have a richer structure for one kind of preference, that is common in real-life problems. In fact, we can have different lattices (P, \leq_p) and (N, \leq_n) . In the following, we will write $+_n$ instead of $+|_N$ and $+_p$ instead of $+|_P$. Similarly for \times_n and \times_p . When \times is applied to a pair in $(N \times P)$, we will sometimes write \times_{np} and we will call it compensation operator.

An example of bipolar structure is the tuple $(N=[-1, 0], P=[0, 1], +=\max, \times, \perp=-1, \square=0, \top=1)$, where \times is such that $\times_p = \max$, $\times_n = \min$ and $\times_{np} = \text{sum}$. Negative preferences are between -1 and 0, positive preferences between 0 and 1, compensation is sum, and the order is given by max. In this case \times is not associative.

In general, operator \times may be not associative. For example, if $\top \times \perp = c \in (N \cup P) - \{\top, \perp\}$ or if there are at least two elements $p \in P - \{\top\}, n \in N - \{\perp\}$ s.t. $p \times n = \square$ and \times_n or \times_p is idempotent, then \times is not associative. Since these conditions often occur in practice, it is not reasonable to require associativity of \times .

The combination of a positive and a negative preference is a preference which is higher than, or equal to, the negative one and lower than, or equal to, the positive one.

Possible choices for combining strictly positive with strictly negative preferences are thus the average, the median, the min or the max operator. Moreover, by monotonicity, if $\top \times \perp = \perp$, then $\forall p \in P, p \times \perp = \perp$. Similarly, if $\top \times \perp = \top$, then $\forall n \in N, n \times \top = \top$.

6 BIPOLAR PREFERENCE PROBLEMS

Once we have defined bipolar preference structures, we can define a notion of bipolar constraint, which is just a constraint where each assignment of values to its variables is associated to one of the elements in a bipolar preference structure. Given a bipolar preference structure

$(N, P, +, \times, \perp, \square, \top)$ a finite set D (the domain of the variables), and an ordered set of variables V , a constraint is a pair $\langle def, con \rangle$ where $con \subseteq V$ and $def : D^{|con|} \rightarrow (N \cup P)$.

A bipolar CSP (V, C) is then just a set of variables V and a set of bipolar constraints C over V .

A solution of a bipolar CSP (V, C) is a complete assignment to all variables in V , say s , with an associated preference $pref(s) = (p_1 \times_p \dots \times_p p_k) \times (n_1 \times_n \dots \times_n n_l)$, where, for $i := 1, \dots, k$ $p_i \in P$, for $j := 1, \dots, l$ $n_j \in N$, and $\exists \langle def, con \rangle \in C$ such that $p_i = def(s|_{con})$ or $n_j = def(s|_{con})$. A solution s is optimal if there is no other solution s' with $pref(s') > pref(s)$. In this definition, the preference of a solution s is obtained by combining all the positive preferences associated to its projections over the constraints, combining all the negative preferences associated to its projections over the constraints, and then, combining the two preferences obtained so far. If \times is associative, then other definitions of solution preference could be used while giving the same result.

7 RELATED AND FUTURE WORK

Bipolar reasoning and preferences have recently attracted some interest in the AI community. In [1], a bipolar preference model based on a fuzzy-possibilistic approach is described, but positive and negative preferences are kept separate and no compensation is allowed. In [6] only totally ordered unipolar and bipolar preference scales are used, while we have presented a way to deal with partially ordered ones. On totally ordered scales the t-norm and t-conorm of [6] correspond to \times_n and \times_p , while the uninorm of [6], similar to \times , is less general than \times , since it is associative.

We plan to adapt constraint propagation and branch and bound techniques to deal with bipolar problems and we intend to develop a solver for bipolar CSPs, which should be flexible enough to accommodate for both associative and non-associative compensation operators. We also intend to consider the presence of uncertainty in bipolar problems, possibly using possibility theory and to develop solving techniques for such scenarios. We also want to generalize other preference formalisms, such as multicriteria methods and CP-nets.

A Connectivity Constraint using Bridges

Patrick Prosser¹ and Chris Unsworth²

1 Introduction

We present a specialised constraint for enforcing graph connectivity. It is assumed that we have a square symmetrical array A of 0/1 constrained integer variables representing potential undirected edges in a simple graph, such that variable $A[u, v]$ corresponds to the undirected edge (u, v) . A search process is then at liberty to select and reject edges. The connectivity constraint ensures that no *critical* edge may be deleted from A , i.e. an edge that if deleted disconnects the graph. This connectivity constraint might then be used when modelling network design problems, modelling molecular structures, problems in bioinformatics [4], or graph problems where connectivity is an essential property [3, 1].

The constraint's internals are founded on the depth first search (dfs) process. The dfs process generates two sets of edges: the set of tree edges T , and the set of back edges B . The connectivity constraint associates a counter $nc[u, v]$, initialised to zero, with each tree edge. On creation of a back edge (t, w) we increment the counters on the tree edges spanned by that back edge, i.e. we increment the set of counters $\{nc[u, v] \mid (u, v) \in path(t, w)\}$ where $path(t, w)$ delivers the set of edges that make up the path from t to w in T . A counter is incremented to indicate that there is at least one more cycle in the graph involving edge (u, v) , i.e. $nc[u, v]$ is a count of the number of cycles passing through edge (u, v) using edges in T and B . If on termination of the dfs process any counter, say $nc[v, w]$, equals zero then that edge (v, w) is a bridge (also known as an isthmus or cut-edge) and must be forced. Consequently the value 0 is removed from the domain of variable $A[u, v]$.

2 Depth First Search with Tree and Back Edges

We assume we have a graph G with vertices V and edges E . The dfs algorithm [2] will produce two sets of edges: T the tree edges, and B the back edges. A vertex may be given one of three colours: white, grey, or black. Initially all vertices are white, signifying that they have not been visited. A vertex v is coloured grey when it has first been visited, i.e. a call to $dfs(v)$ is made. On completing the call to $dfs(v)$ the vertex is coloured black. Therefore a vertex starts white, may then turn grey, and eventually black. In the dfs algorithm, given below, two types of edges may be created.

- (a) Edge (v, w) is a tree edge when v is adjacent to w in G and v is grey and w is white. In the algorithm the call $treeEdge(v, w)$ adds the edge (v, w) to T . A tree edge is created as dfs expands forwards to a new descendant.
- (b) A back edge (v, w) is created when w is adjacent to v , w has already been visited by dfs (i.e. w is grey), the processing of v

is not yet complete (i.e. v is grey), and (w, v) is not already a tree edge. The call $backEdge(v, w)$ does nothing if $(w, v) \in T$, otherwise the edge (v, w) is added to B and the set of counters $\{nc[x, y] \mid (x, y) \in path(v, w)\}$ are incremented, i.e. increment the cycle counters on the tree edges on the path from v to w .

```

procedure dfs(v)
begin
  colour[v] := grey;
  for w in adjacent(v)
  do begin
    if colour[w] = white
    then begin
      treeEdge(v, w)
      dfs(w)
    end
    else if colour[w] = grey
    then backEdge(v, w)
  end
  colour[v] := black;
end

```

3 The Methods of the Constraint

We now present the methods that act upon the constraint. First we describe the actions that take place when the constraint is initially added to a model. Then we describe the methods that are performed when an edge is rejected by the search process. Note that no action need be taken when an edge is selected by the search process as this cannot result in the graph becoming disconnected.

3.1 On Awakening

When the constraint is initially awoken (i.e. added to the model) a dfs is performed from an arbitrary vertex. As noted above we associate cycle counters with each tree edge, i.e $nc[u, v]$ is a count of the number of cycles through the edge (u, v) resulting from back edges and tree edges that span or include edge (u, v) . These counters are initially zero and are incremented when spanned by a back edge. On termination of dfs, any cycle counter $nc[u, v]$ equal to zero indicates that edge (u, v) is a bridge in G and that edge must be selected otherwise G will be disconnected. In addition, if on completion of the call to dfs any vertex is white then that vertex is isolated and the graph cannot be connected; consequently we can raise an exception.

3.2 On Deletion of a Back Edge

If an edge (u, v) is deleted from the graph and (u, v) is a back edge then we decrement the set of counters $\{nc[x, y] \mid (x, y) \in path(u, v)\}$, i.e. decrement all cycle counters on the path from u to v in T . If any counter reaches zero then the corresponding edge is a bridge and must be forced.

² Department of Computing Science, University of Glasgow, Scotland, chrisu@dcs.gla.ac.uk

3.3 On Deletion of a Tree Edge

If a tree edge (u, v) is deleted a new subtree must be produced and one of the back edges spanning (u, v) will become a tree edge. Such a candidate back edge must exist otherwise (u, v) will have been a bridge and that bridge will have been detected and its selection already forced. The following actions (also shown pictorially in Figure 1) need to be performed when tree edge (u, v) is deleted where we assume that u is the parent of v :

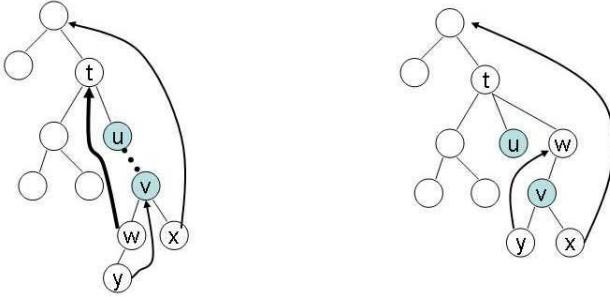

Figure 1. Tree edge (u, v) is deleted on the left and repaired on the right.

1. Let V' be the set of vertices in the subtree rooted on v (and includes v), T' the set of tree edges in that subtree, and B' the set of back edges $\{(t, w) \mid (t, w) \in B \wedge w \in V'\}$.
2. Decrement the *multi-set* of cycle counters $\{\{nc[x, y] \mid (x, y) \in path(t, w) \wedge (t, w) \in B'\}\}$, where $path(t, w)$ delivers the set of edges on the path from t to w in T .
3. Find the back edge $(t, w) \in B'$ where $depth(t) \leq depth(u) < depth(v) < depth(w)$ and $depth(t)$ is a maximum. (The back edge (t, w) is shown on the left of Figure 1).
4. Colour the vertices in the set V' white (i.e. mark them as not visited by dfs).
5. Remove the tree edges T' and back edges B' , i.e. $T = T \setminus T'$ and $B = B \setminus B'$.
6. Colour grey the set of vertices on the path from t to the root of T . Note, that if this was not done then no new back edges could be produced involving ancestors of t in step 7 below.
7. Add new tree edge (t, w) to T , i.e. what was back edge (t, w) becomes a tree edge. Now make a call to $dfs(w)$. (The repaired subtree is shown on the right of Figure 1).
8. Colour black the set of vertices on the path from t to the root of T . This needs to be done to prevent forward edges being produced by subsequent calls to dfs
9. If any cycle counter $nc[x, y]$, where $(x, y) \in T$, is zero then the edge is a bridge and must be selected.

Note that in step 3 we must select the deepest spanning back edge otherwise a cross edge may be produced in step 7 and the cycle counters would be corrupted, and that such a back edge must exist. On the termination of step 7 there will be no white vertices. This could only happen if edge (u, v) was a bridge, and that would be a contradiction.

4 Complexity

The complexity of the algorithm is $O(n^3)$ for a graph with n vertices. The principal activity of the algorithm is the number of times the cycle counters are incremented. The worst case graph would be the clique K_n . A clique would have a dfs tree with back edges as shown in Figure 2, using K_6 as an example. As can be seen, the vertices of the graph have been linearised, and the remaining edges in the clique

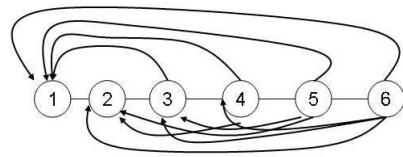

Figure 2. A dfs tree (straight lines) for K_6 with back edges (curved lines). The sum of the number of times edges participate in cycles is $\frac{n^3 - 7n}{6} + 1$

become back edges. The tree has $n - 1$ tree edges, and therefore $n - 1$ cycle counters. A tree edge emanating from a vertex at position i (where the first position is $i = 1$ and the last $i = n - 1$) will be involved in at most $i(n - i) - 1$ cycles. That is, for a vertex at depth i there will be $n - i$ vertices below it. Each one of these $n - i$ vertices can then have back edges to each of the first i vertices. However, the vertex in position $i + 1$ cannot have a back edge to the vertex in position i , otherwise we have a cycle that involves only 2 vertices. Therefore we must remove 1 from our calculation. Consequently the sum of the cycle counters on the dfs tree T for the clique K_n will be as follows:

$$\sum_{i=1}^{n-1} [i(n - i) - 1] = \frac{n^3 - 7n}{6} + 1$$

We should expect that the performance of this can be improved by taking a lazy approach, possibly based on [5].

5 Data Structures and Potential Enhancements

A number of reversible data structures are required to realise the above. Since we need to traverse a subtree in order to delete tree and back edges we associate with each vertex a boolean set of length n , representing the immediate children of that vertex. We also associate with a vertex a boolean set of length n representing the back edges from a vertex. Each vertex also has a parent attribute so that we can traverse from a vertex upwards towards some other vertex downgrading the cycle counters. We also associate a depth with a vertex so that we can compare back edges. All of the above additional space is of order $O(n^2)$ where n is the number of vertices in G .

The constraint can be enhanced to deal with multi-edges. Assuming that an array variable $A[u, v]$ can have a value greater than 1, if the constraint forces the edge (u, v) rather than setting $A[u, v]$ to 1 we remove the value 0. The efficiency of step 2 in 3.3 can be improved by setting counters in the tree edges rooted on v to zero, and decrementing counters on tree edges above u .

Search Better and Gain More: Investigating New Graph Structures for Multi-Agent Negotiations

Samir Aknine¹

Abstract. Combined negotiation in multi-agent systems is a hard task since it involves several levels of difficulty. In order to improve their payoff, first agents behave in a strategic manner while bargaining since they need to deal with various types of behaviors. Second agents have to react to the proposals of other agents in finding the optimal solutions for their negotiation. This paper tackles the problem of winner determination in combined multi-agent negotiations and addresses two fundamental issues. The first contribution of this work is a winner determination algorithm, which finds an optimal solution, which is a combination of several bids selected from a set of bids at one iteration of a combined negotiation. In addition, the problem of dynamically revising these optimal solutions with regards to changes on bids is considered. These changes occur in multi-agent negotiation processes having several iterations and which use multi-phased protocols. To date no work addresses this problem. The second contribution of this work is an iterative algorithm for updating the optimal solutions to avoid integral and repetitive reapplication of the winner determination algorithm. The results of the experiments carried out using our algorithms have confirmed the importance and the originality of our approach based on the use of shared and unshared item graphs.

1 INTRODUCTION

This paper addresses the optimal winner determination problem in a multi-agent combined negotiation and the dynamic revision of the optimal solution. It proposes a search and update algorithm for optimal solutions. Currently, several algorithms [2,3,5,6] determine the best bid or combination of bids maximizing the utility function of an agent during an iteration of a combined negotiation. However, the problem of combined negotiation is that the search for an optimal solution is repetitive since in each iteration or negotiation phase negotiator agents must take a decision and select their new optimal solution if the bids formulated in preceding iterations have changed. Our aim is to propose an algorithm to find this optimal solution incrementally. To date no work addresses this problem.

An optimal solution is recomputed from one iteration to another, and depending on the utility reached by the agents with this solution the negotiation is stopped or resumed. The incremental searching requires an algorithm able to update the optimal solution with minimum computations in order to reduce its complexity. Such an algorithm will compute a new solution by taking into account only the main changes that have appeared in prior iterations.

¹ LIP6, Université Paris 6, Samir.Aknine@lip6.fr

The types of modification to be considered depend on the evolution of the bids. For instance, if a bid at stake becomes invalid – its sender has retracted from the negotiation – this requires an operation to delete this bid and all the solutions using these bids must be revisited. If a bidder sends a new bid, it will imply an operation to complete the list of bids and possibly the solutions. Other changes on the bids may also happen if the bidders decide to increase or decrease their bids. Remember that all these behaviors are feasible in a multi-agent negotiation.

Regarding these new constraints and knowing that the optimal winner determination problem is *NP-complete*, it is not possible to reapply the basic algorithm for optimal solution search at each iteration of a negotiation. An optimal solution should be recomputed in each step of the negotiation but with an algorithm requiring a minimum of computations in order to reduce computational complexity, since in a negotiation based on several phases this search for new solutions could be reiterated as many times as the negotiation requires. Thus the algorithm has to find this new optimal solution by considering the changes that have occurred on the bids.

To address this problem, our approach recommends building two graphs, named shared and unshared item graphs, before building the optimal solution tree for the winner determination problem. These graphs enable us to work with an intentional representation of bids rather than an extensional representation as is done in current algorithms. They provide the sufficient and necessary conditions for the analysis of a bid or a partition of bids. We prove that this method reduces the exploration runtime of the bids. To build the optimal solution tree, these graphs and their properties can be combined with any method for tree construction (depth-first, width-first or mixed, etc.). We have chosen to base our method on certain principals of [5,6,7] for the construction of trees also based on the IDA* method of [4]. We show that our method finds optimal solutions for combined negotiations in a shorter time and explores less search space. These improvements are due to the graph structures we propose.

2 WINNER DETERMINATION

Formally, the winner determination problem in combined negotiations is such that: having a buyer agent which proposes to acquire $L = \{1, 2, 3, \dots, n\}$ items, where each item is defined by a set of properties, for instance the price; and a group of seller agents who propose a set $E = \{O_1, O_2, O_3, \dots, O_m\}$ of bids, where each O_i is a subset of items in L called its structure. A bid is defined by a set of properties such as the price v_i , for instance.

The number of items included in the bid indicates its length. Each item can appear in several bids. We deal with only one property for items, their price, in this algorithm. [5,6,7] have presented several algorithms to solve the winner determination problem. In this paper we essentially focus on the algorithm for multi-agent combined negotiation. Our approach recommends looking first for the similarities and differences between all the various bids in order to reuse them later as well as possible in the search phase for the optimal solution, since we already know that the problem of optimal solution search is *NP-complete* [1,2]. We deal with these properties in the graphs below.

Definition 1 *A shared item graph is a connected directed acyclic graph organized in several levels. First level nodes in this graph are the partitions resulting from the classification of the bids. Intermediate nodes contain items shared by the nodes they connect, i.e. the connected nodes contain either bids, as in the nodes of the first level, or items as in the nodes of intermediate levels. The terminal node of the graph is empty.*

Parallel to the construction of the shared item graph, our approach recommends the construction of the unshared item graph. This second graph highlights the differences between the bids of the partitions, and is defined as follows.

Definition 2 *An unshared item graph is a connected directed acyclic graph organized in several levels. The first level nodes in this graph are the partitions of bids. Each node of the second level contains the items not shared by all the bids of the partition to which this node is connected. The next intermediate nodes contain items shared by the nodes they connect to. The terminal node of the unshared item graph is empty.*

3 REVISING THE OPTIMAL SOLUTIONS

As mentioned previously, several changes may occur from one iteration of the negotiation to another: (1) withdrawals of bids; (2) changes of the properties of bids, for instance the price; (3) insertion of new bids. All these changes impact the partitions of bids and the shared and unshared item graphs built in preceding iterations. Depending on the changes carried out on the shared and unshared item graphs, the new search for the optimal solution requires the most restricted set of operations. Remember that at the end of the first search for the optimal solution, the algorithm has built a solution tree. In this new search, the algorithm is partially based on this tree whose trace has, of course, been updated, as have the shared and unshared item graphs.

The tree is then explored in order to add the changes on the bids which were removed or updated and those which have been recently introduced. Note that during the update phase of the partitions, two lists are processed at the same time, i.e. one for new bids L_{New} and one for removed bids L_{Delete} .

When the exploration of a node of the tree indicates a bid which has only been updated, the value of this bid is put in the solution tree. Moreover this value is also changed in the shared and unshared item graphs. To find the position of the bid in these graphs the algorithm uses several properties. If a bid has been removed, before withdrawing the branch under construction the algorithm tries first to rebuild this removed bid

by combining other bids which would possibly belong to L_{New} . If this case cannot be solved, the exploration of the path in the solution tree is stopped. When a bid is removed the partition which contains it could be removed if there are no more bids in this partition. By removing a partition, its ancestor nodes in the shared and unshared item graphs should be revised.

The new bids integrated in the partitions are processed in two different ways. First when a bid is added in a partition, the ancestor nodes in the shared and unshared item graphs are revised except for singleton bids. Then bids added in the first partition involve the construction of new optimal solution subtrees, which are built in exactly the same way as in the first iteration of the optimal solution search [1]. The bids integrated in other partitions are also processed like those in the first partition. For each of these bids a sub-tree is also generated in order to reduce the cost of integrating the new bids in the branches of existing solutions. This approach has proved to be efficient.

4 CONCLUSION

This paper addressed an important issue in multi-agent combined negotiations. Our approach is a continuation of the work on the winner determination problem [2,3,5,6,7]. It is primarily based on three new principles. (1) We use graph structures for shared and unshared items. These graphs enable us to work on an intentional representation of the bids instead of their extensional representation, and this reduces the time needed for the exploration of bids. (2) We defined new functions for ordering bids and items and several properties for the graphs. (3) We also considered the singularity of the items to speed up the search. The proposed algorithm has been implemented, tested on different distributions of bids to evaluate its performance and proved successful.

Acknowledgment. We would like to thank the Master students for all the implementations they performed.

An argumentation-based framework for designing dialogue strategies

Leila Amgoud¹ and Nabil Hameurlain²

Abstract. A dialogue strategy is the set of rules followed by an agent when choosing a move (act + content) during a dialogue. This paper argues that a strategy is decision problem in which an agent selects i) among the acts allowed by the protocol the best option that, according to some *strategic beliefs* of the agent will at least satisfy the most important *strategic goals* of the agent, and ii) among different alternatives (eg. different offers), the best one that according to some *basic beliefs* of the agent, will satisfy the *functional goals* of the agent. The paper proposes a formal framework based on argumentation for computing the best move to play at a given step of the dialogue.

1 INTRODUCTION

A dialogue protocol identifies the different possible replies after a given act. However, the exact act to utter at a given step of the dialogue is a *strategy* matter. A strategy can be seen as a two steps *decision process*: i) among all the possible replies allowed by the protocol, to choose the move to play. ii) to choose the content of the move if any. In most works on modeling dialogues, the definition of a protocol poses no problems. However, the situation is different for dialogue strategies. There is no formal models for defining them. There is even no consensus on the different ingredients involved when defining a strategy. This paper argues that the strategy is a *decision problem* in which an agent tries to choose among different *alternatives* the best option, which according to its beliefs, will satisfy at least its most important goals. Two kinds of goals (resp. of beliefs) are distinguished: the *strategic* and the *functional* goals (resp. the *strategic* and *basic* beliefs). The strategic goals are the meta level goals of the agent. Such goals will help an agent, on the basis of the strategic beliefs, to select the type of act to utter. Regarding functional goals, they will help an agent to select, on the basis of the basic beliefs, the content of a move.

We propose a formal argumentation-based framework for defining strategies. This framework takes as input two sets of goals: the strategic and the functional goals together with the strategic and basic beliefs and returns among the possible replies allowed by the protocol after a given act, the next move (act + its content) to play. The model is an extension of the argument-based decision framework proposed in [1]. The basic idea behind this model is to construct for each alternative the different arguments (reasons) supporting it, then to use a *criterion* to compare pairs of alternatives on the basis of the quality of their supporting arguments.

nabil.hameurlain@univ-pau.fr

2 AGENT'S MENTAL STATES

Two different kinds of goals are involved when selecting the next act to play and its content:

Strategic goals: For choosing the type of act to utter, an agent refers to what we call *strategic goals*. By strategic goals we mean the meta-level goals of the agent such as “minimizing the dialogue time”, “selling at the end of the dialogue”, etc. Suppose that at a given step of a negotiation dialogue, an agent has to choose between making an offer and asking a question. If the agent wants to minimize the dialogue time then it would choose to make an offer instead of spending more time in questions. However, if the agent wants to get a maximum of information about the wishes of the other agent, then the agent would decide to ask a question. These goals are generally independent of the *subject* of the dialogue.

Functional goals: The goals of the agent which are directly related to the subject of the dialogue are called *functional goals*. They represent what an agent wants to achieve or to get regarding the subject of the dialogue. Let us take the example of the agent negotiation the place of a meeting. The agent may prefer a place which is not warm and not expensive. These functional goals are involved when selecting the content of a move. In a negotiation, an agent proposes offers that satisfy such goals.

As for goals, the beliefs involved in the two decision problems (selecting an act and a content) are also of different nature:

Strategic beliefs: which are the meta-level beliefs of the agent. They may represent the beliefs of the agent about the dialogue and about the other agents involved in the dialogue. In negotiation dialogues where agents are trying to find a common agreement, agents may intend to simulate the reasoning of the other agents. Thus it is important for each agent to consider the beliefs that it has on the other agents' goals and beliefs.

Basic beliefs: represent the beliefs of the agent about the environment and the subject of the dialogue. Let us consider again the example of the agent negotiating the place of a meeting. Basic beliefs of the agent may include for instance the fact that “London is not warm”, “Tunisia is hot”, “London is very expensive”, etc.

3 THE LOGICAL LANGUAGE

Let \mathcal{L} be a propositional language and $Wff(\mathcal{L})$ the set of well-formed formulas built from \mathcal{L} . Let us suppose an additional symbol \bot . Each agent has the following bases:

$\mathcal{B}_f = \{(k_p, \rho_p), p = 1, s\}$ where $k_p \in Wff(\mathcal{L})$, is the basic beliefs. The beliefs are associated with certainty levels ρ_p . A pair (k_p, ρ_p) means that k_p is at least certain at a degree ρ_p .

$\mathcal{B}_s = \{(l_j, \delta_j), j = 1, m\}$ where $l_j \in Wff(\mathcal{L})$ is the strategic beliefs base. Each of these beliefs has a certainty level δ_j .

$\mathcal{G}_s = \{(g_q, \lambda_q), q = 1, t\}$ where $g_q \in Wff(\mathcal{L})$, is a base of strategic goals. The strategic goals can have different priority degrees, represented by λ_q . A pair (g_q, λ_q) means that the goal g_q is important for the agent at least to a degree λ_q .

$\mathcal{G}_f = \{(go_r, \gamma_r), r = 1, v\}$ where $go_r \in Wff(\mathcal{L})$, is the base of the functional goals of the agent. Each functional goal has a degree of importance denoted by γ_r .

The different certainty levels and priority degrees are assumed to belong to a unique linearly ordered scale with maximal element denoted by 1 (corresponding to total certainty and full priority), and a minimal element denoted by 0 corresponding to the complete absence of certainty or priority. We shall denote by \mathcal{B}_f^* , \mathcal{B}_s^* , \mathcal{G}_s^* , \mathcal{G}_f^* the corresponding sets when weights are ignored.

Let \mathcal{S} be the set of speech acts allowed by the protocol. Let us suppose that the function $\text{Replies}: \mathcal{S} \rightarrow 2^{\mathcal{S}}$ returns for each act, all the legal replies to it. Some acts may have a content. For instance, an act **Offer** should be accompanied with a content such as a price, a town, etc. However, the act **Withdraw** does not need any content. Such acts will have an empty content, denoted by the symbol ?. The function $\text{Content}: \mathcal{S} \rightarrow \mathcal{L} \cup ?$ returns for a given act the set of its possible contents. During a dialogue, agents exchange *moves* which are pairs (a, x) , where $a \in \mathcal{S}$ and $x \in \text{Content}(a)$. The strategy problem is formalized as follows: let (a, x) be the current move in a dialogue. What is the next move (a', x') to utter such that $a' \in \text{Replies}(a) ?$ To answer this question, one should find both a' and x' . Indeed, a' is the “best” element in $\text{Replies}(a)$ that satisfies \mathcal{G}_s^* according to \mathcal{B}_s^* , whereas x' is the “best” element among $\text{Content}(a')$ that satisfies \mathcal{G}_f^* according to \mathcal{B}_f^* .

4 THE ARGUMENTATION-BASED DECISION MODEL

Solving a decision problem amounts to defining a pre-ordering, usually a complete one, on a set \mathcal{X} of possible choices, on the basis of the different consequences of each decision. In our case, the set \mathcal{X} may be either the set $\text{Replies}(a)$ of the possible replies to a move, or the set $\text{Content}(a')$ with a' is the chosen act. Recently, Amgoud [1] has shown that argumentation can provide such a pre-ordering. Let \mathcal{B} be any *consistent* and *weighted* beliefs base, and \mathcal{G} be a *consistent* prioritized base of goals. \mathcal{B}^* and \mathcal{G}^* will denote the corresponding sets when weights are ignored. From these bases, different arguments in favor of elements of \mathcal{X} can be built. The idea is that a decision is justified and supported if it leads to the satisfaction of at least the most important goals of the agent, taking into account the most certain part of knowledge. An *argument in favor of* a choice $x \in \mathcal{X}$ is a triple $A = \langle S, g, x \rangle$ such that $S \subseteq \mathcal{B}^*$, $g \in \mathcal{G}^*$, $S \cup \{x\}$ is consistent, $S \cup \{x\} \vdash g$, and S is minimal (for set inclusion) among the sets satisfying the above conditions. S is the *support* of the argument, g is the *goal* which is reached by the decision x and x is the *conclusion* of the argument. The set $\mathcal{A}(\mathcal{B}, \mathcal{G}, \mathcal{X})$ gathers all the arguments which can be constructed from \mathcal{B} , \mathcal{G} and \mathcal{X} . $\text{Arg}(x)$ is the set of arguments whose conclusion is x .

Property 1 If $\mathcal{B} = \emptyset$, or $\mathcal{G} = \emptyset$, then $\mathcal{A}(\mathcal{B}, \mathcal{G}, \mathcal{X}) = \emptyset$.

Since an argument involves two kinds of information (beliefs and goals), its strength depends on the quality of both information. Thus, to each argument we associate a certainty level representing the degree of the less entrenched belief used in it, and a weight representing the importance of the goal reached by the conclusion of that

argument. The *strength* of an argument $A = \langle S, g, x \rangle$ is a pair $\langle \text{Level}(A), \text{Weight}(A) \rangle$ such that: i) $\text{Level}(A) = \min\{\rho_i \mid k_i \in S \text{ and } (k_i, \rho_i) \in \mathcal{B}\}$. If $S = \emptyset$ then $\text{Level}(A) = 1$. It represents the *certainty level* of the argument. ii) $\text{Weight}(A) = \lambda$ with $(g, \lambda) \in \mathcal{G}$. It represents the *degree of satisfaction* of the argument. The strengths of arguments make it possible to compare pairs of arguments in several ways, depending on whether the agent gives the same importance to the certainty level and the weight or not. For the purpose of illustration, let us consider the following particular criterion in which goals take precedence over beliefs: let A and B be two arguments in $\mathcal{A}(\mathcal{B}, \mathcal{G})$. A is *preferred* to B , denoted $A \succeq B$, iff $\text{Weight}(A) > \text{Weight}(B)$, or $\text{Weight}(A) = \text{Weight}(B)$ and $\text{Level}(A) \geq \text{Level}(B)$. At the core of our framework is the use of a *principle* that allows for an argument-based comparison of alternatives. Each combination of a principle with a criterion for comparing arguments captures a particular agent *profile*, thus a particular strategy for selecting moves in a dialogue.

Below we present an example of a principle that takes as input the supporting arguments and prefers an alternative which has at least one supporting argument which is preferred to any supporting argument of the other alternative. Formally, let $x, x' \in \mathcal{X}$. x is preferred to x' , denoted $x \triangleright x'$, iff $\exists P \in \text{Arg}(x) \text{ s.t. } \forall P' \in \text{Arg}(x'), P \succeq P'$.

Property 2 \succeq and \triangleright are total preorder relations i.e. reflexive and transitive.

An *argumentation-based decision framework* is a tuple $\langle \mathcal{X}, \mathcal{A}(\mathcal{B}, \mathcal{G}, \mathcal{X}), \succeq, \triangleright \rangle$ where \mathcal{X} is a set of all possible decisions, $\mathcal{A}(\mathcal{B}, \mathcal{G}, \mathcal{X})$ is a set of arguments built from \mathcal{B} , \mathcal{G} and \mathcal{X} , \succeq is a (partial or complete) pre-ordering on $\mathcal{A}(\mathcal{B}, \mathcal{G}, \mathcal{X})$, and \triangleright defines a (partial or complete) pre-order on \mathcal{X} . This framework can be used for move selection. Indeed, let \mathcal{X} be a set of possible decisions. The set of best decisions is $\text{Best}(\mathcal{X}) = \{x \in X, \text{s.t. } \forall x' \in \mathcal{X}, x \triangleright x'\}$.

Property 3 If $\mathcal{A}(\mathcal{B}, \mathcal{G}, \mathcal{X}) = \emptyset$, then $\text{Best}(\mathcal{X}) = \emptyset$.

Now, let (a, x) be the current move of the dialogue, and an agent has to choose the next one, say (a', x') . The act a' is returned as a best option by the framework $\langle \text{Replies}(a), \mathcal{A}(\mathcal{B}_s, \mathcal{G}_s, \text{Replies}(a)), \succeq, \triangleright \rangle$ (i.e. $a' \in \text{Best}(\text{Replies}(a))$), whereas the content x' is among the best options returned by the framework $\langle \text{Content}(a'), \mathcal{A}(\mathcal{B}_f, \mathcal{G}_f, \text{Content}(a')), \succeq, \triangleright \rangle$, i.e. $x' \in \text{Best}(\text{Content}(a'))$.

Property 4 If $\mathcal{G}_s = \emptyset$, or $\mathcal{B}_s = \emptyset$, then the next move is $(?, ?)$ meaning that there is no rational solution.

5 CONCLUSION

This paper claims that during a dialogue, a strategy is used only for defining the next move to play at each step of the dialogue. This amounts to define the speech act to utter and its content if necessary. The strategy is then regarded as a two steps *decision process*: among all the replies allowed by the protocol, an agent should select the best speech act to play, then it should select the best content for that speech act. We have shown that the choice of the next speech act is based on the strategic beliefs and the strategic goals, whereas the choice of the content is based on the basic beliefs and the functional goals. We have then proposed a formal framework for defining strategies based on argumentation. We have shown also the agents profiles play a key role in defining principles for comparing decisions.

A Multiagent System for Scheduling Activities Onboard a Space System

Francesco Amigoni and Simone Fare¹ and Michèle Lavagna and Guido Sangiovanni²

Abstract. The possible advantages of employing multiple agents to manage activities on a single space system are largely unexplored. This paper presents the experimental validation of a multiagent scheduler for a low Earth orbit satellite.

1 INTRODUCTION

We view a spacecraft as a collection of subsystems, functionally detached but highly interconnected and interdependent in order to reach the goals of the mission. Each subsystem is associated to an agent that is composed of four modules organized in a layered structure [5]: a *planner/negotiator*, a *scheduler*, an *executor*, and a *monitor*. In this paper, we focus on the distributed scheduler.

The separation of functions, the decentralization of activities and responsibilities, and the parallelism enable each agent to quickly answer to local unforeseen events or faults, without involving the overall system. For all these reasons, the multiagent approach is increasingly employed in space applications. However, it is usually applied to formations or constellations of satellites working together [1] or to multi-user scheduling [3]. In our work, we give an original contribution to investigating the use of multiple agents to manage the activities on a *single* space system. This topic is, to the best of our knowledge, largely unexplored (with few exceptions, including the reinforcement learning-based proposal of [4]).

We have developed [6] a multiagent scheduler for *Palamede*, a low Earth orbit satellite under development at the Aerospace Engineering Department of the Politecnico di Milano. The proposed distributed scheduler finds the starting times of the satellite's activities in order to satisfy some temporal and resource constraints.

In this paper, we experimentally show that the multiagent solution to the Palamede's scheduling problems does not introduce any significant loss of performance.

2 THE MULTIAGENT SCHEDULER FOR PALAMEDE

The main task of Palamede is to take pictures of the Earth surface and transmit them to a ground station. The satellite is supposed to orbit around the Earth at a height of approximately 650 km, so one orbit lasts 97 minutes of which 30 minutes are the eclipse period (sun-synchronous midday-midnight orbit).

Our multiagent system for scheduling includes the *Camera* agent, which manages the activities of taking pictures, the *ADCS* agent,

which controls the Attitude Determination and Control System of the satellite, and the *ORBCOMM* agent, which manages the communication flows between Palamede and the ground station via the ORBCOMM transponder. The onboard electrical energy is provided by five body-mounted solar arrays and a Li-Ion battery assembly. By applying a semi-regulated bus system topology, the nominal mode power is provided by the solar arrays; whenever extra power is available, it is used for recharging batteries, nominally discharged during eclipses. To take into account the electrical power consumption in the scheduling activities, a manager agent is associated to this depletable resource: the *Battery* agent. Since the total expected power produced by the solar arrays will be approximately 20 W (excluding the eclipse period) and the onboard data processing subsystem continuously needs 9 W, the management of the power resource is critical, especially during transmission activities that require more than 25 W.

In general, the activities of the agents onboard of Palamede are subject to temporal and resource constraints. These constraints can be either global or local. *Global* constraints involve activities performed by different agents, while *local* constraints involve activities performed by a single agent. *Temporal constraints* determine the temporal ordering in which the activities should be performed. An example of a temporal constraint is *Overlap* between two activities *a* and *b*, which means that *a* must start after *b* has started and must end before *b* ends. For example, in order to take a picture, before a *Grab* (i.e., the action of taking a picture) can be performed, the camera should be on, so *Grab* overlaps *Camera On*. *Resource constraints* determine when it is possible to perform the activities, according to the available onboard resources. The only resource we currently consider is the electrical energy provided by batteries and solar arrays. The resource constraints trivially impose that the power demand should not exceed the power availability. Resource constraints are only global, because electrical power is needed by the activities of all the agents. We decided to introduce the *Battery* agent to handle the aggregate demand of power and to check if it satisfies the resource constraints.

We formulated the scheduling problem as a Distributed Constraint Satisfaction Problem (DCSP):

- there are n sets of activities A_1, A_2, \dots, A_n ; A_i contains the activities of agent i ;
- each activity is associated to a variable representing its starting time, whose time values are taken from a finite domain set H (the scheduling horizon); an activity is characterized also by its duration and its power consumption;
- an agent knows all the temporal constraints (both local and global) relevant to its variables; the resource (global) constraints are known only by the *Battery* agent.

² Dipartimento di Ingegneria Aerospaziale, Politecnico di Milano, Italy,
email: lavagna@aero.polimi.it, sangiovanni@aero.polimi.it

In our application, we considered a scheduling horizon H of two orbits (194 minutes), divided in time quanta of 30 seconds. This means that the domain set of a variable (from which the starting time of an activity is selected) is the set of integers from 0 to 387. A solution is an assignment of values to all the variables such that all the temporal and resource constraints are satisfied.

In our multiagent scheduler, the scheduling of the activities is performed at two levels: at the *local level*, in which each agent determines the sequence of its local activities satisfying its known constraints, and at the *global level*, in which the local plans are harmonized to ensure the consistent consumption of shared resources. At the local level, each agent uses the *dynamic backtracking* algorithm [2]. With this algorithm, an agent finds value assignments to its local variables; these assignments form a *local plan*. A local plan of agent i is a vector of values assigned to variables of i , representing the starting times of the activities in A_i . The local algorithm iteratively picks up at random a variable and assigns to it a value chosen according to the least-constraining heuristic. If a value cannot be found, it backjumps to the variable responsible of the failure. Ties are randomly broken. The local plans found at the local level are harmonized at the global level using a variation of the *asynchronous weak commitment* algorithm [7]. The global plan resulting from this cooperation process is a set of local plans that satisfy all the constraints. More details on Palamede's multiagent scheduler are reported in [6].

3 EXPERIMENTAL RESULTS

We have implemented the multiagent scheduler described above in JAVA with the JADE platform. Experiments have been performed with a computer equipped with a 500 MHz processor and 128 MB RAM. In the following, we show that using distributed scheduling on a single spacecraft does not lead to dramatic loss of solution quality (other experiments are reported in [6]). The measures of performance we considered are the fraction of the successful schedules and the time required to reach a consistent global plan.

We initially considered a single agent to schedule h dummy activities with a schedule horizon of two orbits. All the dummy activities do not require any energy to be performed and have the same duration of $T = 5$ time quanta (recall that a time quantum is 30 seconds). The dummy activities are required not to overlap each other by means of the *Overlap* constraint. Of course, given T and the schedule horizon, the larger h , the more difficult the scheduling problem, and the more difficult to find a consistent local plan within the timeout. Fig. 1 shows the performances of the single agent scheduler facing the problem of allocating an increasing number of not overlapping dummy activities. Each point is the average over 100 trials. Variations between different trials are due to random choices in selecting the variable to instantiate, the value for a variable, and the activity to backjump to in the local algorithm. A timeout of 3 minutes has been given to the system for solving each trial: whenever this time limit was reached the trial was stopped and declared unsuccessful. Note that 3 minutes of scheduling is a very short time when compared with the 194 minutes of the scheduling window. Until the number of activities is smaller than 60, the agent instantaneously finds a solution in all the 100 trials. From 60 to 65 activities the agent finds a solution but with a longer average solving time. The computational limit for our local algorithm is reached for $h = 66$, where the solution is found only in the 12% of the trials, within 90 seconds on average. From these results, 60 appears to be the maximum number of activities that a centralized scheduler can easily manage. Hence, we tried different distributions of 60 dummy activities on four agents.

Table 1 shows the performances of the distributed scheduler. In fair situations, with activities symmetrically assigned to agents, the performances are almost the same of the single scheduling agent case. In situations with activities asymmetrically assigned to agents, the loss of successful schedules is slightly more than 10%.

We can conclude that the use of a multiagent system to distribute the scheduling process has not any dramatic impact on the performances of the system but provides the advantage of modularity.

Benefits of Combinatorial Auctions with Transformability Relationships

Andrea Giovannucci¹ and Jesús Cerquides² and Juan Antonio Rodríguez-Aguilar³

Abstract. In this paper we explore whether an auctioneer/buyer may benefit from introducing his transformability relationships (some goods can be transformed into others at a transformation cost) into multi-unit combinatorial reverse auctions. Thus, we quantitatively assess the potential savings the auctioneer/buyer may obtain with respect to combinatorial reverse auctions that do not consider transformability relationships. Furthermore, we empirically identify the market conditions under which it is worth for the auctioneer/buyer to exploit transformability relationships.

1 Introduction

Consider a company devoted to sell manufactured goods. It can either buy raw goods from providers, transform them into some other goods via some manufacturing process, and sell them to customers; or it can buy already-transformed products and resell them to customers. Thus, either the company buys raw goods to transform via an in-house process at a certain cost, or it buys already-transformed goods. Figure 1 graphically represents an example of a company's inner manufacturing process, more formally *Transformability Network Structure* (TNS), fully described in [1]. This graphical description largely borrows from the representation of Place/Transition Nets (PTN), a particular type of Petri Net [2]. Each circle (corresponding to a PTN place) represents a good. Horizontal bars connecting goods represent manufacturing operations, likewise *transitions* in a PTN. Manufacturing operations are labeled with a numbered t , and shall be referred to as *transformations* (t -relationships henceforth). An arc connecting a good to a transformation indicates that the good is an *input* to the transformation, whereas an arc connecting a transformation to a good indicates that the good is an *output* from the transformation. The labels on the arcs connecting *input goods* to transitions, and the labels on the arcs connecting *output goods* to transitions indicate the units required of each *input good* to perform a transformation and the units generated per *output good* respectively. Each transformation has an associated cost every time it is carried out.

Say that a buying agent requires to purchase a certain amount of goods g_3 , g_5 , g_6 , g_7 , g_8 , g_9 , and g_{10} . For this purpose, it may opt for running a combinatorial reverse auction with qualified providers. But before that, a buying agent may realise that he faces a decision problem: shall he buy g_1 and transform it via an in-house process, or buy already-transformed goods, or opt for a *mixed-purchase* solution and buy some already-transformed goods and some to transform

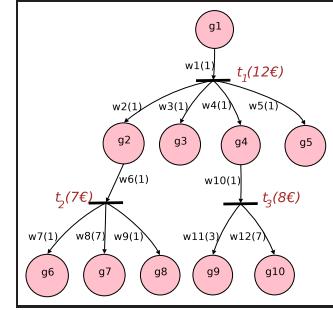

Figure 1. Example of a Transformability Network Structure.
 in-house? This concern is reasonable since the cost of g_1 plus transformation costs may eventually be higher than the cost of already-transformed goods.

The work in [1] addresses the possibility of expressing transformability relationships among the different assets to sell/buy on the bid-taker side in a multi-unit combinatorial reverse auction. The new type of combinatorial reverse auction (the Multi-Unit Combinatorial Reverse Auction with Transformability Relationships among Goods (MUCRAr)) provides to buying agents: (a) a language to express required goods along with the relationships that hold among them; and (b) a winner determination problem (WDP) solver that not only assesses what goods to buy and to whom, but also the transformations to apply to such goods in order to obtain the initially required ones. It is shown that, if the TNS representing the relationships among goods is acyclic, the associated WDP can be modeled by an integer linear program.

The purpose of this paper is twofold. On the one hand, we quantitatively assess the potential savings the auctioneer/buyer may obtain with respect to combinatorial reverse auctions that do not consider transformability relationships. On the other hand, we empirically identify the market conditions under which it is worth for the auctioneer/buyer to exploit transformability relationships. Thus, we provide rules of thumb for an auctioneer/buyer to help him decide when to run a MUCRAr instead of an MUCRA.

2 Empirical Evaluation

Our experiments artificially generate different data sets. Each data set shall be composed of: (1) a TNS; (2) a Request for Quotations (RFQ) detailing the number of required units per good; and (3) a set of combinatorial bids. Then, we solve the WDP for each auction problem regarding and disregarding t -relationships. This is done to quantitatively assess the potential savings that a buyer/auctioneer may obtain thanks to t -relationships, as well as the market conditions where such savings occur. Thus, the WDP for an MUCRA will only con-

¹ IIIA - CSIC, Campus UAB, 08193, Bellaterra, Spain, andrea@iiia.csic.es

² WAI, Dept. de Matemàtica Aplicada i Anàlisi, Universitat de Barcelona, cerquide@maia.ub.es

³ IIIA - CSIC, Campus UAB, 08193, Bellaterra, Spain, jar@iiia.csic.es

sider the last two components of the data set, whereas the WDP for a MUCRA will consider them all. In order to solve the WDP for an MUCRA we exploit its equivalence with the multi-dimensional knapsack problem [3].

2.1 Experimental Settings and Results

Our goal is to determine under which market conditions MUCRAr leads to savings when compared to MUCRA. At this aim, we empirically measure the differences in outcome cost between MUCRA and MUCRAr. Thus, we define the *Savings Index* (*SI*) as: $SI = 100 \cdot (1 - \frac{C^{MUCRAr}}{C^{MUCRA}})$; where C^{MUCRA} and C^{MUCRAr} are the costs associated to the optimal solutions found respectively by MUCRA and MUCRAr WDAs.

With the aim of assessing the most sensitive parameters with respect to *SI*, we employ a fractional factorial experiment design [4], assigning to each parameter different values.

We run 5756 instances of the experiments and for each run we sampled *SI*. In 150 cases (2.606%) the optimizer could not find an optimal solution within the time limit for MUCRA. In 289 cases (5.02%) the solver could not find an optimal solution within the time limit for MUCRAr. As explained above, the total number of samples that have been considered are $5756 - 150 = 5606$. Among these new samples, the optimizer could not find an optimal solution for MUCRAr for 191 (3.407%) tests.

We empirically observe that the savings of MUCRAr with respect to MUCRA go: (1) up to 44%; (2) beyond 3.29% in 50% of the cases; (3) beyond 8.59% in 30% of the cases. Next, we perform a sensitivity analysis in order to determine which parameters most affect an auction's outcome.

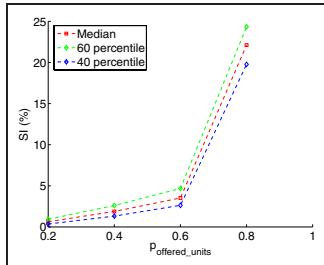

Figure 2. Variation of *SI* for different providers' capacities.

Sensitivity Analysis.

Figure 2 shows how the *SI* vary as the providers capacities increase. From it we can conclude that

C1: *The higher the providers' capacities, the higher the expected savings when introducing t-relationships.*

For this reason, when analysing the behavior of *SI* with respect to the remaining parameters, we will differentiate two cases: (1) $p_{offered_units} < 0.8$; and (2) $p_{offered_units} = 0.8$.

Figure 3 shows the variation of *SI* with respect to the number of required units. Our second conclusion is thus,

C2: *The finer the granularity of the transformations, the higher the expected savings when introducing t-relationships.*

The third factor significantly affecting *SI* is the relationship between the transformation costs of a buying agent with the providers' ones. Experimental results confirm that, as expected,

The behaviour of *SI* when changing the number of transformations within the TNS can be summarized by,

C4: *The more the number of transformations, the more the expected savings with respect to a MUCRA.*

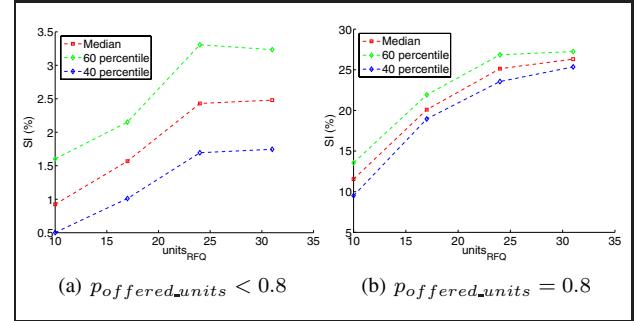

Figure 3. *SI* with respect to the number of required units.

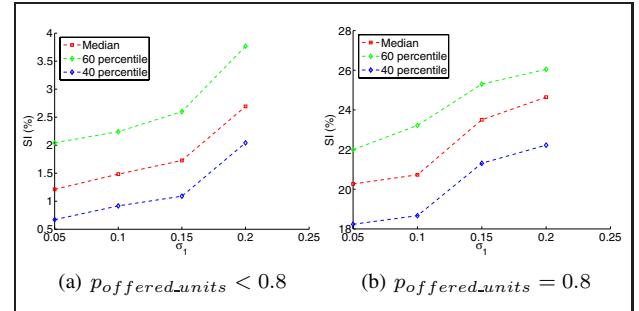

Figure 4. *SI* with respect to the variance of providers' prices.

Figure 4 shows the effect of varying the prices of goods among providers. The fifth conclusion follows:

C5: *The larger the market's prices spread, the higher the expected savings.*

To summarise, we can indeed confirm, based on the observation above, that there are market conditions (identified by **C1**, **C2**, **C3**, **C4**, and **C5**) wherein it is worth using MUCRAr instead of MUCRA.

3 Conclusions and Future Work

In this paper we have performed a set of experiments to quantitatively assess the potential savings in employing a MUCRAr instead of a MUCRA. Furthermore, we have also identified the market conditions for which MUCRAr is expected to lead to better auction outcomes to the auctioneer/buyer, namely: (1) markets with high-capacity providers; (2) auctions whose number of required units per good is large with respect to the units required by transformations (i.e. the likelihood of exploiting transformations is high); (3) auctions run by a buyer whose transformation (production) costs are cheaper than the providers' ones; and (4) markets where providers' competitiveness is not high (the more scattered the providers' competitiveness, the larger the expected savings).

Count-as Conditionals, Classification and Context

Guido Boella¹ and Leendert van der Torre²

Abstract. Searle represents constitutive norms as count-as conditionals, written as ‘ X counts as Y in context C ’. Grossi *et al.* study a class of these conditionals as ‘in context C , X is classified as Y ’. In this paper we propose a generalization of this relation among count-as conditionals, classification and context, by defining a class of count-as conditionals as ‘ X in context C_0 is classified as Y in context C ’. We show that if context C_0 can be different from context C , then we can represent a larger class of examples, and we have a weaker logic of count-as conditionals.

1 Count-as conditionals, classification and context

Searle [7] argues that there is a distinction between two types of rules.

“Some rules regulate antecedently existing forms of behaviour. For example, the rules of polite table behaviour regulate eating, but eating exists independently of these rules. Some rules, on the other hand, do not merely regulate an antecedently existing activity called playing chess; they, as it were, create the possibility of or define that activity. The activity of playing chess is constituted by action in accordance with these rules. The institutions of marriage, money, and promising are like the institutions of baseball and chess in that they are systems of such constitutive rules or conventions” ([7], p. 131).

For Searle, regulative and constitutive norms are related via institutional facts like marriage, money and private property. They emerge from an independent ontology of “brute” physical facts through constitutive rules of the form “such and such an X counts as Y in context C ” where X is any object satisfying certain conditions and Y is a label that qualifies X as being something of an entirely new sort. E.g., “ X counts as a presiding official in a wedding ceremony”, “this bit of paper counts as a five euro bill” and “this piece of land counts as somebody’s private property”. Regulative norms refer to these institutional facts. E.g., consider a society which believes that a field fenced by an agent counts as the fact that the field is the agent’s property. The fence is a physical “brute” fact, while being a property is an institutional fact. Regulative norms forbidding trespassing refer to the abstract concept of property rather than to fenced fields.

Grossi *et al.* [4] study the relation between on the one hand count-as conditionals and on the other hand classification and context. They formalize a class of count-as conditionals as contextual classifications, and thus do not claim that all count-as conditionals can be represented in this way. Roughly, as we understand it, their idea of classification is that X and Y are interpreted as sets (of facts, objects,

events, actions, etc) and that ‘ X is classified as Y ’, or ‘ X is-a Y ’ for short, is interpreted as ‘the set of interpretations of X is a subset of the set of interpretations of Y ’. Thus, classification is the is-a relation frequently studied in conceptual modeling, for example as a subsumption relation in type theory, or as a T-Box expression in description logics.

Moreover, Grossi *et al.* use modal logic to represent their count-as conditionals as contextual classifications. They represent X and Y as propositions, and the context as a modal operator (to be precise, as a particular kind of KD45 modality). Roughly, representing the classification relation as a material implication ‘ $X \rightarrow Y$ ’, they propose the following definition.

‘ X counts as Y in context C ’ is represented by $[C](X \rightarrow Y)$.

For example, consider a regulative norm stating that vehicles are forbidden in the park, and the constitutive norm ‘bicycles count as vehicles in the park’. This count-as conditional classifies bicycles as vehicles in the context of being in the park, and can be formalized as $[park](bicycles \rightarrow vehicles)$.

The logic of Grossi *et al.* turns out to be much stronger than other logics of count-as conditionals, such as the one of Jones and Sergot [5]. In Jones and Sergot’s study of count-as conditionals, the logic of count-as conditionals is very weak. It just satisfies replacements of logical equivalents, left disjunction and right conjunction. Moreover, they are inclined to accept transitivity. In addition, the logic of Grossi *et al.* satisfies, for example, reflexivity and contraposition.

We believe that there are two important advantages in representing count-as conditionals as contextual classifications. The first advantage is that it may help to better understand constitutive norms. Defining count-as conditionals as contextual classifications might lead to a more precise characterization of count-as conditionals – though it will not cover the whole class of count-as conditionals.

The second advantage of defining count-as conditionals as contextual classifications is that it may help us to understand how count-as conditionals are related to regulative norms like obligations and permissions, which is one of the main open questions in normative systems. Since regulative norms can be defined as classifications of behaviors in obligatory, permitted and unnormed ones, count-as conditionals as contextual classifications may explain this relation.

Given these two advantages, we are interested in generalizing the class of count-as conditionals that can be considered as contextual classifications. One reason to look for generalizations is that the formalization does not seem to take Searle’s distinction between brute and institutional facts into account. For example, since X are brute facts and Y are institutional facts, this distinction may suggest that X and Y themselves refer to distinct contexts. Another reason is that it does not seem straightforward to represent examples. For example, what is the context in “this bit of paper counts as a five euro bill” or in “this piece of land counts as somebody’s private property”?

2 Contexts as views

To generalize the notion of count-as conditionals as contextual classifications, we again make use of the terminology and methodology developed in conceptual modeling. As we already observed, classification is a central relation used in conceptual modeling. In software engineering, for example, the world (or a system) is modeled using various models of the Unified Modelling Language (UML) (class diagrams, sequence diagrams, *etc.*), and the is-a relation is used to define classification of concepts in class diagrams.

In this paper we use the notion of viewpoint and view to give an interpretation of context. A viewpoint is a particular way to look at the world [1]. For example, a structural viewpoint only describes the things staying the same over time, an action or process viewpoint describes the behavior over time, a brute viewpoint describes only brute facts, an institutional viewpoint describes only institutional facts, a power viewpoint describes the world in terms of powers of agents, a dependency viewpoint describes the world in terms of dependencies among actors, etc. Such a viewpoint is associated with a stakeholder having particular concerns; this aspect is not further discussed here. Each viewpoint gives a view on the system or the world.

There are two issues in conceptual modeling: defining each of these models or views, and defining the relations among them. In practice, it is the latter which is most problematic [3]. System descriptions often comprise many heterogeneous models and other descriptions, with ill-defined or completely lacking relations, inconsistencies, and a general lack of coherence and vision. UML for example does not define the relations among its models (nor does it define a semantics for its models).

In this interpretation, ' X counts as Y in context C ' is interpreted as ' X counts as Y in viewpoint C '. Our notion of context as view seems to be compatible with the framework of Grossi *et al.* In this interpretation, the conditional is interpreted as ' X is classified as Y in viewpoint C '. However, the count-as conditional can be used only to classify concepts within a single view, not to relate concepts in two or more views.

3 Count-as as relations among contexts or views

Generalizing the contextual classification to incorporate relations among contexts is straightforward. If we represent the classification relation again as a conditional ' $X \rightarrow Y$ ', then we propose the following definition.

' X in context C_0 counts as Y in context C ' is represented by
 $[C_0]X \rightarrow [C]Y$.

The following examples illustrate our definition. The third example illustrates how counts-as conditionals can be used to define properties of regulative norms too.

1. [brute](' p is a piece of paper') \rightarrow [institutional](' p is money'): This piece of paper p counts as money. The contexts or views are the physical world and social (institutional) reality, respectively.
2. [facts]('this is a piece of paper') \rightarrow [actions]('using the piece of paper for paying'): This piece of paper can be used to pay for things. The contexts or views are facts and actions, respectively.
3. [brute]('the occurrence of behavior p ') \rightarrow [deontic](' p is a violation'): Behavior p counts as a violation. The contexts or views are physical world and deontic reality, respectively.

The context or view C_0 often refers to the world of physical (observable) facts. As an abbreviation, we can thus use ' X counts as Y

in context C ' to mean that ' X in context 'brute facts' counts as Y in context C '. Moreover, as a first approximation of the relation between count-as conditionals, classification and context, we can use the following definition:

' X counts as Y in context C ' is represented by $(X \rightarrow [C]Y)$.

The advantage of this definition is that we can compare the logical properties among count-as conditionals of our proposal with the existing ones in the literature. In this case we end up with a weaker logic than the one proposed by Grossi *et al.*, since we no longer have reflexivity or contraposition. It is more in line with earlier proposals, such as the approach of Jones and Sergot.

4 Concluding remarks

Constitutive norms play an important role in normative systems like organizations and institutions, which have received much attention in artificial intelligence and multi-agent systems. According to Searle, the simple mechanism of count-as conditionals can explain the complexity of the construction of social reality. This aspect of constitutive norms does not get a satisfactorily explanation in Grossi *et al.*'s definition of count-as conditional as a contextual classification. It is hard to believe that all complex mechanisms found in social reality, can be explained by classifications only.

When count-as conditionals act also as bridges between contexts or views, then they can be used to define new contexts from existing ones. They can be used to relate for example observable brute facts and institutional facts, or observable and legal facts. This at least partly explains why constitutive norms play such an important role in the construction of social reality. However, there are still aspects of count-as conditionals which cannot be satisfactorily explained by our generalized contextual classifications. For example, as we have shown in [2], constitutive norms can also be used to formalize how normative systems like organizations can regulate their own evolution. How to incorporate this aspect is subject of further research.

Another subject of further research is the logical analysis of counts-as conditionals as contextual classifications. We do not have that X counts as X , the absence of this reflexivity property was suggested also by Jones and Sergot's analysis. We thus need a logical framework of conditionals that not necessarily satisfy this property, such as the framework of input/output logic [6].

Finally, a subject of further research is to examine relationships between concepts. For example, the context [facts] consists of the contexts [brute] and [institutional]. Existing logics of context may be useful here.

Fair Distribution of Collective Obligations

Guido Boella¹ and Leendert van der Torre²

Abstract. In social mechanism design, obligation distribution creates individual or contractual obligations that imply a collective obligation. A distinguishing feature from group planning is that also the sanction of the collective obligation has to be distributed, for example by creating sanctions for the individual or contractual obligations. In this paper we address fairness in obligation distribution for more or less powerful agents, in the sense that some agents can perform more or less actions than others. Based on this power to perform actions, we characterize a trade-off in negotiation power. On the one hand, more powerful agents may have a disadvantage during the negotiation, as they may be one of the few or even the only agent who can see to some of the actions that have to be performed to fulfill the collective obligation. On the other hand, powerful agents may have an advantage in some negotiation protocols, as they have a larger variety of proposals to choose from. Moreover, powerful agents have an advantage because they can choose from a larger set of possible coalitions. We present an ontology and measures to find a fair trade-off between these two forces in social mechanism design.

1 Ontology

Power may affect the distribution of obligation in various ways, and we therefore propose to analyze the obligation distribution problem in terms of social concepts like power and dependence. Power has been identified as a central concept for modeling social phenomena in multi-agent systems by various authors [5, 6, 8, 12], as Castelfranchi observes both to enrich agent theory and to develop experimental, conceptual and theoretical new instruments for the social sciences [6]. In most of these proposals, power is interpreted as the ability of agents to achieve goals. For example, in the so-called power view on multi-agent systems [2], a multi-agent system consists of a set of agents (A), a set of goals (G), a function that associates with each agent the goals the agent desires to achieve (*goals*), and a function that associates with each agent the sets of goals it can achieve (*power*). To be precise, to represent conflicts the function *goals* returns a set of set of goals for each set of agents. Such abstract structures have been studied as qualitative games by Wooldridge and Dunne [11].

To model the role of power in obligation distribution in normative multiagent systems, we associate with each norm the set of agents that has to fulfill it, and of each norm we represent how to fulfill it, and what happens when it is not fulfilled.

- First, we associate with each norm n a set of goals $O(n) \subseteq G$. Achieving these normative goals $O(n)$ means that the norm n has been fulfilled; not achieving these goals means that the norm is

violated. We assume that every normative goal can be achieved by the group, i.e., that the group has the power to achieve it.

- Second, we associate with each norm a set of goals $V(n)$ which will not be achieved if the norm is violated (i.e., when its goals are not achieved), this is the sanction associated to the norm. We assume that the sanction affects at least one goal of each agent of the group the obligation belongs to, and that the group of agents does not have the power to achieve these goals.

Definition 1 Let a normative multi-agent system be a tuple $\langle A, G, \text{goals}, \text{power}, N, OD, O, V \rangle$ where:

- the agents A , goals G and norms N are three finite disjoint sets;
- $\text{goals} : A \rightarrow 2^G$ is a function that associates with each agent the goals the agent desires;
- $\text{power} : 2^A \rightarrow 2^{2^G}$ is a function that associates with each set of agents the sets of goals the set of agents can achieve;
- $OD : N \rightarrow 2^A$ is a function that associates with every norm a set of agents that have to see to it that the norm is fulfilled.
- $O : N \rightarrow 2^G$ is a function that associates with each norm the goals which must be achieved to fulfill the norm; We assume for all $n \in N$ that there exists $H \in \text{power}(OD(n))$ with $O(n) \subseteq H$;
- $V : N \rightarrow 2^G$ is a function that associates with each norm the goals that will not be achieved if the norm is violated; We assume that for all $n \in N$ and $a \in OD(n)$ that $V(n) \cap \text{goals}(a) \neq \emptyset$, and for all $B \subseteq OD(n)$ and $H \in \text{power}(B)$ that $V(n) \cap H = \emptyset$.

2 Power of the people

Some studies of obligation distribution consider logical relations among collective and individual obligations [9]. Cholvy and Garion [7] claim that if there is a set of agents subject to an obligation to perform some task, then the derivation of individual obligations from collective obligations depends on several parameters, among which the ability of the agents. If an agent is the only one able to perform a part of that task, then it is obliged to do that part and it is also obliged to do that towards the other members of the set.

For example, they consider three children who are obliged by their mother to prepare the table for dinner. The oldest child is the only one who is tall enough to get the glasses on the cupboard. The whole group is responsible for the violation of the collective obligation, but in case the violation is due to the fact that the oldest boy did not bring the glasses, only he can be taken responsible by the group because he was the only one able to take the glasses.

This disadvantage of more powerful agents is measured for each agent a and norm n as the number of normative goals it has the power to achieve, each weighted by the number of other agents within the group that can achieve the same goal. $m_1(a, n) = 0$ if $a \notin OD(n)$, and otherwise:

$$\bullet m_1(a, n) = \sum_{g \in \text{power}(a) \cap O(n)} \frac{1}{|\{b \in OD(n) | g \in \text{power}(b)\}|}$$

3 Power of the king

An analysis based on power and dependence, as is common in social theory, suggests that the ability possessed by only one agent makes the remaining agents depend on him, since they lack the power to do part of the task they are obliged to. In this sense the oldest boy is in the best position, rather than having an additional burden and being sanctioned both for not respecting the collective obligation and his own obligation.

The dependence on more powerful agents can be made explicit when the negotiation process is made explicit. For example, the oldest boy has more power in the negotiation for the distribution of the task, and, by exercising this power, he may end up doing less than the other boys. An agreement is the result of a negotiation which has to take into account the dependence relations among the agents. E.g., the kids are first obliged to negotiate the distribution of the obligation, and then, only if they find a successful distribution of obligations, the oldest kid becomes obliged to see to the glasses. Note that in this negotiation model the distribution is not centralized, which is another reason why it is more complex than a planning problem.

In the negotiation protocol proposed in [4], each agent in turn makes a proposal of a complete distribution, which can be accepted or rejected by the other agents. Agents may not repeat their own proposal. If no proposal is accepted, then the norm will be violated. Roughly, when an agent can make many proposals, he has the advantage that he can propose deals which are beneficial to himself in all rounds. This models the intuition that an agent with more possible proposals has more power in the negotiation. This holds regardless of the penalty for breaking the negotiation.

For example, assume for a norm n that an agent $a \in OD(n)$ is allowed to propose a distribution $d(n) : OD(n) \rightarrow 2^{\text{power}(OD(n))}$ that associates with every agent some of the goals he has the power to achieve, such that the distribution implies all the goals of the norm $O(n) \subseteq \cup_{a \in OD(n)} d(n)(a)$ (note that here we assume that if a goal can be achieved by a set of agents, then it can be achieved by an individual agent). With $D(n)$ we refer to the set of all such $d(n)$. Moreover, assume that an agent cannot make two proposals in which itself is dealt the same goals. The measure of this example is the number of elements of $D(n)$ in which $d(n)(a)$ is distinct.

$$\bullet m_2(a, n) = |\{d(n)(a) \mid d(n) \in D(n)\}|$$

If the distributions that may be proposed have to satisfy other criteria, for example related to the distribution of the sanction [4], then the definition of d can be adapted accordingly.

4 Coalition power

Agents depend on more powerful agents not only to accomplish collective obligations, but also to fulfill their other desires. Thus, if we not only consider the collective obligation that has to be distributed but also the other desires of the agents, then powerful agents have an additional advantage in negotiation. For example, they may threaten to do something the other agents dislike, who therefore will accept an inferior solution.

A framework to study such dependencies is coalition formation. In contrast to the negotiation model in the previous section, coalition formation considers not only a single collective obligation to be distributed, but many of them. Such a setting is given in our definition of normative multi-agent system in Definition 1. A way to calculate the possible coalitions from a power view on normative multi-agent systems is given in [1, 3]. In that paper, a coalition is only considered

in a power structure if each agent contributes and receives something in a coalition (called do-ut des).

$$\bullet m_3(a) = |\text{coalitions}(a)|$$

Of the three measures proposed in this paper, this third measure is the most abstract. It is tempting to make it more precise by quantifying over the goals of the norms the agent is involved in. However, the impact of the dependencies in coalition formation on obligation distribution has not been studied in any detail thus far, and therefore we have chosen this more general measure. Consequently, it can only be taken as an indication of the impact on obligation distribution.

5 Concluding remarks

In some social mechanisms the agents with more power will end up doing more, but in other ones they will end up doing less. In the extreme case, a very powerful agent might do nothing at all - or the distribution is not made at all. The measures discussed in this paper can be used to enforce fairness in the distribution of agents. Another solution is to build a normative system that ensures a fair distribution. In this approach, there are norms that, for example, indicate the number of deals an agent can propose.

Most multi-agent system models concerned with complex cognitive tasks like obligation creation, negotiation and distribution [4, 7, 9, 10] are based on relatively detailed cognitive models incorporating, for example, beliefs, obligations, desires, intentions, goals, preferences, and so on. Some of these elements can be used to make the measures more precise. For example, another advantage may have more reliable knowledge about the goals and abilities of other agents. If we extend the model with such beliefs of agents about the power and goals of other agents, then this advantage can be measured too.

Proactive Identification of a Physician's Information Needs¹

Loes M.M. Braun² and Floris Wiesman³ and H. Jaap van den Herik² and Arie Hasman³

1 INTRODUCTION

Information retrieval (IR) in the medical domain has proven to be vital to the quality of care [3]. However, physicians often lack the time and skills to formulate adequate information needs and in some situations physicians are even not aware of their information needs [2]. We define an *information need* as an expression of missing information needed to perform a particular task – in this case treating a patient. An example of an information need is *Does Clarithromycin cause pancreatitis?*

Our goal is to investigate to which extent an agent can support a physician in formulating his⁴ information needs, without requiring any effort from the physician. Therefore, we have developed and implemented an intelligent agent that identifies patient-related information needs automatically and proactively. Based on these information needs, the agent can retrieve relevant, patient-related literature.

For this purpose, we have modelled general information needs into information-need templates [1]. We consider an *information-need template* to be an abstract, natural-language representation of an information need. For instance, the information-need template corresponding to the information need *Does Clarithromycin cause pancreatitis?* is *Does [Chemical] cause [Disease or Syndrome]?* An information-need template contains data slots that can be filled with medical concepts.

Our agent transforms information-need templates into patient-related information needs by instantiating the data slots in the templates with data from the electronic patient record (EPR) of a specific patient [1]. The resulting information needs are used to initiate search actions in medical literature databases without requiring any effort of the physician.

Experiments indicate that the number of information needs formulated by our agent is too high for adequate use [1]. Such a high number of information needs will lead to a *literature overload* of the physician, i.e., the retrieval of an unmanageable amount of literature. Therefore, our agent should be improved, i.e., the number of formulated information needs should be reduced. That is the topic of this two-pager.

2 REDUCING INFORMATION NEEDS

One way to reduce the number of information needs is by employing additional knowledge. We focus on six types of knowledge that

¹ This research is funded by the Netherlands Organisation for Scientific Research (grant number 634.000.021).

³ AMC, University of Amsterdam, email: {f.j.wiesman; a.hasman}@amc.uva.nl

⁴ For brevity we will use the pronoun he (his) where he or she (his or her) is meant.

might be used by our agent, viz. (a) entry time, (b) entry order, (c) domain knowledge, (d) specialism, (e) user model, and (f) formulation history.

Entry time. The entry time represents the time at which data are entered into the EPR. Our agent may use knowledge of this type to determine the relevance of specific data entries. If data are entered outside a certain time interval, they might be considered irrelevant and can be discarded during the formulation of information needs.

Entry order. The entry order represents the order in which data are entered into the EPR. Our agent can use this type of knowledge to detect nonsensical information needs. The entry order is particularly applicable to information-need templates containing data slots that are temporally dependent.

Domain knowledge. Many hospitals use alert systems that automatically forewarn physicians about potentially harmful actions. The alerts issued by an alert system fulfil some of the physician's information needs. Therefore, our agent should discard these information needs. To determine which information needs should be discarded, our agent has to predict the alerts by using the domain knowledge employed by the alert system.

Specialism. In a multidisciplinary hospital department, a physician's information needs are probably closely connected to his specialism. Consequently, our agent might discard information needs if they are not connected to the physician's specialism.

User model. By employing a user model, the information preferences of a physician are recorded, actively or passively. When preferences are recorded actively, the physician indicates what information he prefers. When preferences are recorded passively, the system monitors the use of the system by the physician and infers the physician's preferences from the recorded data. Since a physician's preferences may change over time, the information model can be adapted at any given moment.

Formulation history. A physician's formulation history represents the information needs that have been formulated previously. This knowledge can be used to prevent the agent from formulating information needs repeatedly. Information needs that have been formulated for a physician should not be formulated anew for that physician within a certain time frame.

The usefulness of each of the knowledge types presented above depends heavily on the specific cause underlying the excess of information needs. To determine the nature of this cause, we performed an experimental analysis of the information needs formulated. The results of the analysis provide directions for determining which knowledge type is most appropriate for our purpose.

In the experiment, we simulated the formulation of information needs based on patient data in the field of intensive care medicine.

The patient data concerned 82 patients and were entered by 31 physicians over six months of time. The patient data included data entries of four different types, viz. (a) disease or syndrome, (b) diagnostic procedure, (c) therapeutic or preventive procedure, and (d) chemical. We confined the analysis to these types, since they represent the majority of the data entries in the EPRs. The information-need templates used concerned three subjects, viz. (a) prognosis, (b) therapy (including prevention), and (c) side effects (including etiology).

The results of our experiment indicated that five of the information-need templates (see table 1) generated many more information needs than the other templates. From our analysis of these five templates we may conclude that the large number of information needs can only be explained by the large amount of patient data available. Consequently, reducing the number of data entries that are used to instantiate information-need templates seems the best way to reduce the number of information needs formulated.

Based on the observations above, we have ordered the six knowledge types according to their ability to reduce the number of patient data (see conclusions).

3 EXPERIMENTS AND RESULTS

To determine the actual performance of the knowledge types presented in section 2, we conducted an experiment. We limited the scope of the experiment in two respects: (a) we focused on the two knowledge types that are most appropriate according to our analysis (section 2): formulation history and entry order, and (b) we focused on the five information-need templates generating the majority of information needs (table 1).

To determine the performance of the knowledge types we let our agent formulate information needs in four different settings: (i) using no additional knowledge, (ii) using only the formulation history, (iii) using only the entry order, and (iv) using both knowledge types simultaneously.

Figure 1 shows the results of our experiment. With respect to figure 1, three observations can be made.

First, regarding the formulation history, we observe that for all five templates, the use of formulation history results in a reduction. The largest reduction (75%) occurs in template (c). Furthermore, for four of the templates (a, c, d, and e) the use of the formulation history realizes a larger (or equal) reduction than the use of the entry order, as was expected (see section 2).

Second, with respect to the entry order, we observe that for four of the templates (a, b, c, and d) the use of the entry order results in a reduction. The largest reduction (75%) occurs in template (c). For template (e) the use of the entry order does not result in a reduction. For template (b), the use of the entry order results in a larger reduc-

Table 1. Information-need templates generating most information needs.

- (a) Can [Chemical] be used as a prophylaxis against [Disease or Syndrome] in a patient with [Disease or Syndrome] and no clinical risk factors for [Disease or Syndrome]?
- (b) Give a description of the advantages and disadvantages of [Health Care Activity] in relation to [Health Care Activity] in case of [Finding]/[Disease or Syndrome].
- (c) How can [Health Care Activity] be used on the evaluation of [Health Care Activity]?
- (d) How does [Health Care Activity] compare with [Health Care Activity] in the setting of [Sign or Symptom]/[Pathologic Function]?
- (e) What is the interaction of [Chemical] with [Chemical]?

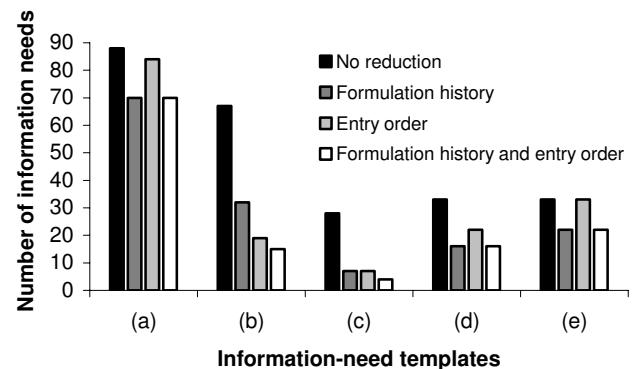

Figure 1. Number of information needs formulated from five information-need templates, using various knowledge types.

tion than the use of the formulation history. Furthermore, for all five templates, the use of the entry order results in a smaller reduction than the use of both knowledge types simultaneously.

Third, regarding the use of both knowledge types simultaneously, we observe that for two templates (b) and (c) the combination of both knowledge types realizes a greater reduction than the use of each knowledge type separately. The largest reduction (85.7%) occurs in template (c). For the remaining three templates, the reduction resulting from the combination of both knowledge types is equal to the reduction resulting from the use of the formulation history only.

4 CONCLUSIONS

In this paper we presented six types of knowledge that may be used to reduce the number of information needs formulated by our agent. Furthermore, we ordered the knowledge types according to their usefulness in the field of intensive care medicine and assessed the performance of the two most-promising knowledge types. With respect to these investigations we arrived at three conclusions.

First, we may conclude that the large number of information needs formulated is mainly due to the large number of data entries used to instantiate information-need templates.

Second, we tentatively conclude that the knowledge types can be ordered according to their appropriateness as follows: (1) formulation history, (2) entry order, (3) specialism, (4) domain knowledge, (5) entry time, and (6) user model.

Third, we provisionally conclude that for four of the templates in table 1, the use of the formulation history results in a reduction larger than or equal to the use of the entry order, as was expected.

Finally, we remark that for two of the templates in table 1, combining the formulation history and the entry order has a positive effect.

Acyclic Argumentation: Attack = Conflict + Preference

Souhila Kaci¹ and Leendert van der Torre² and Emil Weydert²

Abstract. In this paper we study the fragment of Dung's argumentation theory in which the strict attack relation is acyclic. We show that every attack relation satisfying a particular property can be represented by a symmetric conflict relation and a transitive preference relation in the following way. We define an instance of Dung's abstract argumentation theory, in which 'argument A attacks argument B' is defined as 'argument A conflicts with argument B' and 'argument A is at least as preferred as argument B', where the conflict relation is symmetric and the preference relation is transitive. We show that this new preference-based argumentation theory characterizes the acyclic strict attack relation, in the sense that every attack relation defined as such a combination satisfies the property, and for every attack relation satisfying the property we can find a symmetric conflict relation and a transitive preference relation satisfying the equation.

1 Acyclic argumentation framework

Argumentation is a reasoning model based on constructing arguments, determining potential conflicts between arguments and determining acceptable arguments. Dung's framework [7] is based on a binary attack relation among arguments. We restrict ourselves to *finite* argumentation frameworks, i.e., when the set of arguments \mathcal{A} is *finite*.

Definition 1 (Argumentation framework) An argumentation framework is a tuple $\langle \mathcal{A}, \mathcal{R} \rangle$ where \mathcal{A} is a set of arguments and \mathcal{R} is a binary attack relation defined on $\mathcal{A} \times \mathcal{A}$.

An acyclic argumentation framework is an argumentation framework in which the attack relation is acyclic, a symmetric argumentation framework is an argumentation framework in which the attack relation is symmetric, etc. In this paper we define an acyclic strict attack relation as follows. Assume the attack relation is such that there is an attack path where argument A_1 attacks argument A_2 , argument A_2 attacks argument A_3 , etc, and argument A_n attacks argument A_1 , then we have that all the arguments in the attack path attack the previous one. Consequently, if argument A strictly attacks B if A attacks B and not vice versa, then the strict attack relation is acyclic.

Definition 2 (Acyclic argumentation framework) A strictly acyclic argumentation framework is an argumentation framework $\langle \mathcal{A}, \mathcal{R} \rangle$ in which the attack relation $\mathcal{R} \subseteq \mathcal{A} \times \mathcal{A}$ satisfies the following property:

If there is a set of attacks $A_1 \mathcal{R} A_2, A_2 \mathcal{R} A_3, \dots, A_n \mathcal{R} A_1$ then we have that $A_2 \mathcal{R} A_1, A_3 \mathcal{R} A_2, \dots, A_1 \mathcal{R} A_n$.

The semantics of Dung's argumentation framework are based on the two notions of defence and conflict free.

¹ C.R.I.L., Rue de l'Université SP 16 62307, Lens, France.

² Department of Computer Science, University of Luxembourg, Luxembourg.

Definition 3 (Defence) A set of arguments \mathcal{S} defends A iff for each argument B of \mathcal{A} which attacks A , there is an argument C in \mathcal{S} which attacks B .

Definition 4 (Conflict-free) Let $\mathcal{S} \subseteq \mathcal{A}$. The set \mathcal{S} is conflict-free iff there are no $A, B \in \mathcal{S}$ such that $A \mathcal{R} B$.

The following definition summarizes various semantics of acceptable arguments proposed in the literature. The output of the argumentation framework is derived from the set of selected acceptable arguments with respect to an acceptability semantics.

Definition 5 (Acceptability semantics) Let $\mathcal{S} \subseteq \mathcal{A}$.

- \mathcal{S} is admissible iff it is conflict-free and defends all its elements.
- A conflict-free \mathcal{S} is a complete extension iff we have $\mathcal{S} = \{A \mid \mathcal{S} \text{ defends } A\}$.
- \mathcal{S} is a grounded extension iff it is the smallest (for set inclusion) complete extension.
- \mathcal{S} is a preferred extension iff it is a maximal (for set inclusion) complete extension.
- \mathcal{S} is a stable extension iff it is a preferred extension that attacks all arguments in $\mathcal{A} \setminus \mathcal{S}$.

For the general case, in which the attack relation can be any relation, many properties and relations among these semantics have been studied. However, of instances of Dung's argumentation framework, not much is known (with the exception of symmetric argumentation frameworks, see [6]). In this paper we consider acyclic argumentation.

2 Conflict+preference argumentation framework

Consider an argumentation theory in which each argument is represented by a propositional formula, and 'argument A attacks argument B' is defined as ' $A \wedge B$ is inconsistent'. Unfortunately, such a simple argumentation theory is not very useful, since the attack relation is symmetric, and the various semantics reduce to, roughly, one of the following two statements: 'an argument is acceptable iff it is part of all/some maximal consistent subsets of the set of arguments.' However, such a simple argumentation theory is useful again when we add the additional condition that argument A is at least as preferred as argument B. We start with some definitions concerning preferences.

Definition 6 A pre-order on a set \mathcal{A} , denoted \succeq , is a reflexive and transitive relation. \succeq is total if it is complete and it is partial if it is not. The notation $A_1 \succeq A_2$ stands for A_1 is at least as preferred as A_2 . \succ denotes the order associated with \succeq . $A_1 \succ A_2$ means that we have $A_1 \succeq A_2$ without $A_2 \succeq A_1$.

The new preference-based argumentation framework considers a conflict and a preference relation. The conflict relation should not be interpreted as an attack relation, since a conflict relation is symmetric, and an attack relation is usually asymmetric.

Definition 7 (Conflict+preference argumentation framework) A conflict+preference argumentation framework is a triplet $\langle \mathcal{A}, \mathcal{C}, \succeq \rangle$ where \mathcal{A} is a set of arguments, \mathcal{C} is a binary symmetric conflict relation defined on $\mathcal{A} \times \mathcal{A}$ and \succeq is a (total or partial) pre-order (preference relation) defined on $\mathcal{A} \times \mathcal{A}$.

Starting with a set of arguments, a symmetric conflict relation, and a preference relation, we combine this conflict relation with preference relation to compute Dung's attack relation. Then we use any of Dung's semantics to define the acceptable set of arguments. In contrast to most other approaches [1, 8] (but see [2, 3] for exceptions), our approach to reason about preferences in argumentation does not refer to the internal structure of the arguments.

Definition 8 Let $\langle \mathcal{A}, \mathcal{R} \rangle$ be an argumentation framework and $\langle \mathcal{A}, \mathcal{C}, \succeq \rangle$ a conflict+preference argumentation framework. We say that $\langle \mathcal{A}, \mathcal{C}, \succeq \rangle$ represents $\langle \mathcal{A}, \mathcal{R} \rangle$ iff for all arguments A and B of \mathcal{A} , we have $A \mathcal{R} B$ iff $A \mathcal{C} B$ and $A \succeq B$. We also say that \mathcal{R} is represented by \mathcal{C} and \succeq .

Since the attack relation is defined on the basis of conflict \mathcal{C} and preference relation \succeq , also the other relations defined by Dung are reused by the conflict+preference argumentation framework. For example, to compute the grounded semantics of the conflict+preference framework, first compute the attack relation, and then compute the grounded semantics as in the general case.

3 Acyclic attack = conflict + preference

To prove that acyclic attacks are characterized by conflicts and preferences, we have to show that the implication holds in both ways. We first show that the implication from right to left holds, which is the easiest direction.

Lemma 1 If the conflict+preference argumentation framework $\langle \mathcal{A}, \mathcal{C}, \succeq \rangle$ represents the argumentation framework $\langle \mathcal{A}, \mathcal{R} \rangle$, then $\langle \mathcal{A}, \mathcal{R} \rangle$ is a strictly acyclic argumentation framework (in the sense of Definition 2).

Proof. Assume a set of attacks $A_1 \mathcal{R} A_2, A_2 \mathcal{R} A_3, \dots, A_{n-1} \mathcal{R} A_n, A_n \mathcal{R} A_1$. Since $\langle \mathcal{A}, \mathcal{C}, \succeq \rangle$ represents $\langle \mathcal{A}, \mathcal{R} \rangle$, we have also $A_i \mathcal{C} A_{(i \bmod n)+1}$ and $A_i \succeq A_{(i \bmod n)+1}$. Due to symmetry of \mathcal{C} , we also have $A_{(i \bmod n)+1} \mathcal{C} A_i$. Moreover, due to transitivity of \succeq , we have $A_{(i \bmod n)+1} \succeq A_i$ for $1 \leq i \leq n$. Consequently we have $A_{(i \bmod n)+1} \mathcal{R} A_i$, and thus $\langle \mathcal{A}, \mathcal{R} \rangle$ is strictly acyclic.

Now we show that the implication from left to right holds. We prove this lemma by construction: given an acyclic argumentation framework, we construct a conflict+preference framework representing it.

Lemma 2 If $\langle \mathcal{A}, \mathcal{R} \rangle$ is a strictly acyclic argumentation framework, then there is a conflict+preference argumentation framework $\langle \mathcal{A}, \mathcal{C}, \succeq \rangle$ that represents it.

Proof. Let $\langle \mathcal{A}, \mathcal{R} \rangle$ be a strictly acyclic argumentation framework. Moreover, consider a conflict+preference argumentation framework $\langle \mathcal{A}, \mathcal{C}, \succeq \rangle$ defined as follows:

- $\mathcal{C} = \{(a, b) \mid (a, b) \in \mathcal{R} \text{ or } (b, a) \in \mathcal{R}\}$ is the symmetric closure of \mathcal{R}
- \succeq is the transitive and reflexive closure of \mathcal{R}

$\mathcal{R} \subseteq \mathcal{C} \cap \succeq$ by construction. The other direction we prove by contradiction, so assume ACB and $A \succeq B$ without ARB . Since ACB we have also BCA (since \mathcal{C} is symmetric) and we must have BRA (due to ACB and BCA we have either ARB or BRA). Since $A \succeq B$ we must have either $A = B$ (added by reflexive closure) or there is an attack path from A to B (added by transitivity). In both cases we obtain a contradiction:

1. If $A = B$ then BRA without ARB is directly a contradiction.
2. If there is a path from A to B , then together with BRA there is a cycle, and due to the acyclicity property we have ARB , which contradicts the assumption.

Summarizing, strictly acyclic argumentation frameworks are characterized by conflict+preference argumentation frameworks.

Theorem 1 $\langle \mathcal{A}, \mathcal{R} \rangle$ is a strictly acyclic argumentation framework if and only if there is a conflict+preference argumentation framework $\langle \mathcal{A}, \mathcal{C}, \succeq \rangle$ that represents it.

4 Concluding remarks

The preference-based argumentation theory introduced in this paper is a variant of the preference based framework of Amgoud and Cayrol [1], who define that argument A attacks argument B if A defeats B and B is not preferred to A . Note that our representation theorem does not hold for such a definition. As far as we know it is an open problem which properties the attack relation satisfies (if the defeat relation is symmetric).

Another subject for further research is how to use the strictly acyclic or conflict+preference frameworks. It may also be worthwhile to consider the generalizations of Dung's framework in propositional argumentation [4, 5].

Finally, a subject for further study is the complexity of the argumentation frameworks discussed in this paper. Is the computation of acceptable arguments in some sense easier or more efficient for strictly acyclic argumentation frameworks? Also, can we find more efficient or anytime algorithms for these frameworks?

Semantic Knowledge Model and Architecture for Agents in Discrete Environments

Michal Laclavik and Marian Babik and Zoltan Balogh and Emil Gatial and Ladislav Hluchy¹

1 Introduction

Multi-Agent Systems (MAS) is a powerful paradigm for distributed heterogeneous information systems when representation and reasoning using knowledge is needed. According to the Agent Technology Roadmap [3], which is the result of AgentLink, there are a number of broad technological challenges for research and development over the next decade in the agent technology. Within the presented work we are trying to partially cover some of them. These are:

- Providing better semantic infrastructure
- Apply basic principles of software and knowledge engineering
- Make stronger connection with existing commercial technologies

In the MAS, knowledge is usually represented by states, rules or predicate logic [12] [2]. Although this is extremely powerful, it is hard to capture knowledge from a person or from current information systems in the form of states or predicate logic clauses. Moreover, another difficulty is to present information and knowledge expressed in e.g. predicate logic to the end user [8]. Ontology as understood in the Semantic Web is closer to current information systems. It is based on XML/RDF [9], which can be more easily captured or returned from/to a person and existing information systems because information systems usually have XML based interfaces and XML can be easier presented to user after XSL transformations [10].

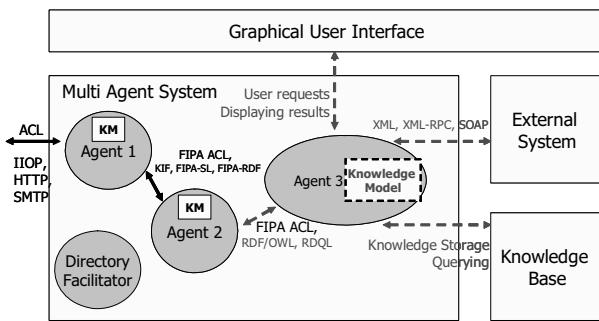

Figure 1. Missing features of FIPA compliant agent architecture

The current MAS platforms follows FIPA [12] standards. FIPA [12] describes the knowledge model based on ontology, but leaves internal agent memory model, its manipulation and understanding of design of agent on developer's decisions. In addition FIPA defines a

¹ Institute of Informatics, Slovak Academy of Sciences, Dubravská cesta 9, 845 07 Bratislava, Slovakia, email: laclavik.ui@savba.sk

knowledge manipulation based on content languages such as FIPA-SL [12], FIPA-KIF, which are powerful but lack any interconnection with commercial tools and standards. JADE agent system for example supports FIPA-SL language for message passing, but no FIPA-SL query engine or repository of such knowledge model is available. This is why we see ontology description from the semantic web area (RDF/OWL [9]) more appropriate for real application. Therefore we have decided to integrate semantic web technologies into MAS and create architecture, methodology and software for such integration. In addition, we have developed a generic ontology suitable for representing an agent knowledge model suitable for discrete environment. This model can be further extended, thus enabling its use in many areas especially for the knowledge and experience management [14], [6], [8].

2 Agent Knowledge Model

Most of the agent architectures are combinations of basic architecture types - the so called hybrid architectures. We focused on behavioral architecture, where an agent memory model used for behaviors implementations was created within this work. Proposed Knowledge Model is generic and suitable for applications with discrete, fully observable environments where environment changes can be captured by events.

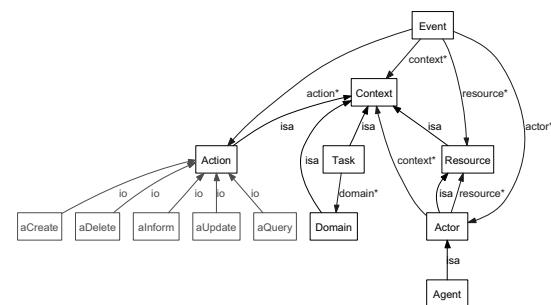

Figure 2. Basic Ontology for Knowledge Modeling

Our model is based on five main elements: Resources, Actions, Actors, Contexts and Events. Figure 2 shows formal graph representation of a model. The proposed model is described also using Description Logic [7] compatible with OWL-DL [9]. In proposed model we expect that all agents share same ontology.

Here we describe only the *Actor* class using Description Logic, which consists of important properties: *context.Actor*, *resource.Actor*.

$$\begin{aligned} Actor \subseteq \\ resource.Actor(\{resource\}) \cap \\ context.Actor(\{actor\}) \cap \\ Resource \end{aligned} \quad (1)$$

The *context.Actor* represents actor's current context. The system or application environment is based on stored events. The events model the environment state. Current state of the environment or actor related environment/context is thus affected by relevant new events.

$$\begin{aligned} context.Actor(\{actor\}) = \\ f_C(\forall event; actor.Event(\{actor\}) \in \{event\}) \end{aligned} \quad (2)$$

The *resource.Actor* property stands for all current resources of the actor. These resources are results of actors' intentions or objectives. Such resources are dependable on current actors' environment state/context (*context.Actor*).

$$\begin{aligned} resource.Actor(resource) = \\ f_R(contextActor(\{actor\})) \end{aligned} \quad (3)$$

Functions/algorithms for context and resource updating are specified by (2) and (3). An advantage of such model is that it enables achievement of better results when such algorithms are changed in the future, using the same model and data. Due to storing all events we can model the environment at any moment from past and process it later from any starting point with improved algorithms for context and resource updating. In addition, this model can be successfully used outside the MAS [6]. It can be used in the knowledge intensive application, where we need to model actors and their knowledge model. Often this is the case when we need to model users of the system who are mostly main actors in any application.

3 Modeling and Development Methodology for Agent Design

The developed methodology follows CommonKADS methodology [4]. However CommonKADS is not tied with any modeling tool, knowledge representation or ontologies, we represent knowledge based on the OWL ontology and we model it in the Protégé ontology editor similar as in [4]. Design of the system is based on UML, AUML and MAScommonKADS. When using this methodology, good results can be archived only after several iterations of the process and remodeling after the first developing, use and evaluation of the first system version. Modeling a knowledge model for an application we follow first three CommonKADS models: Organizational or in our case the Environment Model; the Task Model; the Agent or the Actor Model. Modeling the knowledge model we have to extend the generic agent model (Figure 2) with new elements and relations. Results of models is the knowledge model which consists of :

- Ontology developed in Protégé in the OWL format.
- Algorithms for each agent (actor) updating actors' context f_C (2) and resources f_R (3). Often such algorithms are similar or the same for all actors.

The design methodology of a system is based on three UML diagram types in a similar way as known in object oriented programming: Use Case Diagram; Sequence Diagram; Class Diagram.

4 Design and Specification of Agent Software Library

The developed library is based on the JADE agent system [1] and the Jena [13]. It covers functionalities which we identified as missing in current agent architectures such as JADE, the Agent Knowledge Model based on RDF/OWL; Action resource as basics for communication and incorporated in the OWL ontology; Sending ACL based RDF/OWL messages; Receiving ACL based RDF/OWL messages; Incorporation of received information into a model; XMLRPC receiving messages; XMLRPC returning RDF and XML; An inference or RDQL messages handling. The JADE based agent can be developed using this library to support the Jena OWL model as the Agent memory and furthermore it is possible to include XML-RPC based functionalities for presenting knowledge or receiving events from external systems as RDF messages based on a used ontology. Moreover it allows communication among agents based on RDF/OWL.

The developed library is published on the JADE website as the 3rd party software [5] as a way to put together Jena RDF/OWL and JADE Multi-agent system features. The developed library is quite popular and in year 2005 was downloaded 577 times.

5 CONCLUSION

The paper describes how semantic web technologies can be applied in MAS. An agent knowledge model was created enabling the possibility to model the agent environment, agent context and its results. The agent library to support such an agent knowledge model was developed and extends the JADE agent system, which is currently the most popular MAS toolkit. It was proved that such model and the agent architecture are implementable and can be used in different knowledge intensive applications [6], [8] in discrete environments, which was tested in several R&D projects, mainly in the Pellucid IST project. More details with demonstration examples can be found in [8] or on library website [5].

Partial Local FriendQ Multiagent Learning: Application to Team Automobile Coordination Problem¹

Julien Laumonier and Brahim Chaib-draa²

1 Introduction

In real world cooperative multiagent problems, each agent has often a partial view of the environment. If communication has a cost, the multiagent system designer has to find a compromise between increasing the observability and total cost of the multiagent system. To choose a compromise, we propose, to take into account the degree of observability, defined as the agent's vision distance, for a cooperative multiagent system by measuring the performance of the associated learned policy. Obviously, decreasing observability reduces the number of accessible states for agents and therefore decreases the performance of the policy. We restrict our application to team game, a subclass of coordination problems where all agents have the same utility function. We consider problems where agents' designer does not know the model of the world. Thus, we can use learning algorithms which have been proven to converge to Pareto-optimal equilibrium such as Friend Q-learning [4]. One can take an optimal algorithm to find the policy for the observable problem. The following assumptions are defined: (1) Mutually exclusive observations, each agent sees a partial view of the real state but all agents together see the real state. (2) Possible communication between agents but not considered as an explicit part of the decision making. (3) Only negative interactions between agents. One problem which meets these assumptions is the choosing lane decision problem related to Intelligent Transportation Systems which aims to reduce congestion, pollution, stress and increase safety of the traffic.

2 Formal Model and Algorithms

Reinforcement learning allows an agent to learn by interacting with its environment. For a mono agent system, the basic formal model for reinforcement learning is a Markov decision process. Using this model, Q-Learning algorithm calculates the optimal values of the expected reward for the agent in a state s if the action a is executed. On the other hand, game theory studies formally the interactions of rational agents. In a one-stage game, each agent has to choose an action to maximize its own utility which depends on the others' actions. In game theory, the main solution concept is the Nash equilibrium which is the best response for all agents. A solution is Pareto optimal if there does not exist any other solution such that one agent can improve its reward without decreasing the reward of another. The model which combines reinforcement learning and game theory, is

Markov games. This model contains a set of agents Ag , a finite set of states S , a finite set of actions A , a transition function \mathcal{P} , an immediate reward function \mathcal{R} . Among the algorithms which calculate a policy for team Markov games, Friend Q-Learning algorithm, introduced by Littman [4], allows to build a policy which is a Nash Pareto optimal equilibrium in team games. More specifically, this algorithm, based on Q-Learning, uses the following function for updating the Q-values: $Q(s, \vec{a}) = (1 - \alpha)Q(s, \vec{a}) + \alpha[r + \gamma \max_{\vec{a} \in \vec{A}} Q(s', \vec{a})]$ with \vec{a} , the joint action for all agents.

3 Problem Description

The vehicle coordination problem presented here is adapted from Moriarty and Langley [5]. More precisely, three vehicles have to coordinate to maintain velocity and to avoid collisions. Each vehicle is represented by a position and a velocity and can change lane to the left, to the right or stay on the same lane. The objective for a learning algorithm is to find the best policy for each agent in order to maximize the common reward which is the average velocity at each turn and to avoid collision. The dynamic, the state and the actions are sampled in the simplest way. For this example, we simulate the road as a ring meaning that a vehicle is placed on the left side when it quits through the right side. Collisions occur when two agents are in the same case. At each step, a vehicle can choose three actions: stay on the same lane, change to the right lane and change to the left lane. We assume, in this problem, that each agent is able to see only his local state and other's states with communication.

4 Partial Observability

To measure the effect of partial observability on the performance we define the partial state centered on one agent by introducing a distance of observability d . The initial problem becomes a d -partial problem. The distance d can be viewed as an influence area for the agent. Increasing this distance increases the degree of observability. We define d_{total} as the maximal possible distance of observability for a given problem. In d -partial problem, the new state is defined as the observation of the center agent for a range d . More precisely, an agent j is in the partial state of a central agent i if its distance is lower or equal than d from i . The function $f_d^i(s)$ uses the parameter d to calculate the new local state. The partial local view can reduce the set of state and/or the set of joint actions. The new size of the set of state is set from $O((X \times Y \times |V|)^N)$ with X the number of lane, Y the length of the road, V the set of possible velocity and N the number of agents to $O(((2d + 1)^2 \times V)^N)$. The number of states is divided by around $(Y/(2d + 1))^N$. The Partial Joint Action (PJA) algorithm takes into account only the actions of agents that are in the partial local view as specified by d . This reduces dramatically

¹ This research is funded by the AUTO21 Network of Centers of Excellence, an automotive research and development program focusing on issues relating to the automobile in the 21st century. AUTO21 is a member of the Networks of Centers of Excellence of Canada program.

² DAMAS Laboratory, Department of Computer Science and Software Engineering, Laval University, Canada {jlaumoni;chaib}@damas.ift.ulaval.ca

the number of joint actions which has to be tested during the learning. This partial local observability allow us to consider a variable number of agents in the multiagent system. Formally, we define a function g^i which transforms the joint action \vec{a} into a partial joint action $g_d^i(\vec{a}, s)$. This partial joint action contains all actions of agent which are in the distance d of agent i . The PJA Q-value update function is :

$$\begin{aligned} Q(f_d^i(s), g_d^i(\vec{a}, s)) &= (1 - \alpha)Q(f_d^i(s), g_d^i(\vec{a}, s)) \\ &\quad + \alpha[r + \gamma \max_{\vec{a}_d \in G_d^i(\vec{A}, S)} Q(f_d^i(s'), \vec{a}_d)] \end{aligned}$$

5 Results

We compare empirically the performance of the totally observable problem (FriendQ) and the performance of approximated policy (PJA) on a small problem defined by size $X = 3, Y = 7$ with 3 agents. Figure 1 shows that for $d = 0 \dots 2$, PJA converges to a local maximum, which increases with d . In these cases, the approximated values are respectively about 76%, 86% and 97% from the optimal value given by Friend Q-Learning. When $d = 3$, that is, when the local view is equivalent to the totally observable view, the average sum rewards converges to the total sum rewards of Friend Q-learning.

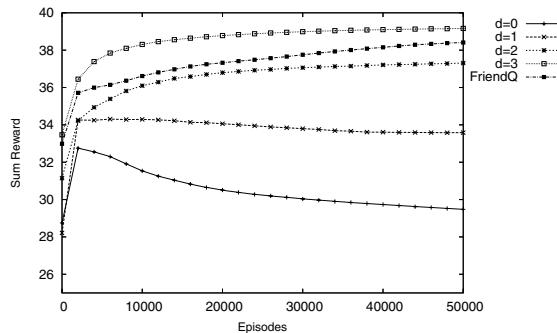

Figure 1. Rewards for Partial Joint Action Q-learning

The generalization of these results can be done applying PJA on larger problems. Calculating the near optimal policy, using an approximated optimal distance d_{app} , can be intractable if we need to compare with the results of Friend Q-Learning. We calculate the ratio $DS = XY/N$ which represents the degree of space for each agent. As we study a problem where the team of agent has to handle only negative interactions, the higher the ratio, the more space agents have. We compare the performance of PJA algorithm for different ratios. To discover a relation between the ratio DS and the value of d_{app} , we compare the link between DS and $\frac{d_{app}}{d_{total}}$. We can see that the degree of observability decreases with the degree of space for each agent and that the needed observability decreases and tends to 0 when DS increases. With this relation between both parameter observability and degree of space, we can evaluate, for other problems how would be the d_{app} value.

6 Related Work

Concerning the space search reduction, Sparse Cooperative Q-Learning [3] allows agents to coordinate their actions only on predefined sets of states. The joint actions set reduction has been studied

by Fulda and Ventura who propose Dynamic Joint Action Perception [2]. Introducing communication into decision has been studied by Xuan, Lesser, and Zilberstein [8] who proposed a formal extension to MDP with communication and by Pynadath and Tambe [7] who proposed an extension to distributed POMDP with communication called COM-MTDP, which take into account the cost of communication during the decision process. The locality of interactions in an MDP has been theoretically developed by Dolgov and Durfee [1]. Regarding the reinforcement learning in a vehicle coordination problem, Ünsal, Kachroo and Bay [9] have used multiple stochastic learning automata to control longitudinal and lateral path of one vehicle and Pendrith [6] presented a distributed variant of Q-Learning applied to lane change advisory system.

7 Conclusion

We proposed an approach to evaluate a good approximation of a multiagent decision process, introducing a degree of observability for each agents. Without taking into account explicit communication to obtain a degree of observability, we proposed Friend Q-learning algorithms extension which uses only observable state and observable actions from the other agents. We show that only partial view is needed to obtain a good policy approximation for some team problems, especially the changing lane problem between vehicles. We show a relation between a good degree of observability and the space allowed for each agent. However, this relation is only empirical and our approach is only restricted to negative interaction management problems. It is possible that in other problems, this relation could be different. For future work, we plan to evaluate more theoretically the relation between the degree of observability and the performance of the learned policy. Also, it will be very interesting to study the effect of partial local view to non cooperative and non negative interactions cases.

Mutual Enrichment for Agents Through Nested Belief Change: A Semantic Approach

Laurent Perrussel and Jean-Marc Thévenin¹ and Thomas Meyer²

1 Introduction

This paper focuses on the dynamics of nested beliefs in the context of agent interactions. Nested beliefs represent what agents believe about the beliefs of other agents. We consider the *tell* KQML performative [1] which allows agents to send their own beliefs to others. Whenever agents accept a new belief, or refuse to change their own beliefs after receiving a message, both receiver and sender enrich their nested beliefs by refining their beliefs about (i) the other agent's beliefs and (ii) the preferences of the other agent. The main objective of nested beliefs is to improve cooperation between agents. We propose a logical formalisation of the acquisition process of nested beliefs and preferences. This acquisition process is the first step towards the elaboration of sophisticated interaction protocols.

2 The Logical Framework

To represent an agent's beliefs we use signed statements. A *signed statement* is a pair $\langle \text{statement}, \text{origin of the statement} \rangle$ (usually the sender of the statement). Let \mathcal{L}_0 be a propositional language and A a set of agent identities. We define a signed statement as a pair $\langle \phi_0, a \rangle$ where ϕ_0 is a \mathcal{L}_0 -formula and $a \in A$ is the origin of ϕ_0 . Let S be the set of all sets of signed statements: $S = 2^{\mathcal{L}_0 \times A}$. The *belief state* of an agent is a pair $\langle \text{set of signed statements}, \text{set of sets of signed statements} \rangle$. The first set describes the *basic beliefs* of the agent: what it currently believes. The second set describes the *nested beliefs* of the agent: what it believes about the basic beliefs of others.

Definition 1 (Belief state) A belief state BS_a^n of agent a is a pair $\langle CB_a^n, NB_a^n \rangle$ s.t. (i) $CB_a^n \in S$ represents the basic beliefs of agent a at time n and (ii) $\forall CB_{a,b}^n \in NB_a^n, CB_{a,b}^n \in S$ represents the nested beliefs of agent a about agent b at n . Let \mathcal{B} be the set of all possible belief states.

Agents revise their basic beliefs and nested beliefs each time they receive a *tell* performative. Let S be a set of signed beliefs and $*$ be a revision operator [2]; $S_{\langle \phi_0, a \rangle}^*$ denotes the revision of S by $\langle \phi_0, a \rangle$.

Preferences may be defined taking various matters into account [5]. We simply assume that agents have preferences over the set of

agents A which describe the reliability of the sources of information, i.e. the level of trust an agent has about the other agents with which it interacts. We suppose that agents are equally reliable when they can't be distinguished, which entails a total preorder. Let \preceq_a^n be a total preorder over A representing agent a 's preferences at time n . $b \preceq_a^n c$ stands for agent c is at least as preferred as b for agent a at time n . As is the case for beliefs, agents can handle nested preferences. Nested preferences represent what agents believe about the preferences of other agents. $c \preceq_{a,b}^n d$ means: agent a believes that for agent b agent d is at least as preferred as c at n .

Definition 2 (Preference state) A preference state PS_a^n of agent a is a pair $\langle \preceq_a^n, NP_a^n \rangle$ s.t. (i) \preceq_a^n is a total preorder representing basic preferences of agent a at time n and (ii) every $\preceq_{a,b}^n \in NP_a^n$ is a total preorder representing agent b 's preferences according to a at time n . \mathcal{P} is the set of all possible preference states.

Let $\langle BS_a^n, PS_a^n \rangle = \langle \langle CB_a^n, NB_a^n \rangle, \langle \preceq_a^n, NP_a^n \rangle \rangle$ be a tuple which represents the whole state of agent a at n , i.e. all its beliefs and preferences.

Let S be any set of signed statements (basic or nested beliefs) and \preceq the corresponding preference relation (basic or nested). The logical closure of S w.r.t. \preceq is obtained as follows. By $\min(S, \preceq)$ we denote the set of the least preferred agent identities w.r.t. \preceq among agent identities signing beliefs of S . We suppose that statements entailed by S are signed with the least preferred agent identities of the minimal subsets of S entailing them: $Cn(S, \preceq) = \{ \langle \psi_0, a \rangle | \exists S' \subseteq S \text{ s.t. } \bigwedge_{\langle \phi_0, b \rangle \in S'} \phi_0 \models_{\mathcal{L}_0} \psi_0 \text{ and } \#S'' \subset S' \text{ s.t. } \bigwedge_{\langle \phi_0, b \rangle \in S''} \phi_0 \models_{\mathcal{L}_0} \psi_0 \text{ and } a \in \min(S', \preceq) \} \cup \{ \langle \psi_0, a \rangle | \models_{\mathcal{L}_0} \psi_0 \text{ and } a \in A \}$.

Now, we present the *action performatives* which lead to the dynamics of belief and preference states change. When an agent issues a *tell* performative to inform a receiver agent about its basic beliefs the receiver uses a prioritised belief revision operator $*$ to change its nested beliefs about the sender. As an acknowledgment of the *tell* performative, the receiver informs the sender with an *accept* (respectively *deny*) performative if the incoming statement has been incorporated in its basic beliefs. The sender in turn applies prioritised revision to its nested beliefs about the receiver. More formally:

- $\text{Tell}(s, r, \phi_0, a)$ stands for: agent s informs r that it believes ϕ_0 signed by a according to the standard KQML semantics [1]. When receiving a *Tell* performative, agent r revises its belief state by $\langle \phi_0, a \rangle$ in a non-prioritised way [3] according to its preferences.
- $\text{Accept}(r, s, p)$ stands for: agent r informs s that it accepts the performative p . If $p = \text{Tell}(s, r, \phi_0, a)$ then $\text{Accept}(r, s, p)$ means that agent r has revised its basic beliefs by $\langle \phi_0, a \rangle$ and thus believes ϕ_0 .
- $\text{Deny}(r, s, p)$ stands for: agent r informs s that it refuses to process

the performative p . If performative $p = \text{Tell}(s, r, \phi_0, a)$ it means that agent r has not revised its basic beliefs by $\langle\phi_0, a\rangle$.

The dynamics of the system is given by the execution of performatives. A sequence of actions σ is a function which associates integers representing state labels with performatives.

3 The Dynamics of Mutual Enrichment

Let us first express the honesty postulate (Hon) as follows. This postulate, which is recommended in a cooperative context, states that if a Tell performative occurs, then at the same time the sender believes the corresponding signed statement. This actually enforces the standard KQML semantics of Tell [1].

(Hon) For any n if $\sigma(n) = \text{Tell}(s, r, \phi_0, a)$ then $\langle\phi_0, a\rangle \in \text{Cn}(CB_s^n, \preceq_s^n)$.

Basically, after a performative $\text{Tell}(s, r, \phi_0, a)$, the belief state and preference state of agents do not change, except for the receiver. The receiver applies a non-prioritised revision of its basic beliefs using its basic preferences. It also applies a prioritised revision of its nested beliefs about the sender since it believes ϕ_0 signed by a according to the honesty postulate. It can also refine its nested preferences about the sender if it has removed a nested belief $\neg\phi_0$ signed by an agent b during the prioritised revision. Indeed the sender has preferred a to b . Finally the receiver acknowledges the Tell performative with an Accept or Deny performative, as formalized below, depending on the outcome of the non-prioritised revision of its basic beliefs so that the sender can in turn change its nested beliefs and nested preferences about the receiver. The non-prioritised revision is based on basic preferences in the following way: if the receiver believes $\neg\phi_0$ and the signatures of $\neg\phi_0$ are at least as preferred as a (the signature of ϕ_0 in the Tell), the receiver denies the Tell performative.

(DT) $\sigma(n+1) = \text{Deny}(r, s, \text{Tell}(s, r, \phi_0, a))$ iff $\sigma(n) = \text{Tell}(s, r, \phi_0, a) \& \exists \langle\neg\phi_0, b\rangle \in \text{Cn}(CB_r^n, \preceq_r)$ s.t. $a \preceq_r b$

Otherwise there is no conflict or a is strictly more preferred than all the signatures of $\neg\phi_0$, and r thus accepts the Tell performative.

(AT) $\sigma(n+1) = \text{Accept}(r, s, \text{Tell}(s, r, \phi_0, a))$ iff $\sigma(n) = \text{Tell}(s, r, \phi_0, a) \& \forall \langle\neg\phi_0, b\rangle \in \text{Cn}(CB_r^n, \preceq_r), b \prec_r a$

Due to space restrictions we focus on the formulas describing how nested beliefs and nested preferences of the sender change (see [6] for the complete formalisation of the dynamics).

According to (AT), if r accepts the message of s , agent s believes that r believes ϕ_0 and thus does not believe $\neg\phi_0$, which results in s revising its nested beliefs about r with $\langle\phi_0, a\rangle$ (a prioritised revision).

(AdNB3-1) If $\sigma(n) = \text{Accept}(r, s, \text{Tell}(s, r, \phi_0, a))$ then $CB_{s,r}^{n+1} = (CB_{s,r}^n)_{\langle\phi_0, a\rangle}^*$.

According to (DT), if r refuses the Tell performative then s concludes that r believes $\neg\phi_0$ and r believes that the signature of $\neg\phi_0$ has to be more trusted than a . So s revises its nested beliefs about r with the signed statement $\langle\neg\phi_0, b\rangle$ (again, a prioritised revision) so that signature b of $\neg\phi_0$ is preferred to a w.r.t. the nested preferences of s about r :

(AdNB3-2) If $\sigma(n) = \text{Deny}(r, s, \text{Tell}(s, r, \phi_0, a))$ then $CB_{s,r}^{n+1} = (CB_{s,r}^n)_{\langle\neg\phi_0, b\rangle}^*$ s.t. $a \preceq_{s,r} b$

This bring us to the sender's nested preferences. Firstly, the sender's nested preferences about agents other than r do not change. Next, agent s draws conclusions about a depending on whether r accepts or denies the performative $\text{Tell}(s, r, \phi_0, a)$. Whenever agent r accepts, agent s refines its nested preferences only if s currently believes that r believes $\neg\phi_0$ so that a be strictly more preferred than the signatures of $\neg\phi_0$. If r denies the message, the nested preferences of s about the signatures of $\neg\phi_0$ change. According to condition (DT) they have to be as preferred as a . Finally, we need to take care of nested preferences, about r , of s that do not change. In order to formalise these requirements, we give an explicit procedure to change the nested preferences. The Accept performative helps the sender to refine its nested preferences since it allows to remove some preferences; i.e. it helps agent s to go toward a stricter order. Removing preferences means that agent s already believes that r believes $\neg\phi_0$ and thus a is strictly preferred to all the signatures of $\neg\phi_0$.

(Ad-KeNP2) Let $\langle CB_{s,r}^n, \preceq_{s,r}^n \rangle$ be the nested beliefs and preferences of s about r . Let $\sigma(n) = \text{Tell}(s, r, \phi_0, a)$ and $\sigma(n+1) = \text{Accept}(r, s, \text{Tell}(s, r, \phi_0, a))$. All nested preferences at n are propagated at time $n+1$ as follows: $\preceq_{s,r}^{n+1} = \preceq_{s,r}^n - \{a \preceq_{s,r} b | \langle\neg\phi_0, b\rangle \in CB_{s,r}^n\} \cup \{b \preceq_{s,r} a | \langle\neg\phi_0, b\rangle \in CB_{s,r}^n\}$.

If r does not accept the incoming message, agent s also changes its nested beliefs about r . The Deny performative does not help agent s to refine its nested preferences since we only add nested preferences.

(AdNP3) Let $\langle CB_{s,r}^n, \preceq_{s,r}^n \rangle$ be the nested beliefs and preferences of s about r . Let $\sigma(n) = \text{Tell}(s, r, \phi_0, a)$ and $\sigma(n+1) = \text{Deny}(r, s, \text{Tell}(s, r, \phi_0, a))$. All nested preferences at n are propagated at time $n+1$ as follows: $\preceq_{s,r}^{n+1} = \preceq_{s,r}^n \cup \{a \preceq_{s,r} b | \langle\neg\phi_0, b\rangle \in CB_{s,r}^n\}$.

It is easily shown that the conditions preserves the ordering for nested preference as a total preorder.

4 Conclusion

In this paper we have given a sketch of a formalisation for handling the dynamics of nested beliefs and preferences in the context of agent interactions where agents are cooperative (see [6] for the detailed formalisation). We have shown how agents acquire nested beliefs and preferences. For this we have presented a logical framework to describe nested beliefs, preferences, and performatives. This framework is useful for specifying properly the expected behaviour of agents handling the Tell , Accept and Deny performatives. We have started to build a logical language based on dynamic epistemic logic [4] in order to reason about dialogues. Our aim is to define a semantics based on the semantics proposed in this paper.

Multi-Agent Least-Squares Policy Iteration

Victor Palmer¹

Abstract. Least-Squares Policy Iteration [3] is an approximate reinforcement learning technique capable of training policies over large, continuous state spaces. Unfortunately, the computational requirements of LSPI scale poorly with the number of system agents. Work has been done to address this problem, such as the Coordinated Reinforcement Learning (CRL) approach of Guestrin, et al [1], but this requires that one have prior information about the learning system such as knowing interagent dependencies and the form of the Q -function. We demonstrate a hybrid gradient-ascent/LSPI approach which is capable of using LSPI to efficiently train multi-agent policies. Our approach has computational requirements which scale as $O(N)$, where N is the number of system agents, and does not have the prior knowledge requirements of CRL. Finally, we demonstrate our algorithm on a standard multi-agent network control problem [1].

1 Introduction

Least-Squares Policy Iteration [3] is an approximate reinforcement learning algorithm capable of efficiently training policies over large, continuous state spaces. Unfortunately, like almost all reinforcement learning algorithms, LSPI has computational requirements which scale exponentially with the number of system agents, making it difficult to use the algorithm in a multi-agent setting. This exponential scaling is due to the fact that the action-space for a multi-agent system scales exponentially with the number of system agents. Work has been done to address this problem, most notably the Coordinated Reinforcement Learning approach of Guestrin, et. al. [1], although this suite of techniques requires that we know prior information about interagent dependencies and that we make assumptions about the form of the joint state-action valuation (discounted reward) function Q . Here we introduce a gradient-based 'wrapper' to LSPI which allows the algorithm to be performed efficiently on multi-agent domains.

2 Reinforcement Learning / LSPI Review

We work in the standard reinforcement learning context [4], where a system of agents $n_i \in \mathcal{N}$ interacts with an environment modeled by an MDP. The environment can take on states $s_t \in \mathcal{S}$, and at each time step, each agent can perform actions $a_t \in \mathcal{A}$. The joint action of our agent system will be denoted as the vector $\mathbf{a}_t \in \mathcal{A}^N$, where each component represents the action of a single agent. Let our policy be denoted $\pi(\mathbf{a}; s)$, which is the probability of performing actions \mathbf{a} when the environment is in state s . We will use the standard notion of discounted reward $Q^\pi(s, a)$, and also the *average reward* $\eta(\pi) = \sum_{s,a} \rho^\pi(s) \pi(a; s) R(s, a)$, where $\rho^\pi(s)$ is the stationary probability distribution of the policy, as in [2].

¹ Texas A&M University, College Station, Texas, email: vpalmer@cs.tamu.edu

In many modern control domains, it is not possible to explicitly represent the discounted reward function Q . Assuming that we approximate Q as: $Q^\pi(s, a) \approx \hat{Q}^\pi(s, a; \vec{\omega}) = \sum_{i=1}^k \phi_i(s, a) \omega_i$, [3] shows us how we can find the $\vec{\omega}$ such that the error $\sum_{s,a} |Q^\pi(s, a) - \hat{Q}^\pi(s, a; \vec{\omega})|$ is minimized. Specifically, [3] shows how to solve for the error-minimizing $\vec{\omega} = \Omega(\pi)$ by creating a policy-dependent matrix $\mathbf{A}(\pi)$, and a vector \mathbf{b} and solving the system $\mathbf{A}(\pi)\vec{\omega} = \mathbf{b}$ for $\vec{\omega}$. Solving this system performs *policy valuation*, after which an immediately improved policy can be constructed by: $\pi'(s) = \arg \max_a \hat{Q}(s, a; \vec{\omega})$. This new policy can be used to construct a new matrix $\mathbf{A}(\pi')$, and the process can be repeated to perform approximate policy iteration [3]. Unfortunately, the matrix \mathbf{A} ends up being proportional to the size of the joint action space, which grows exponentially with the number of agents in the system. As such, it is difficult to perform LSPI in large multi-agent domains.

3 Policy Gradient Ascent

An alternative to value-based reinforcement learning algorithms such as LSPI is the class of gradient-based algorithms such as REINFORCE [5] or the Conjugate Policy Gradient techniques of Kakade, et. al. [2]. Such algorithms directly search the space of policies by performing updates in the direction of some objective function (usually the average reward $\eta(\pi)$) gradient. Recently an interesting connection was drawn between the gradient of the average reward and approximate policy iteration techniques such as LSPI. Specifically, it was shown that $\nabla \eta(\pi(\omega)) = \Omega(\pi(\omega))$ [2].

Imagine that our joint policy conforms to the following ansatz:

$$\pi(\mathbf{a}; s) = \pi_{n_1}(\mathbf{a}_1; s) \pi_{n_2}(\mathbf{a}_2; s) \dots \pi_{n_N}(\mathbf{a}_N; s) \quad (1)$$

This models the case where each agent's policy is executed independently. Note that this is automatically true for deterministic policies. If we want to perform gradient ascent on the average reward $\eta(\pi)$ of this joint policy, we need to compute:

$$\nabla \eta(\pi) = \nabla \eta(\pi_{n_1}, \pi_{n_2}, \dots, \pi_{n_N}) \quad (2)$$

In an LSPI context, each of these single agent policies can be parameterized by a parameter vector $\vec{\omega}_{n_i}$ as $\pi_{n_i} = \pi_{n_i}(\vec{\omega}_{n_i}) = \arg \max_{a'} \hat{Q}(s, a'; \vec{\omega}_{n_i})$ so that we have (since the policy parameters are just the $\vec{\omega}_{n_i}$):

$$\nabla \eta(\pi) = \sum_{i=1}^N \nabla_{\vec{\omega}_{n_i}} \eta(\pi) \quad (3)$$

$$\nabla \eta(\pi) = \sum_{i=1}^N \nabla_{\vec{\omega}_{n_i}} \eta\left(\pi_{n_1}(\vec{\omega}_{n_1}), \dots, \pi_{n_N}(\vec{\omega}_{n_N})\right) \quad (4)$$

but by the chain rule:

$$\nabla \eta(\pi) = \sum_{i=1}^N \nabla_{\omega_{n_i}} \eta(\pi_{n_i}(\vec{\omega}_{n_i})) \quad (5)$$

where, for the computation of each gradient $\nabla_{\omega_{n_i}} \eta(\pi_{n_i})$, the other agents follow an unaltered policy:

$$\forall j \neq i, \quad \pi_{n_j} = \pi_{n_j}(\vec{\omega}_{n_j}) \quad (6)$$

Because each of the $\nabla \eta$ terms are single-agent policy $\eta(\pi)$ expressions, the reader should note that at this point, our original, multi-agent gradient computation task has been decomposed into N , single-agent gradient computation tasks. Further, since single-agent LSPI can be used to compute each of the single-agent gradients, we do not run into the problem of the exponential computational requirements of performing LSPI over multiple agents. Since each iteration of policy iteration scales as $O(k^3)$ [3], where k is the number of basis functions used for approximation, this hybrid gradient-ascent/LSPI approach should scale as $O(Nk^3)$ per iteration ... as opposed to $O(C^N)$ as if LSPI were used directly to train all N agents.

4 Experiments

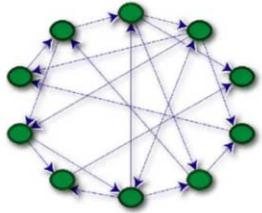

Figure 1. This figure shows a typical, randomly generated network used in our simulations (an $N = 10$ network is shown)

We tested this gradient-ascent/LSPI approach on the SysAdmin domain, which is a multi-agent network control problem [1]. In this domain, a network of computers are managed by a system of N agents (one agent per computer). Agents get reward when processes complete on their computers, but healthy computers can become faulty and then fail, and faulty computers execute tasks more slowly, and failed computers execute no tasks at all. Further, connected faulty and failed machines may 'infect' their connected neighbors, making them fail as well. An agent may 'reboot' its machine and to return it to 'healthy' status, but at the expense of losing all running processes. The goal is for all agents to coordinate their actions to maximize total reward. A nice property of this problem is that it has an easily calculable 'utopic upper bound' on total reward (basically assuming that no computer ever infects its neighbors, and that each machine is rebooted appropriately) that good policies can come close to achieving [1]. We generated random N -computer networks and created random links between the nodes such that each node had exactly two incoming connections. This was done to emulate the 'ring-of-rings' network topology used in the CRL paper [1].

We trained joint policies using our gradient ascent technique. All experiment parameters were as in [1]. Following the approach of [3], we used $k = 10N$ basis functions to approximate the single-agent $Q^\pi(s, a)$ function. We found that as predicted, training time scaled polynomially (specifically, as $O(N^4)$ here since $k \propto N$), and that the policies were of comparable quality to those generated by CRL

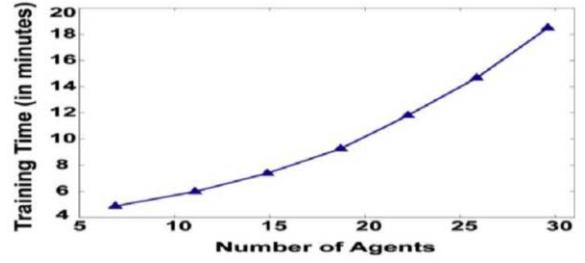

Figure 2. The total training time required to train our networks of various sizes. We predicted this to scale as $O(N^4)$, and in fact, dividing each point by N^4 results in a monotonically decreasing function (not shown).

[1]. Note that unlike in CRL, here we did not have to integrate knowledge of interagent dependencies into the learning algorithm.

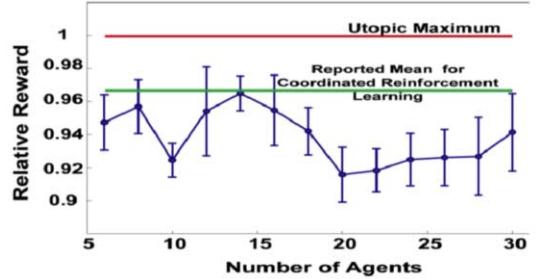

Figure 3. Shows the (relative) average reward of the final policies obtained by our gradient ascent technique. All rewards are relative to the utopic maximum as described in the Guestrin work. We plot the mean reward (over all agent counts) reported in [1] for CRL on the ring-of-rings network.

5 Conclusions

We have shown how a hybrid gradient-ascent approach can be used to train a multi-agent system with LSPI. The approach scales computationally as $O(N)$ where N is the number of agents, and can be used without prior knowledge of interagent dependencies. We tested our approach on the SysAdmin multi-agent network control problem [1] and found that our policies were competitive with those generated by Coordinated Reinforcement Learning [1].

Finding Instances of Deduction and Abduction in Clinical Experimental Transcripts

Maria Amalfi¹, Katia Lo Presti², Alessandro Provetti³ and Franco Salvetti⁴

Abstract. This article describes the design and implementation of a prototype that analyzes and classifies transcripts of interviews collected during an experiment that involved lateral-brain damage patients. The patients' utterances are classified as instances of categorization, prediction and explanation (abduction) based on surface linguistic cues. The agreement between our automatic classifier and human annotators is measured. The agreement is statistically significant, thus showing that the classification can be performed in an automatic fashion.

1 Introduction

This article describes a software that we have designed and implemented in the context of our work on measuring utterances that are evidence of inferential ability, viz., prediction and explanation, trying to match a human annotator. The starting point was an experiment that involved patients with lateral-hemisphere brain damage (along with a control group) that was carried out at the Boston VA hospital and for which the results were available in writing. The experiment consisted in showing to the subject the picture in and asking them "*I have a picture here. As you see, there's a lot going on. Look it over and tell me about it.*"

In this article we are not concerned with the cognitive interpretation of the data, nor with the validation of a particular hypothesis relating lateral brain damage to particular types of reasoning impairment. Rather, we would like to validate our approach to automated text classification by showing, via statistical analysis, that the results are comparable with those of human annotators. Our architecture is designed to avoid commitment to any particular model of rationality but could serve as a tool for validating Cognitive Science theories.

Indeed, one could say that the relatively simple software architecture described here is effective for textual analysis only when simple sentences having a limited lexicon are considered. However, the advantage of using an automated tool will be felt when similar experiments will be administered to large populations and human annotation will become uneven or even impossible. Although our software, which has SWI Prolog as its core and is described next, is not suitable for large-scale activities *as is*, standard computational complexity analysis yields that our approach can indeed scale up to several hundred transcripts.

Let us now describe in detail the architecture and the data representation adopted in this project⁵. The system consists of two main

¹ Grad. Student at University of Messina, Italy. maria.amalfi@gmail.com

⁴ Umbria Inc. Boulder CO U.S.A. E-mail:franco.salvetti@umbrialistens.com

⁵ The software (source and binary codes), the results and documentation is available from our group page: <http://mag.dsi.unimi.it/>

components that have been designed and implemented for the experiment described above.

1. program *patients-aggregator* takes as input data:

- the patients' transcript;
- local vocabulary⁶ and
- the general-purpose deduction rules for the Prolog inferential engine

and produces:

- rules data about categorizations, explanations and predictions;
- patients' data

Patients-aggregator scans the transcripts and creates a suitable Prolog representation of the phrases. Then, it also produces the schematic rules that the subsequent Prolog interpretation will use to discover the instances of prediction and explanation in the transcripts.

2. program *inference-finder* is written in Prolog; it takes as input the data generated by patients-aggregator and it produces:

- statistics;
- patient predictions and explanations and
- firing rules.

2 Results and comparisons

All the interviews considered in this work were annotated by two independent panels of human annotators, here called B and M. Each panel was made of two graduate students of Computer Science, who received similar instructions and very precise instructions on how to annotate interviews.

2.1 Validation of the results

The overall No. of annotations obtained during our experiment is illustrated in Table 1.

In the following we described a statistical analysis of the results that supports a more sophisticated understanding of the results.

The Kappa index [1], introduced by Cohen [2], has been proposed as a measure of the specific agreement for category among two observers. Kappa measures the accord among the answers of two observers (or the same observer in different moments), that appraises couples of objects or diagnostic categories.

⁶ The number of words of interest is finite and rather limited, i.e., 149 words as categorizations. So, it has been possible to represent all tokens of interest by means of Prolog facts.

Instances Found		
-	expl.	pred.
B panel	99	71
M panel	87	35
Program	71	32

Table 1. Overall no. of instances found

Predictions			
-	B	M	Program
B panel	1	0,244	0,260
M panel	-	1	0,447
Program	-	-	1

Table 3. The K degree of agreement on predictions

This index captures and corrects the so-called *accidentals agreements*. An agreement is called accidental when two observers reach the same conclusion even though they did so by employing completely different sets of criteria to distinguish between the presence/absence of relevant conditions. In such cases the raw agreement index would not reflect a real agreement. The idea underlying the Kappa index is that the actual accord between two observers is as the difference between the raw agreement and the agreement we would have under the hypothesis that between the two there is no accord and thus their answers may coincide only by chance.

The value of K is given by the ratio between the excess agreement ($P_o - P_e$) and the maximum obtainable agreement ($1 - P_e$) :

$$K = \frac{P_o - P_e}{1 - P_e} \quad (1)$$

where:

P_o it is the proportion of frequencies observed of accords among the two evaluation, and

P_e it is the proportion of accords obtained under the condition that the void hypothesis is true.

If there is complete agreement, then K will be equal to 1. If the observed agreement is greater or equal than the agreement attended only by chance obtained then the K index will result near zero or even slightly negative. Values of K above 0.75 suggest that there is an excellent agreement; values below 0.40 represent a weak agreement, whereas values between 0.40 and 0.75 can represent a good agreement. To sum it up, k is the right type of index to assess the quality of our program vis-à-vis human analysis of some experimental results. The degree of agreement among the human panels and the program is as follows:

Explanations			
-	B	M	Program
B panel	1	0,331	0,335
M panel	-	1	0,433
Program	-	-	1

Table 2. The K degree of agreement on explanations

Between the M panel and the system there is a good enough agreement (values between 0.75 and 0.40); while group B has weak agreement both with group M and with the system (values below 0.40).

2.2 Interpretation of the results

The statistics described above show a good agreement between the program scores and those given by the M panel. Vice versa, the B

panel results have a low agreement index K with both the program and the M panel. The B panel consistently finds more instances of reasoning (of any type) than the M panel and the system. These differences can be explained by the fact that the mental model of the M panel annotators is reflected in the program.

These results are very satisfying from an Artificial Intelligence perspective: they show that, e.g., from the point of view of the B panel, the classification expressed by the M panel and that of the system are *indistinguishable*.

3 Conclusions

We have described the design and implementation of a prototype that analyzes and classifies transcripts of interviews collected during a cognitive science experiment that concerned assessing reasoning bias in lateral-brain damage patients. Our Prolog-based software takes a static description of reasoning rules and matches them on patients' transcripts. Hence, patients' utterances were classified as instances of categorization, prediction and explanation (abduction) based on surface linguistic cues. The agreement between our automatic classifier and human annotators is measured. The agreement is statistically significant, thus showing that the classification can be performed in an automatic fashion. The statistical results support our claim that our software can be safely applied to automate the analysis of experimental results of the type described earlier. Our program can be useful as a provider of second opinions to reveal possible overlooks or mistakes in the diagnostic analysis.

From a Cognitive science point of view, our project may be considered limited by the fact that it can analyze only verbal (transcribed) responses to experiments. Vice versa, from an A.I. point of view we can see that the pattern matching mechanism, though rather basic vis-à-vis current natural language processing techniques is implemented fairly elegantly and efficiently in Prolog.

We are currently working to incorporate such techniques, (e.g., regular expressions) into our program. It would be interesting to apply our classifier to the transcripts of the experiment in [3] since their experiment seems within the reach of the techniques we have employed. Another promising direction of research consist in attaching to the token words some *semantics* obtained by automated reference to Wordnet⁷.

A Semantics for Active Logic

Mikael Asker and Jacek Malec¹

1 Introduction

Active logics [2] is a family of logics intended to model awareness of resource limitations of the reasoning process. Active logics can be used for reasoning *in time*, handling contradictions and for introspection. Active logics are usually defined syntactically, as axiomatic theories, but until recently have had no formally defined semantics.

A major property of a logic capturing common intuitions about resource-awareness is *paraconsistency*. Speaking informally, this property guarantees that presence of a contradictory pair of sentences in a theory does not necessarily lead to inference of arbitrary consequences, i.e., that the logic is not *explosive*.

The first and so far the only serious attempt to build a semantics for active logics is *active consequence* from [1], presented briefly below. However, it has been recently shown in [3] that active consequence is indeed explosive.

The active consequence relation can be modified in order to escape explosiveness. In this paper we describe our attempt to constrain the active consequence relation so that an active logic based on it becomes paraconsistent.

2 Active consequence

Active consequence was defined in [1] as an attempt to create a semantics for a simple active logic. The language \mathcal{L} is a sorted first-order language defined in two parts: a propositional language \mathcal{L}_w to express facts about the world, and a first order language \mathcal{L}_a used to express facts about the agent and its beliefs. We will use $Sn_{\mathcal{L}}$ to denote the set of all sentences of a language \mathcal{L} .

\mathcal{L}_w is built around a set of sentence symbols, the propositional connectives \neg and \rightarrow and parentheses. The semantics of \mathcal{L}_w is defined by truth assignments. An \mathcal{L}_w -interpretation h is a function $h : Sn_{\mathcal{L}_w} \rightarrow \{\top, \perp\}$. \mathcal{L}_a is built around a set of constant symbols that can refer to points in time, to sentences in \mathcal{L}_w and in \mathcal{L}_a itself, the predicates *now*, *contra* and *bel* and the propositional connective \neg . The intended meanings of *now*, *contra* and *bel* are to indicate the current time, the existence of a direct contradiction at some time and that the agent has a belief at some time, respectively. The semantics of \mathcal{L}_a is based on \mathcal{L}_a -structures H_t^a , which describe the reasoning history of agent a at time t . An \mathcal{L}_a -structure H_t^a can be built from the time sequence $\langle KB_k^a \rangle_{k=0}^t$ of the knowledge bases of agent a up to time t .

The language \mathcal{L} is defined so that $Sn_{\mathcal{L}} = Sn_{\mathcal{L}_w} \cup Sn_{\mathcal{L}_a}$. Its semantics is based on active structures $M_t^a = \langle h_t, H_t^a \rangle$, consisting of one \mathcal{L}_w -interpretation h_t and one \mathcal{L}_a -structure H_t^a . More details about the languages \mathcal{L} , \mathcal{L}_w and \mathcal{L}_a can be found in [1] or [3].

The basic idea of *active consequence* is that the agent perceives only a part of its database, and thus only some of the direct contradictions in the database are visible at a given instant. Active consequence models this by watching the database through a *perception function*, which maps the \mathcal{L} -sentences in the database to another language \mathcal{L}' . PER_t is the set of all possible perception functions at time t . By adding extra indexes to the sentence symbols S_j in the \mathcal{L}_w formulas in the database, they are mapped to symbols S_j^i in another language \mathcal{L}'_w . For a direct contradiction to be visible, the sentence symbols in both of the formulas involved in the contradiction must be mapped to the same indexes. If they are not, then the \mathcal{L}'_w -symbols are different and there is no contradiction, so we can hide a direct contradiction by mapping the symbols in the \mathcal{L} -formulas involved to different extra indexes. The basic idea of active consequence is now that one database follows from another, if there are ways to perceive the databases (perception functions) for which there is classical consequence between the perceptions. Unfortunately, in [3] it was proved that active consequence is explosive.

3 Local consequence

An analysis of the explosivity proof in [3] shows that one important problem is that we can map the same variable to two values at the same time. This is what causes the explosion, and in this sense, the perceptions functions in active consequence are too general.

One idea about how to cure the problems is to restrict the choice of perception functions. One reasonable way to restrict the choice of perception functions is to take subsets of the lhs and rhs formulas. If we require the subsets to be consistent, then classical logical consequence between the perceptions is meaningful in the sense that models do exist. What we want to do is to take a consistent subset of the lhs and take the subset of the rhs which contains the new formulas. Technically, this can be realized inside the framework of active consequence, by mapping the symbols in a formula to index 1 iff the formula is a member of the subset. Otherwise its terms are mapped to unique indexes different from 1 to avoid restricting the model set. One more requirement which turns out to be necessary is that the old formulas on the right side are mapped to the same indexes as on the left side.

Definition 1 (Local perception function pair) Let Σ and $\Theta \subseteq Sn_{\mathcal{L}}$ and denote with Γ_1 the set $\Sigma \cap Sn_{\mathcal{L}_w}$ and with Γ_2 the set $\Theta \cap Sn_{\mathcal{L}_w}$. Order the formulas in Γ_1 and Γ_2 lexicographically as $\varphi_{11}, \varphi_{12}, \dots, \varphi_{1m_1}$ and $\varphi_{21}, \varphi_{22}, \dots, \varphi_{2m_2}$, respectively. Let $\langle S_{j_{11}}, S_{j_{12}}, \dots, S_{j_{1n_1}} \rangle$ and $\langle S_{j_{21}}, S_{j_{22}}, \dots, S_{j_{2n_2}} \rangle$ be the finite sequences of all sentence-symbol tokens occurring in the strings $\varphi_{11}\varphi_{12}\dots\varphi_{1m_1}$ and $\varphi_{21}\varphi_{22}\dots\varphi_{2m_2}$, the concatenated formulas. For each k_1 in $\{1, \dots, n_1\}$ or k_2 in $\{1, \dots, n_2\}$, there is a corresponding formula φ_{1l} , $1 \leq l \leq m_1$ or φ_{2l} , $1 \leq l \leq m_2$, to which the sentence symbol $S_{j_{1k_1}}$ or $S_{j_{2k_2}}$ belongs.

¹ Department of Computer Science, Lund University, Sweden, email: jacek@cs.lth.se, URL: <http://ai.cs.lth.se>

For each $\Delta \subseteq \Gamma_1$, we can define a sequence of positive integers $\langle i_{11}, i_{12}, \dots \rangle$ by $i_{1k} = 1$ if $\varphi_{1l} \in \Delta$, where φ_{1l} is the formula in Γ_1 containing $S_{j_{1k}}$ or if $k > n_1$, $k+1$ otherwise.

We also define the sequence $\langle i_{21}, i_{22}, \dots \rangle$ of positive integers as $i_{2k} = 1$ if $\varphi_{2l} \in \Gamma_2 \setminus \Gamma_1$, where φ_{2l} is the formula in Γ_2 containing $S_{j_{2k}}$ or if $k > n_2$, otherwise $\varphi_{2l} \in \Gamma_2 \cap \Gamma_1 \subseteq \Gamma_1$ - use the same value as that used for φ_{2l} in the i_{1k} sequence.

The sequences $\langle i_{11}, i_{12}, \dots \rangle$ and $\langle i_{21}, i_{22}, \dots \rangle$ above together define a pair of perception functions ($\text{pert}_t, \text{pert}_{t+1}$).

The set $\text{PER}_{lt}(\Sigma, \Theta)$ is the set of perception function pairs defined as above for all consistent subsets $\Delta \subseteq \Sigma \cap \text{Sn}_{\mathcal{L}_w}$. This defines the function $\text{PER}_{lt} : \Sigma_t^\omega \times \mathcal{P}(\text{Sn}_{\mathcal{L}}) \rightarrow \mathcal{P}(\text{PER}_t) \times \mathcal{P}(\text{PER}_{t+1})$ which generates the set of possible local perception function pairs from the sets of premisses and results.

Definition 2 (Local consequence) Let $\Sigma \in \Sigma_t^\omega$ be t -weakly consistent, and let $\Theta \subseteq \text{Sn}_{\mathcal{L}}$ be arbitrary. We say that Θ is a 1-step local consequence of Σ at time t , written $\Sigma \models_{l1} \Theta$, if and only if

$$\begin{aligned} \exists (\text{pert}_t, \text{pert}_{t+1}) \in \text{PER}_{lt} : \forall a : [KB_t^a = \Sigma \rightarrow \\ [H_{t+1}^a \models (\text{pert}_{t+1}(\Theta) \cap \text{Sn}_{\mathcal{L}_a}) \wedge M(\text{pert}_t(\Sigma) \cap \text{Sn}_{\mathcal{L}'_w}) \neq \emptyset \wedge \\ (\text{pert}_t(\Sigma) \cap \text{Sn}_{\mathcal{L}'_w}) \models (\text{pert}_{t+1}(\Theta) \cap \text{Sn}_{\mathcal{L}'_w})]] \end{aligned}$$

n -step local consequence is defined recursively:

$$\Sigma \models_{ln} \Theta \Leftrightarrow \exists \Gamma \subseteq \text{Sn}_{\mathcal{L}} : \Sigma \models_{l(n-1)} \Gamma \wedge \Gamma \models_{l1} \Theta$$

Finally, local consequence in general is defined as:

$$\Sigma \models_l \Theta \Leftrightarrow \exists n \in \mathbb{N} : \Sigma \models_{ln} \Theta$$

The following theorems show that Definition 2 is correct, in the sense that the new consequence relation has the desired properties:

Theorem 1 (Local consequence is local)

$$\begin{aligned} \forall (\Sigma, \Theta) \in \Sigma_t^\omega \times \mathcal{P}(\text{Sn}_{\mathcal{L}}) : \Sigma \models_{l1} \Theta \Rightarrow \\ \exists \Sigma' \subseteq \Sigma \cap \text{Sn}_{\mathcal{L}_w} : M(\Sigma') \neq \emptyset \wedge \Sigma' \models (\Theta \setminus \Sigma) \cap \text{Sn}_{\mathcal{L}_w} \\ \forall (\Sigma, \Theta) \in \mathcal{P}(\text{Sn}_{\mathcal{L}_w}) \times \mathcal{P}(\text{Sn}_{\mathcal{L}_w}) : \\ (\exists \Sigma' \subseteq \Sigma : M(\Sigma') \neq \emptyset \wedge \Sigma' \models \Theta \setminus \Sigma) \Rightarrow \Sigma \models_{l1} \Theta \end{aligned}$$

Theorem 2 (Local consequence is active) $\models_l \subset \models_a$.

Theorem 3 (Local consequence is paraconsistent)

$$\neg \forall \Sigma \in \Sigma_t^\omega : \forall (\varphi, \psi) \in \text{Sn}_{\mathcal{L}_w}^2 : \{\varphi, \neg\varphi\} \subseteq \Sigma \Rightarrow \Sigma \models_l \Sigma \cup \{\psi\}$$

4 Relation to classical logic

Theorem 4 (The world part of local consequence is classical)

$$\forall (\Sigma, \Theta) \in \Sigma_t^\omega \times \mathcal{P}(\text{Sn}_{\mathcal{L}}) : \Sigma \models_{l1} \Theta \Rightarrow \Sigma \cap \text{Sn}_{\mathcal{L}_w} \models \Theta \cap \text{Sn}_{\mathcal{L}_w}$$

Next, we show that for strongly consistent databases, \models_l is equivalent to classical consequence:

Theorem 5

$$\forall (\Sigma, \Theta) \in [\mathcal{P}(\text{Sn}_{\mathcal{L}_w})]^2 : M(\Sigma) \neq \emptyset \Rightarrow (\Sigma \models_{l1} \Theta \Leftrightarrow \Sigma \models \Theta)$$

Let \models_{amp} be the consequence relation which is generated by the *active modus ponens* inference rule, the active logics variant of the traditional modus ponens rule:

$$\frac{t : \varphi, \varphi \rightarrow \psi}{t + 1 : \psi}, \quad \text{where } \varphi, \psi \in \text{Sn}_{\mathcal{L}_w} \quad (1)$$

Active modus ponens is certainly a rule which we want to be locally sound. But unfortunately, because $\{\neg(S_1 \rightarrow S_1), (\neg(S_1 \rightarrow S_1)) \rightarrow S_2\} \not\models_l \{S_2\}$ it isn't, $\models_{amp} \setminus \models_l \neq \emptyset$! We want to handle active modus ponens, but still be paraconsistent. So we have to find a consequence relation \models_x “between” \models_l and \models_a , with $\models_l \subset \models_x$ to include active modus ponens, but with $\models_x \subset \models_a$ to remain paraconsistent.

The part of \models_{amp} that is inside \models_l is the part where the premisses have models and the reasoning is “truly meaningful”. The part of \models_{amp} that is outside \models_l , the *semantic residual*, is exactly the part where the premisses are inconsistent. We interpret the residual as a reflection of artifacts in the proof theory. The residual models the proof theory when it is doing “meaningless” reasoning with inconsistent premisses.

We believe that there is a reason for why the proof theory does this kind of “meaningless” reasoning, and that the reason is that the inference rule has no way to find out that the reasoning is “meaningless”. Inference rules are syntactic operations which can be implemented efficiently with simple pattern matching, and are “too stupid” to discover inconsistency. Computationally, discovering inconsistency is expensive. The residual part is present also in classical logic, it is just that nobody has bothered about it before.

The residual part must be included in a semantic consequence relation to achieve soundness, and because active modus ponens is *active* sound, we can include the residual in the semantic consequence relation and still have that relation being a subset of active consequence. Now the utility of being a subset of active consequence as proved in Theorem 2 becomes apparent. That property enables us to go outside \models_l to other parts of \models_a to cover the residual parts of the rules.

5 Conclusions

The work described in this paper directly builds on the earlier work on Active Logics: logics aware of passage of time and the computational cost of inference.

Active consequence in its original form is not very useful as a semantics for active logics itself, because it is explosive. But this text shows that it is indirectly useful, in that can be used as a framework for defining other consequence relations which are subsets of active consequence, by restricting the choice of perception functions.

One such subset is local consequence, which was defined and shown to be paraconsistent. What we aim at as our final semantic consequence relation is probably a part of local consequence, plus some semantic residuals to compensate for the stupidity of other inference rules.

An alternative inference for Qualitative Choice Logic

Salem Benferhat and Daniel Le Berre and Karima Sedki¹

Abstract. *Qualitative Choice Logic* adds to classical propositional logic a new connective, called *ordered disjunction*, used to express preferences between alternatives. We present an alternative inference relation for the *QCL* language that overcomes some *QCL* limitations.

1 Introduction

Recently, a new logic for representing choices and preferences has been proposed [1]. This logic is called *Qualitative Choice Logic (QCL)* and is an extension of propositional logic. The non-standard part of *QCL* logic is a new logical connective $\vec{\times}$, called *Ordered disjunction*, which is fully embedded in the logical language. Intuitively, if A and B are propositional formulas then $A \vec{\times} B$ means: “if possible A, but if A is impossible then at least B”. *QCL* logic is very useful to represent preferences. However, its inference tool is less satisfactory. In fact, the way the negation is handled in *QCL* logic is not fully satisfactory. In *QCL* when a negation is used on a *QCL* formula with ordered disjunction, that negated *QCL* formula is logically equivalent to a propositional formula obtained by replacing the ordered disjunction ($\vec{\times}$) by the propositional disjunction (\vee). We propose to equip the *QCL* framework with a new inference relation that overcomes the *QCL* original inference relation.

2 Basic Choice Formulas (BCF)

Let $PROP_{PS}$ be a propositional language based on a set of propositional symbols PS . Basic choice formulas are ordered disjunctions of propositional formulas. They propose a simple way to order available alternatives. The operator $\vec{\times}$ is associative. Given propositional formulas a_1, a_2, \dots, a_n , the formula $a_1 \vec{\times} a_2 \vec{\times} \dots \vec{\times} a_n$ is used to express an ordered list of alternatives: some a_i must be true, preferably a_1 , but if this is not possible then a_2 , if this is not possible a_3 , etc. The language composed of *basic choice formulas* and propositional formulas is denoted by BCF_{PS} , and defined by:

Definition 1 *The set BCF_{PS} of basic choice formulas is the smallest set of words defined inductively as follow:*

1. If $\phi \in PROP_{PS}$ then $\phi \in BCF_{PS}$
2. If $\phi, \psi \in BCF_{PS}$ then $(\phi \vec{\times} \psi) \in BCF_{PS}$
3. Every *basic choice formula* is obtained by applying the two rules above a finite number of times.

¹ CRIL-CNRS FRE 2499, Université d'Artois, France, email: {benferhat,leberre,sedki}@cril.univ-artois.fr

The semantics of BCF is based on the degree of satisfaction of a formula in a particular model. As in standard propositional logic, an interpretation I is an assignment of the classical truth values T,F to the atoms in PS .

I will be represented by the set of its satisfied literals.

Definition 2 [1]

- Let $\phi = a_1 \vec{\times} a_2 \vec{\times} \dots \vec{\times} a_n \in BCF_{PS}$.
 $I \models_k a_1 \vec{\times} a_2 \vec{\times} \dots \vec{\times} a_n$ iff $I \models a_1 \vee a_2 \vee \dots \vee a_n$ and $k = \min(j \mid I \models a_j)$.
- Let $\phi \in PROP_{PS}$. $I \models_1 \phi$ iff $I \models \phi$.

Namely, a basic choice formula $a_1 \vec{\times} a_2 \vec{\times} \dots \vec{\times} a_n$ is satisfied to a degree k by an interpretation I if I satisfies a_k but fails to satisfy a_i for all $1 \leq i < k$.

The language of *basic choice formulas* has strong relationships with possibility theory, in particular with guaranteed possibility distributions, (see [1] for more details).

The following introduces the notion of equivalences between *basic choice formulas*.

Definition 3 [1] *Two basic choice formulas ϕ and ψ are said to be equivalent, denoted simply by $\phi \equiv \psi$, if for all interpretation I , and integer k we have $I \models_k \phi$ iff $I \models_k \psi$.*

In the following, K is a set of propositional formulas which represents knowledge or integrity constraints, and T is a set of preferences. To define the inference relation between $(K \cup T)$ and a propositional formula ϕ , we first need to define the notion of models and preferred models.

Definition 4 *Let K be a set of propositional formulas and T be a set of preferences. An interpretation I is a model of $K \cup T$ iff*

1. *I satisfies K, and*
2. *I satisfies each formula of T to some degree (i.e., $\forall \phi \in T, \exists k$ such that $I \models_k \phi$).*

The satisfaction degree on formulas helps us to determine preferred models. There are different ways of doing this. In [1] a lexicographic ordering on models, based on the number of formulas satisfied to a particular degree is used. The lexicographic ordering is defined as follows:

Definition 5 *Let $M^k(T)$ denote the subset of formulas of T satisfied by a model M to a degree k . A model M_1 is $K \cup T$ -preferred over a model M_2 if there is a k such that $|M_1^k(T)| > |M_2^k(T)|$ and for all $j < k$: $|M_1^j(T)| = |M_2^j(T)|$. M is a preferred model of $K \cup T$ iff M is maximally $(K \cup T)$ -preferred.*

Definition 6 Let K be a set of propositional formulas and T be a set of preferences, and A be a propositional formula of $PROP_{PS}$. $K \cup T \not\vdash A$ iff A is satisfied in all preferred models of $K \cup T$.

Example 1 As an example consider $K = \emptyset$ and $T = \{\text{Air-France} \vec{x} \text{EasyJet}\}$. We have three models $\{\text{Air-France}\}$, $\{\text{Air-France}, \text{EasyJet}\}$, $\{\text{EasyJet}\}$ with respective satisfaction degree 1, 1, 2. This means that $\{\text{Air-France}\}$ and $\{\text{Air-France}, \text{EasyJet}\}$ are maximally preferred and we have $\text{Air-France} \vec{x} \text{EasyJet} \not\sim \text{Air-France}$.

After building examples of general QCL formulas, we noticed that the QCL logic has two main limitations:

- **The double negation of a QCL formula does not preserve the initial formula, namely $\neg\neg\phi \not\equiv \phi$.** For instance, let $\phi = (a \vec{x} b) \vee \neg c$, where a, b, c are three independent propositional symbols. Then, in QCL framework
 $\neg\neg\phi \equiv \neg\neg((a \vec{x} b) \vee \neg c)$
we have: $\equiv \neg((\neg a \wedge \neg b) \wedge c)$
 $\equiv a \vee b \vee \neg c$.
- **Implication is not well handled.** For instance, the QCL framework does not make distinction between the following three rules:
 $(\text{AirFrance} \vec{x} \text{EasyJet}) \Rightarrow \text{HotelPackage}$,
 $(\text{EasyJet} \vec{x} \text{AirFrance}) \Rightarrow \text{HotelPackage}$,
 $(\text{AirFrance} \vee \text{EasyJet}) \Rightarrow \text{HotelPackage}$.

3 An alternative inference relation for the QCL language

Let QCL_{PS} be $PROP_{PS}$ augmented by the binary connective \vec{x} . The main limitations we identified for QCL_{PS} are the consequences of using the negation on formulas containing ordered disjunctions. It is not easy to give a precise meaning of negative preferences: what does really mean “I do not prefer flying with Air France than EasyJet”? Most of existing works on logic-based representation of preference ignore or does not allow the representation of negated preferences [2, 3, 4]. In our mind, preserving the double negation and the use of implications are desirable properties.

To define our new inference relation on QCL_{PS} , we will follow the same steps as used in [1], namely:

1. First, we transform the set of *general choice formulas* into a set of *basic choice formulas*,
2. Then use Definition 2, 4, 5 to draw the set of consequences.

The transformation of $\phi \otimes \psi$ (with $\otimes = \vee, \wedge, \vec{\otimes}$ a binary connective from the QCL logic) is equivalent to $\phi' \otimes \psi'$ where ϕ' and ψ' are the transformation of ϕ and ψ .

The transformation should also respect De Morgan’s law.

For the specific cases of a conjunction of BCF or the negation of a BCF , we use the following transformation rules.

Let $\phi = a_1 \vec{x} a_2 \vec{x} \dots \vec{x} a_n$, and $\psi = b_1 \vec{x} b_2 \vec{x} \dots \vec{x} b_m$ such that a_i ’s and b_i ’s are propositional formulas.

- $((a_1 \vec{x} a_2 \vec{x} \dots \vec{x} a_n) \wedge (b_1 \vec{x} b_2 \vec{x} \dots \vec{x} b_m)) \equiv c_1 \vec{x} c_2 \vec{x} \dots \vec{x} c_k$ where $k = \max(m, n)$, and

$$c_i = \begin{cases} (a_i \wedge b_i) & \text{if } i \leq \min(m, n) \\ a_i & \text{if } m \leq i \leq n \\ b_i & \text{if } n \leq i \leq m \end{cases}$$

- $\neg(a_1 \vec{x} a_2 \vec{x} \dots \vec{x} a_n) \equiv \neg a_1 \vec{x} \neg a_2 \vec{x} \dots \vec{x} \neg a_n$.

Example 2

Here is an example of the way disjunctions of BCF are handled in our new inference system:

$$\begin{aligned} \neg\neg\phi &\equiv \neg\neg((a \vec{x} b) \vee \neg c) \\ &\equiv \neg(\neg a \vec{x} \neg b) \wedge c \\ &\equiv a \vec{x} b \vee \neg c \quad \equiv a \vee \neg c \vec{x} b \end{aligned}$$

Hence, contrary to the QCL we do not loose the ordered disjunction in the scope of a negation. A more interesting result arises when considering implications:

$$\text{AirFrance} \vec{x} \text{EasyJet} \Rightarrow \text{FirstClass}$$

$$\equiv (\neg \text{AirFrance} \vee \text{FirstClass}) \vec{x} \neg \text{EasyJet}$$

While:

$$\text{EasyJet} \vec{x} \text{AirFrance} \Rightarrow \text{FirstClass}$$

$$\equiv (\neg \text{EasyJet} \vee \text{FirstClass}) \vec{x} \neg \text{AirFrance}$$

Therefore the order of preferences is very important.

Let us consider finally the example where our knowledge base K contains $\neg \text{EasyJet} \vee \neg \text{AirFrance}$ (1) and T contains the following preferences:

$$\left\{ \begin{array}{l} \text{AirFrance} \vec{x} \text{EasyJet} \Rightarrow \text{HotelPackage}(2) \\ \text{EasyJet} \vec{x} \text{AirFrance} \Rightarrow \neg \text{HotelPackage}(3) \\ \text{AirFrance} \vec{x} \text{EasyJet}(4) \end{array} \right.$$

The following truth table summarizes at which degree of satisfaction is satisfied each preference (1 or 2) with the new inference relation.

AirFrance	EasyJet	Hotel	(1)	(2)	(3)	(4)
F	F	F	1	1	1	-
F	F	T	1	1	1	-
F	T	F	1	1	2	2
F	T	T	1	1	1	2
T	F	F	1	2	1	1
T	F	T	1	1	1	1
T	T	F	-	-	-	1
T	T	T	-	1	1	1

The given $T \cup K$ has one preferred model (bold line), $I = \{\text{AirFrance}, \text{Hotel}\}$, from which we get the expected conclusion $K \cup T \not\sim \text{Hotel}$, not derivable from QCL framework.

4 Conclusion

We presented a limitation of the original QCL inference, resulting from the way negations are handled: negated QCL formulas are equivalent to plain propositional formulas. We thus proposed a new inference framework for the QCL language that overcomes this limit: the new inference scheme preserves preferential information in negated QCL formulas.

On the Existence of Answer Sets in Normal Extended Logic Programs¹

Martin Caminada² and Chiaki Sakama³

Abstract. One of the serious problems in *answer set programming* is that relatively small pieces of information can cause a total absence of answer sets. To cope with this problem, this paper introduces a class of *normal extended logic programs* which are extended logic programs, whose defeasible rules are comparable to normal defaults in default logic. Under suitable program transformations, we show that every normal extended logic program always yields at least one answer set.

1 Introduction

Answer set programming (ASP) is a declarative programming paradigm which is useful for AI problem solving [1, 5]. In ASP a program is represented as an *extended logic program* whose declarative meaning is given by the *answer set semantics* [4]. However, it is well-known that a program does not always have an answer set. A notorious example is the rule like $p \leftarrow \text{not } p$. The existence of such a “negative loop” – an atom depending on its default negation, can cause a total absence of answer sets, and blocks all useful inferences from other parts of the program.

From the knowledge representation viewpoint, a negative loop is often considered anomalous information. So there would be a good reason that a program including such anomalous information is unusual anyway. The problem, however, is that even programs that do not include any such anomalous information often fail to have an answer set. This is illustrated by, for instance, the “Married John” example from [2]: (a) “John wears something that looks like a wedding ring.” (b) “John parties with his friends until late.” (c) “Someone wearing a wedding ring is usually married.” (d) “A party-animal is usually a bachelor.” (e) “A married person, by its definition, has a spouse.” (f) “A bachelor, by definition, does not have a spouse.” These sentences are represented by the following program:

$$\begin{array}{ll} r \leftarrow & p \leftarrow \\ m \leftarrow r, \text{not } \neg m & b \leftarrow p, \text{not } \neg b \\ hs \leftarrow m & \neg hs \leftarrow b \end{array}$$

This program contains no negative cycle, and encodes given information in a natural way. The program has no answer set, however.

One may consider that interpreting strict (NAF-free) rules as *clauses* in propositional logic and representing them as disjunctive facts would solve the problem. Rewriting the strict rules as disjunctive facts in the above program would yield the following.

$$\begin{array}{ll} r \leftarrow & p \leftarrow \\ m \leftarrow r, \text{not } \neg m & b \leftarrow p, \text{not } \neg b \\ hs \vee \neg m \leftarrow & \neg hs \vee \neg b \leftarrow . \end{array}$$

This program has two answer sets: $\{r, p, m, \neg b, hs\}$ and $\{r, p, b, \neg m, \neg hs\}$. Unfortunately, such rewriting does not work in general. For instance, the following program contains only normal defeasible rules and disjunctive facts but still has no answer set.⁴

$$\begin{array}{ll} \neg a \leftarrow b, \text{not } a, & b \leftarrow a, \text{not } \neg b, \\ c \leftarrow \neg a, \text{not } \neg c, & d \leftarrow c, \text{not } \neg d, \\ a \leftarrow d, \text{not } \neg a, & a \vee b \vee c \leftarrow . \end{array}$$

The above discussion indicates that specifying syntactic restrictions under which an extended logic program is guaranteed to have answer sets is not a trivial task, especially when one also want to preserve a form of strict reasoning.

2 Basic Definitions

A *program* considered in this paper is an *extended logic program* (ELP) [4], which is a finite set of *rules* of the form:

$$c \leftarrow a_1, \dots, a_n, \text{not } b_1, \dots, \text{not } b_m \quad (1)$$

where each c , a_i and b_j is a positive/negative literal and *not* stands for *default negation* or *negation as failure* (NAF). *not* b_j is called an *NAF-literal*. If a is an atom, we identify $\neg \neg a$ with a . The literal c is the *head* and the conjunction $a_1, \dots, a_n, \text{not } b_1, \dots, \text{not } b_m$ is the *body*. The head is nonempty, while the body is possibly empty. For each rule r of the form (1), *head(r)* represents the literal c , and *body⁺(r)* and *body⁻(r)* represent the sets $\{a_1, \dots, a_n\}$ and $\{b_1, \dots, b_m\}$, respectively. A rule is called *strict* if it is of the form:

$$c \leftarrow a_1, \dots, a_n. \quad (2)$$

Otherwise, a rule (1) is called *defeasible*. Given a program P , we use the notation *strict(P)* for the set of all strict rules of P , and *defeasible(P)* for the set of all defeasible rules of P . Clearly, $P = \text{strict}(P) \cup \text{defeasible}(P)$. A program is *NAF-free* if it consists of strict rules only. A program (rule, literal) is *ground* if it contains no variable. Throughout the paper, we handle finite ground programs unless stated otherwise.

The semantics of ELPs is given by the *answer set semantics* [4]. Let Lit be the set of all ground literals in the language of a program. A set $S (\subseteq \text{Lit})$ satisfies a ground rule r if $\text{body}^+(r) \subseteq S$ and $\text{body}^-(r) \cap S = \emptyset$ imply $\text{head}(r) \in S$. S satisfies a program P if

⁴ We invite those who claim to have found one to verify the minimality of their solution.

S satisfies every rule in P . Let P be an NAF-free ELP. Then, a set $S(\subseteq \text{Lit})$ is an *answer set* of P if S is a minimal set such that (i) S satisfies every rule from P ; and (ii) if S contains a pair of complementary literals L and $\neg L$, $S = \text{Lit}$. Next, let P be any ELP and $S \subseteq \text{Lit}$. For every rule r of P , the rule $\text{head}(r) \leftarrow \text{body}^+(r)$ is included in the *reduct* P^S if $\text{body}^-(r) \cap S = \emptyset$. Then, S is an *answer set* of P if S is an answer set of P^S . An answer set is *consistent* if it is not *Lit*. A program P is *consistent* if it has a consistent answer set; otherwise P is *inconsistent*. Remark that, by the definition, an ELP P has the answer set *Lit* iff $\text{strict}(P)$ has the answer set *Lit*.

3 Normal Extended Logic Programs

Extended logic programs often fail to have an answer set. A similar problem arises in the context of Reiter's *default logic*. To deal with the problem of the potential non-existence of extensions in default logic, a possible solution is to restrict the syntax of knowledge representation. In [6], for instance, it is shown that a *normal default theory*, in which every default has the form $\frac{\alpha:\beta}{\beta}$, always yields at least one extension. In spite of their restricted syntax, normal default theories are useful to encode a large class of commonsense knowledge. An interesting question is then whether such an approach would also be feasible for logic programming. That is, can we state some possible restrictions on the syntax and content of an ELP, under which the existence of answer sets is guaranteed?

Analogously to default logic, one possible solution would be to restrict the use of NAF in defeasible rules. That is, we restrict default negation only to occur for a literal that is the opposite of the head of the same rule. More precisely, a defeasible rule of the form:

$$c \leftarrow a_1, \dots, a_n, \text{not } \neg c \quad (3)$$

is called a *normal rule*. There is a good reason to call this type of rules normal. In fact, according to [4], the above normal rule is essentially the same as a normal default of the form: $a_1 \wedge \dots \wedge a_n : c / c$.

Unfortunately, the mere restriction that all defeasible rules should be normal rules is not enough to guarantee the existence of answer sets. The "Married John" example illustrated in Section 1 is a counter-example of this restriction. One possible diagnosis of the "Married John" example is that, apparently, some information is missing. From our commonsense knowledge, we know that someone without a spouse is not married ($\neg m \leftarrow \neg hs$) and that someone who has a spouse is not a bachelor ($\neg b \leftarrow hs$). Notice that these two rules are actually contrapositive forms of the existing rules $hs \leftarrow m$ and $\neg hs \leftarrow b$. Adding these rules yields the following logic program.

$$\begin{array}{ll} r \leftarrow & hs \leftarrow m \\ p \leftarrow & \neg m \leftarrow \neg hs \\ m \leftarrow r, \text{not } \neg m & \neg hs \leftarrow b \\ b \leftarrow p, \text{not } \neg b & \neg b \leftarrow hs. \end{array}$$

The above program has two answer sets: $\{r, p, m, hs\}$ and $\{r, p, b, \neg hs\}$. This outcome can be seen as more desirable than the outcome of the original program, where no answer set exists.

Nevertheless, contraposition (or even *transposition*, as introduced in [2]) may not be enough to guarantee the existence of answer sets. Consider the following program:

$$\begin{array}{ll} a \leftarrow & b \leftarrow a, \text{not } \neg b \\ c \leftarrow b & \neg b \leftarrow c. \end{array}$$

In this program, all defeasible rules are normal, but even when one adds the rules $\neg b \leftarrow \neg c$ and $\neg c \leftarrow b$ (which makes the set of strict rules closed under contraposition) the program still does not yield any answer sets. It indicates that in order to guarantee the existence of answer sets, additional requirements are necessary.

Definition 3.1 (transpositive, transitive, antecedent-cleaned)

Let s_1 and s_2 be strict rules. We say that s_2 is a *transpositive* version of s_1 iff:

$$s_1 = c \leftarrow a_1, \dots, a_n \text{ and}$$

$$s_2 = \neg a_i \leftarrow a_1, \dots, a_{i-1}, \neg c, a_{i+1}, \dots, a_n \text{ for some } 1 \leq i \leq n.$$

Let s_1, s_2 and s_3 be strict rules. We say that s_3 is a *transitive* version of s_1 and s_2 iff:

$$s_1 = c \leftarrow a_1, \dots, a_n,$$

$$s_2 = a_i \leftarrow b_1, \dots, b_m \text{ for some } 1 \leq i \leq n, \text{ and}$$

$$s_3 = c \leftarrow a_1, \dots, a_{i-1}, b_1, \dots, b_m, a_{i+1}, \dots, a_n.$$

Let s_1 and s_2 be strict rules. We say that s_2 is an *antecedent cleaned* version of s_1 iff:

$$s_1 = \neg a_i \leftarrow a_1, \dots, a_i, \dots, a_n \text{ and}$$

$$s_2 = \neg a_i \leftarrow a_1, \dots, a_{i-1}, a_{i+1}, \dots, a_n.$$

The intuition behind transposition can be illustrated by translating a strict rule $c \leftarrow a_1, \dots, a_n$ to a material implication $c \subset a_1 \wedge \dots \wedge a_n$. This implication is logically equivalent to $\neg a_i \subset a_1 \wedge \dots \wedge a_{i-1} \wedge \neg c \wedge a_{i+1} \wedge \dots \wedge a_n$, which is again translated to $\neg a_i \leftarrow a_1, \dots, a_{i-1}, \neg c, a_{i+1}, \dots, a_n$. Notice that, when $n = 1$, transposition coincides with classical contraposition. Transitivity and antecedent cleaning can be analyzed similarly.

Definition 3.2 (closed) Let S be a set of strict rules. Then,

- (i) S is *closed under transposition* iff for each rule s_1 in S , a rule s_2 is in S if s_2 is a transpositive version of s_1 .
- (ii) S is *closed under transitivity* iff for each rule s_1 and s_2 in S , a rule s_3 is in S if s_3 is a transitive version of s_1 and s_2 .
- (iii) S is *closed under antecedent cleaning* iff for each rule s_1 in S , a rule s_2 is in S if s_2 is an antecedent cleaned version of s_1 .

Definition 3.3 (normal ELP) A program P is called a *normal extended logic program* (normal ELP, for short) iff:

- (1) $\text{strict}(P)$ is closed under transposition, transitivity and antecedent cleaning, and
- (2) $\text{defeasible}(P)$ consists of normal rules only.

Theorem 1 Any normal ELP P has at least one answer set.

Finally, it is worth mentioning that in the context of the well-founded semantics a semi-normal extended logic program, which consists of a set of defeasible rules of the form $c \leftarrow a_1, \dots, a_n$, $\text{not } b_1, \dots, \text{not } b_m$, $\text{not } \neg c$ and a consistent set of strict rules closed under transposition (but not necessarily under transitivity and antecedent cleaning) always has a consistent well-founded model [3]. In contrast to the present work, the study shows that for well-founded semantics, weaker conditions on the content of the program apply.

Smoothed particle filtering for dynamic Bayesian networks

Theodore Charitos¹

Abstract. Particle filtering (PF) for dynamic Bayesian networks (DBNs) with discrete-state spaces includes a resampling step which concentrates samples according to their relative weight in regions of interest of the state-space. We propose a more systematic approach than resampling based on regularisation (smoothing) of the empirical distribution associated with the samples, using the kernel method. We show in our experiments that the smoothed particle filtering (SPF) leads to more accurate estimates than the PF.

1 Introduction

Let $\mathbf{V}_n = (V_n^1, \dots, V_n^m)$, $m \geq 2$, denote the set of variables at time step n . Then, a time-invariant DBN is a tuple (B_1, B_2) , where B_1 is a Bayesian network that represents the prior distribution for the variables at the first time step \mathbf{V}_1 , and B_2 defines the *transition model* in two consecutive time steps, so that for every $n \geq 2$

$$p(\mathbf{V}_n \mid \mathbf{V}_{n-1}) = \prod_{j=1}^m p(V_n^j \mid \pi(V_n^j))$$

where $\pi(V_n^j)$ denotes the set of parents of V_n^j , for $j = 1, \dots, m$. We assume that the set \mathbf{V}_n can be split in two mutually exclusive and collectively exhaustive sets $\mathbf{X}_n = (X_n^1, \dots, X_n^s)$, $\mathbf{Y}_n = (Y_n^1, \dots, Y_n^{m-s})$, where \mathbf{X}_n and \mathbf{Y}_n represent the hidden and observable variables per time step respectively. We use the term *observation model* to denote the probability to observe an instantiation of values \mathbf{y}_n for \mathbf{Y}_n given an instantiation of values \mathbf{x}_n for \mathbf{X}_n . We also denote by $\mathbf{y}_{1:k} \triangleq \{\mathbf{y}_1, \mathbf{y}_2, \dots, \mathbf{y}_k\}$ the observations up to and including time step k .

Monitoring a DBN amounts to compute the probability distribution of the hidden state at time step n given the observations, that is, $p(\mathbf{x}_n \mid \mathbf{y}_{1:n})$. For this task, Murphy [6] introduced the interface algorithm that exploits efficiently the *forward interface* \mathbf{FI}_n , which is the set of variables at time step n that affect some variables at time step $n+1$ directly. However, the computational complexity of the interface algorithm is in every time step exponential in the number of hidden variables and hence exact monitoring can be prohibitive [4], [6]. A way to handle these problems is to use sequential Monte Carlo methods that are easy to implement, work on almost any kind of DBNs and with a large number of samples are guaranteed to provide the exact answer [1], [2], [5].

2 Particle filtering

Let us assume that we are able to sample N independent and identically distributed random samples $\{\mathbf{x}_n^{(i)}; i = 1, \dots, N\}$ according

 - $\omega_n^{(i)} = \omega_n^{(i)} \times p(v_n^j \mid \mathbf{u})$
 - Return $(\mathbf{x}_n^{(i)}, \omega_n^{(i)})$
-

Figure 1: Pseudocode for sampling in DBNs.

to $p(\mathbf{X}_n \mid \mathbf{y}_{1:n})$. Then, an empirical estimate of this distribution is given by

$$p(\mathbf{x}_n \mid \mathbf{y}_{1:n}) \approx \frac{1}{N} \sum_{i=1}^N \delta_{\mathbf{x}_n^{(i)}}(d\mathbf{x}_n)$$

where $\delta(d\cdot)$ denotes the Dirac delta function. Typically, we cannot sample efficiently from the posterior distribution $p(\mathbf{X}_n \mid \mathbf{y}_{1:n})$, so instead we sample from a proposal or importance distribution $q(x)$ and weight the samples according to

$$\omega_n^{(i)} \propto \frac{p(\mathbf{x}_n^{(i)} \mid \mathbf{x}_{n-1}^{(i)}, \mathbf{y}_n)}{q(\mathbf{x}_n^{(i)} \mid \mathbf{x}_{n-1}^{(i)}, \mathbf{y}_n)}$$

to obtain the following mass approximation of $p(\mathbf{x}_n \mid \mathbf{y}_{1:n})$

$$p(\mathbf{x}_n \mid \mathbf{y}_{1:n}) \approx \sum_{i=1}^N \tilde{\omega}_n^{(i)} \delta_{\mathbf{x}_n^{(i)}}(d\mathbf{x}_n) \quad (1)$$

where $\tilde{\omega}_n^{(i)}$ is the normalised weight. For DBNs, the generation of a new sample is focused on the Bayesian network constructed on the variables $\mathbf{FI}_{n-1} \cup \mathbf{V}_n$, that represents the transition model B_2 . A pseudocode of this scheme is shown in Figure 1. The PF for monitoring DBNs consists of two consecutive steps: sampling and resampling. Schematically, for $i = 1, \dots, N$, the PF works according to

$$\{\mathbf{x}_n^{(i)}, \tilde{\omega}_n^{(i)}\} \longrightarrow \{\mathbf{x}_n^{(i')}, N^{-1}\} \longrightarrow \{\mathbf{x}_{n+1}^{(i)}, \tilde{\omega}_{n+1}^{(i)}\}$$

The success of the PF depends on whether the Dirac-point mass approximation provides an adequate representation of the posterior distribution. In the resampling step, any particular sample with a high weight will be duplicated many times. As a result, the cloud of samples may eventually collapse to a single sample. This problem is more evident if there is no system noise or the observation noise has very small variance [2]. More refined approaches such as kernel smoothing [7] can help surmount this problem.

3 Smoothed particle filtering

A smoothing scheme was proposed in [4], where the idea was to smooth the joint probability distribution of the hidden state at each time step by adding a smoothing parameter α_o to all entries in the state-space that are consistent with the observations. Sampling from the smoothed probability distribution was then performed in a two-phase process that requires the computation of a constant M which represents the total number of states consistent with the observations. Although simple to implement, this scheme has the disadvantage that the computation of M in general is $\#$ -P hard, while the cost of computing M can be as high as doing exact inference [6, pp. 89].

We propose a smoothing scheme where instead of the joint probability distribution of the hidden state we focus on the marginal probability distribution of the variables that represent the hidden state after inference has been performed. More precisely, from (1) the probability of the hidden variable X_n^j for x_h is

$$p_h = p(X_n^j = x_h \mid \mathbf{y}_{1:n}) \approx \sum_{i:X_n^{j(i)}=x_h} \tilde{\omega}_n^{(i)} \quad (2)$$

As we already argued, the PF can estimate erroneously p_h to be zero or very small. An additional reason for this can be when X_n^j is a multi-valued variable, since in this case it is possible that the sampling algorithm in Figure 1 may miss certain values of X_n^j . To avoid this problem, we apply discrete kernel methods to smooth p_h [8]. Suppose that the hidden variable X_n^j has K values where the probability for each value $h = 1, \dots, K$, is given from (2). Then, the function

$$z = \frac{N}{K-1} \sum_{h=1}^K \frac{(p_h - 1/K)^2}{1/K}$$

denotes the χ^2 Pearson test for the hypothesis that all the categories are equiprobable, standardised by the degrees of freedom $K-1$. A method of smoothing p_h is via the kernel method which gives

$$\hat{p}_h = \sum_{\ell=1}^K p_\ell W_\ell(h, \lambda) \quad (3)$$

where

$$W_\ell(h, \lambda) = \begin{cases} \lambda & \text{if } \ell = h \\ (1-\lambda)/(K-1) & \text{if } \ell \neq h \end{cases}$$

and $\lambda = (N + \alpha)/(N + \alpha K)$ with $\alpha = \begin{cases} z^{-1} & z \geq 1 \\ 1 & z < 1 \end{cases}$. The smoothing parameter α plays the role of placing some mass in value h that may have probability zero. An alternative formulation of (3) is a convex combination of p_h and the uniform estimate $1/K$, that is

$$\hat{p}_h = (1 - \epsilon)p_h + \epsilon/K \quad (4)$$

where $\epsilon = \alpha K/(N + \alpha K)$. The magnitude of α determines a trade-off between bias and variance, since a smaller value of α leads to a less biased, but with higher variance, smoothed estimator, while a larger value of α leads to a smaller variance, but biased, smoothed estimator [8].

To create a sample that will be propagated to the next time step, we need to focus on the hidden variables at time step n that belong to the forward interface \mathbf{FI}_n . That is because every variable $X_n^j \in \mathbf{FI}_n$ belongs to at least one set of parents $\pi(V_{n+1}^j)$ of a variable V_{n+1}^j , and hence a value x_n^j needs to be assigned to it in the sampling algorithm in Figure 1. This can be done easily by generating a value $x_n^{j(i')}$ for sample i' from the established smoothed distribution of X_n^j denoted as $\hat{p}(X_n^j \mid \mathbf{y}_{1:n})$. As a result, the SPF algorithm for monitoring in DBNs consists of two consecutive steps: sampling and smoothing. Schematically, for $i = 1, \dots, N$, the SPF works according to

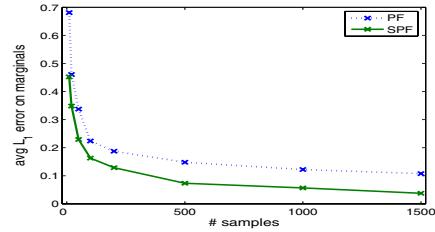

Figure 2: Error as a function of samples.

$$\{\mathbf{x}_n^{(i)}, \tilde{\omega}_n^{(i)}\} \longrightarrow \{x_n^{j(i')}, X_n^j \in \mathbf{FI}_n, \hat{p}(X_n^j \mid \mathbf{y}_{1:n})\} \longrightarrow \{\mathbf{x}_{n+1}^{(i)}, \tilde{\omega}_{n+1}^{(i)}\}$$

The samples thus generated by SPF will not suffer from the impoverishment of the support of the sample that is inevitable with PF. We must also ensure that these samples converge to random samples generated by the true distribution $p(\mathbf{x}_n \mid \mathbf{y}_{1:n})$ as N goes to infinity. Intuitively, this will happen if SPF resembles PF as N becomes larger. From (4) we notice that $\hat{p}_h \rightarrow p_h$ as $N \rightarrow \infty$, and thus we are certain that the estimate given by SPF converges to the true one.

To study the performance of the SPF we performed experiments on the *Mildew* model [3]. In doing so, we randomly created a transition and an observation model for the network where we assume that every variable could take 4 values, and subsequently generated an observation sequence. Our goal was to compare the results at each time step given by the PF and the SPF with the correct distributions computed using exact inference, which is feasible for a model of this size. We used the L_1 -norm to compute the average error on the marginal probability distributions of all the hidden variables. Figure 2 shows the error as a function of the number of samples, where we report the average error over the entire run.

4 Conclusions

We have proposed a sequential importance sampling algorithm, called SPF, to perform inference in DBNs with discrete state space. Our algorithm extends the standard PF in a sense that it replaces the resampling step with a smoothing step. We showed that the smoothing step can be done efficiently using discrete kernel methods that have the effect of placing some mass in hidden states that have erroneously been estimated to have probability zero.

Goal Revision for a Rational Agent

Célia da Costa Pereira¹ and Andrea G.B. Tettamanzi¹ and Leila Amgoud²

Abstract. We propose a general framework to represent changes in the mental state of a rational agent due to the acquisition of new information and/or to the arising of new desires; fundamental postulates and properties of the function which generates the goal set are also provided.

1 Introduction

While constructing plans is central in planning, the problem of how goals arise also needs to be addressed. That problem may be approached as in over-subscription planning [8], or as a revision problem, in a spirit akin to belief revision.

Although there has been much discussion on belief revision [6, 5, 10], goal revision has not received much attention. The few works on goal change [4, 9, 7] do not build on belief revision. Their main lack is that agents do not use their own knowledge for revising goals.

We propose an approach for dynamically constructing the goal set to be pursued by a rational agent, by considering changes in its mental state. The key to understanding goal change lies in the fundamental assumption, which is a consequence of agent rationality, that the set of desires an agent pursues must only depend on the agent's state, and not on the history of its previous states.

2 Preliminaries

Following [3], we distinguish two disjoint sets of formulas: the set \mathcal{D} of all possible desires of agents and the set \mathcal{K} of all possible knowledge items.

Definition 1 (Desire-generating Rule) A desire-generating rule is an expression of the form $b_1 \wedge \dots \wedge b_n \wedge d_1 \wedge \dots \wedge d_m \Rightarrow d$, where $b_i \in \mathcal{K}$ and $d_j, d \in \mathcal{D}$, with $d \neq d_j$ for all j .

Definition 2 (Planning Rule) A planning rule is an expression of the form $d_1 \wedge \dots \wedge d_n \rightarrow d$, where $d_i, d \in \mathcal{D}$, $d \neq d_i$ for all i .

We shall denote $\text{lhs}(R)$ the set of literals that make up the conjunction on the left-hand side of a rule R , and $\text{rhs}(R)$ the literal on the right-hand side of R . Given a set S of rules, $\text{rhs}(S) = \{\text{rhs}(R) : R \in S\}$.

Definition 3 (Agent's bases) An agent is equipped with four bases:

- belief base: $\mathcal{B} \subseteq \mathcal{K}$;
- desire base: $\mathcal{J} \subseteq \mathcal{D}$;
- desire-generating rule base: \mathcal{R}_J ;
- planning rules base: \mathcal{P} .

¹ University of Milan, Italy, email: pereira,tettamanzi@dti.unimi.it

² IRIT-CNRS, France, email: amgoud@irit.fr

The state of an agent is completely described by a 4-tuple $\mathcal{S} = \langle \mathcal{B}, \mathcal{R}_J, \mathcal{J}, \mathcal{P} \rangle$. For the sake of simplicity, we assume here that the planning rules are given and fixed.

Definition 4 (Active Desire-generating Rule) A desire-generating rule R is active in \mathcal{S} iff $\mathcal{S} \models \text{lhs}(R)$.

The activation of a desire-generating rule brings about changes in the desire base of an agent. These changes, in turn, may cause the activation/deactivation of other rules. Let $\text{Act}_z^{\mathcal{S}}$ be the set of all desire-generating rules activated by belief or desire z in \mathcal{S} , and $\text{Deact}_z^{\mathcal{S}}$ the set of all desire-generating rules deactivated by belief or desire z in \mathcal{S} .

We do not expect a rational agent to formulate desires out of whim, but based on some rational argument. To model that state of affairs, desire-generating rules play the role of rational arguments and we define a desire to be justified as follows.

Definition 5 (Justified Desire) A desire d is justified in state \mathcal{S} iff d is in \mathcal{J} , i.e., there is an active desire-generating rule R in \mathcal{R}_J such that $\text{rhs}(R) = d$.

3 Changes in the State of an Agent

The state \mathcal{S} of an agent may change either because of the acquisition of a new belief b , in which case the well known AGM operator $*$ for belief revision [1] is applied to \mathcal{B} , or because a new desire d arises. A desire d is retracted from the desire set \mathcal{J} if and only if d becomes not justified, i.e., all active desire-generating rule such that $\text{rhs}(R) = d$ become inactive. A desire d is added to a desire set \mathcal{J} if and only if the new information activates a desire-generating rule R with $\text{rhs}(R) = d$.

If $A_b^{\mathcal{S}}$ be the set of desires acquired because of the new belief b , $A_b^{\mathcal{S}} = \text{rhs}(\text{Act}_b^{\mathcal{S}})$; if $L_b^{\mathcal{S}}$ is the set of desires lost because of the acquisition of the new belief b , $L_b^{\mathcal{S}} = \{d : d \in \text{rhs}(\text{Deact}_b^{\mathcal{S}}) \wedge \neg \exists R (\mathcal{S} \models \text{lhs}(R) \wedge R \notin \text{Deact}_b^{\mathcal{S}} \wedge \text{rhs}(R) = d)\}$.

Let us denote by \oplus a desire revision operator. Then, $\mathcal{J} \oplus b = (\mathcal{J} \cup A_b^{\mathcal{S}}) \setminus L_b^{\mathcal{S}}$. It is easy to verify that $A_b^{\mathcal{S}} \cap L_b^{\mathcal{S}} = \emptyset$, for all state \mathcal{S} .

Proposition 1 The order in which two different pieces of information b_i and b_j are acquired does not affect the content of the final set of desires: $(\mathcal{J} \oplus b_i) \oplus b_j = (\mathcal{J} \oplus b_j) \oplus b_i$.

For the sake of simplicity, we consider that a new desire arises when a desire-generating rule with an empty left hand side is inserted into \mathcal{R}_J . Let us denote by \otimes the operator for updating a desire-generating rule base. When a new desire d arises, the desire-generating rule $\Rightarrow d$ is added to \mathcal{R}_J , d is added to \mathcal{J} , all desire-generating rules R in $\text{Act}_d^{\mathcal{S}}$ become activated, and all desires in the right hand side of these rules are also added to \mathcal{J} . Therefore, $\mathcal{J} \oplus d = \mathcal{J} \cup \{d\} \cup \{\text{rhs}(R), \forall R \in \text{Act}_d^{\mathcal{S}}\}$, and $\mathcal{R}_J \otimes d = \mathcal{R}_J \cup \{\Rightarrow d\}$.

Proposition 2 *The order in which two different desires d_1 and d_2 arise does not affect the final state \mathcal{S} of an agent: $\mathcal{J} \oplus d_1 \oplus d_2 = \mathcal{J} \oplus d_2 \oplus d_1$, and $\mathcal{R}_J \otimes d_1 \otimes d_2 = \mathcal{R}_J \otimes d_2 \otimes d_1$.*

Proposition 3 *Let b be a new piece of information and let d be a new desire for an agent. The new set of desires obtaining from the old set of desires \mathcal{J} by considering b and d does not depend of the order in which these two news components are known by the agent: $\mathcal{J} \oplus b \oplus d = \mathcal{J} \oplus d \oplus b$, and $\mathcal{R}_J \otimes b \otimes d = \mathcal{R}_J \otimes d \otimes b$.*

4 Comparing Desires and Sets of Desires

An agent may have many desires. However, it is essential to be able to represent the fact that not all desires have the same importance or urgency for a rational agent. One approach would be to define a function $u : \mathcal{D} \rightarrow \mathbb{R}$ which associates a real value, utility, to all desires. An alternative approach would be to establish a (partial or total) ordering among desires. In either case, we can define a reflexive and transitive preference relation \succeq between desires, by saying that $d \succeq d'$ iff the agent desires d at least as much as it desires d' . If utilities are defined, $d \succeq d'$ iff $u(d) \geq u(d')$. The \succeq relation can be easily extended from desires to sets of desires: we omit the details due to lack of space.

5 Revising Goal Sets

The main point about desires is that we expect a rational agent to try and manipulate its surrounding environment to fulfill them. In general, not all desires can be fulfilled at the same time, especially when they are conflicting [2]. Therefore, a rational agent will select a justified, coherent and feasible set of desires to realize.

Definition 6 (Coherence of a Desire) *A desire d is coherent, w.r.t. \mathcal{S} , with a set of desires \mathcal{J} iff $\exists \mathcal{I} \models \mathcal{S}$, s.t. $\forall w \in \mathcal{J}, \mathcal{I} \models d \wedge w$.*

Definition 7 (Partial plan) *A partial plan for achieving desire d is a pair $\langle H, d \rangle$ such that: $d \in \mathcal{J}$ and $H = \{d_1, \dots, d_n\}$ if there exists a planning rule $P = d_1 \wedge \dots \wedge d_n \rightarrow d$.*

Definition 8 (Complete Plan) *A complete plan [2] for achieving a desire d is a pair $\langle C, d \rangle$ with $d \in \mathcal{J}$ and C is a finite tree such that its root is a partial plan $\langle H, d \rangle$, a node $\langle \{d_1, \dots, d_n\}, d' \rangle$ has exactly n children $\langle H_1, d_1 \rangle, \dots, \langle H_n, d_n \rangle$, where $\langle H_i, d_i \rangle$ is a partial plan for d_i , and the leaves are partial plans of the form $\langle \emptyset, d_l \rangle$. The function $\text{Des}(C)$ returns the set of all desires in C .*

Definition 9 (Feasible Desire) *A desire d is feasible if there exists a complete plan $\langle C, d \rangle$ to achieve it.*

Definition 10 (Conflict between complete plans) *Two complete plans $\langle C, d \rangle$ and $\langle C', d' \rangle$ are conflicting in a state \mathcal{S} , denoted as $\langle C, d \rangle \bowtie_{\mathcal{S}} \langle C', d' \rangle$, iff $\forall \mathcal{I} \models \mathcal{S}, \mathcal{I} \not\models \text{Des}(C) \cup \text{Des}(C') \cup \mathcal{B}$.*

Definition 11 (Feasible set of Desires) *A set of feasible desires $\{d_1, \dots, d_n\}$ with the respective complete plans $\langle C_1, d_1 \rangle, \dots, \langle C_n, d_n \rangle$, is said to be feasible in state \mathcal{S} iff the plans C_i are not conflicting, i.e., iff there is an interpretation \mathcal{I} such that $\mathcal{I} \models \mathcal{S}$ and $\mathcal{I} \models \text{Des}(C_1) \cup \dots \cup \text{Des}(C_n) \cup \mathcal{B}$.*

Definition 12 (Consistency of a desire with a set) *A feasible desire d is consistent, w.r.t \mathcal{S} , with a set \mathcal{J} of desires, $\text{cons}(d|\mathcal{J})$, iff d is coherent with \mathcal{J} , justified and $\{d\} \cup \mathcal{J}$ is a feasible set.*

Definition 13 (Goal Set) *A goal set is a set of desires $\mathcal{G} \subseteq \mathcal{J}$ such that, $\forall d \in \mathcal{G}, \text{cons}(d|\mathcal{G})$.*

5.1 Postulates for Goal Revision

In general, given a set of desires \mathcal{J} , there are many possible goal sets $\mathcal{G} \subseteq \mathcal{J}$. However, a rational agent in state \mathcal{S} will elect as the set of goals it is pursuing one precise goal set \mathcal{G}^* , which depends on \mathcal{S} .

Let us call G the function which maps a state \mathcal{S} into the goal set elected by a rational agent in state \mathcal{S} : $\mathcal{G}^* = G(\mathcal{S})$. Let \odot be the goal revision operator. The goal election function G must obey three fundamental postulates:

- (**G ⊙ 1**) $\forall \mathcal{S}, G(\mathcal{S})$ is a goal set;
- (**G ⊙ 2**) $\forall \mathcal{S}$, if $\mathcal{G} \subseteq \mathcal{J}$ is a goal set, then $G(\mathcal{S}) \succeq \mathcal{G}$, i.e., a rational agent always selects the most preferable goal set.

A new desire d may become a goal in state $\mathcal{S}_d = \langle \mathcal{B}, \mathcal{J} \oplus d, \mathcal{R}_J \otimes d, \mathcal{P} \rangle$ either if d is consistent with $G(\mathcal{S})$ or if d is not consistent with $G(\mathcal{S})$, but it is preferred to all goals whose complete plans are all conflicting with all its complete plans. Therefore, revising the goal set $G(\mathcal{S})$ must be equivalent to updating the state of the agent, in particular \mathcal{J} and \mathcal{R}_J , then electing the new goal set by means of function G .

Proposition 4 $G(\mathcal{S}) \odot d = G(\mathcal{S}_d)$.

6 Conclusion

Goal revision is more complex than AGM belief revision, because the last desire does not always prevail on previous desires, and a completely different approach is required for a satisfactory treatment.

Many simplifying hypotheses have been made, but we plan on relaxing them in future work.

A Redundancy-based Method for Relation Instantiation from the Web

Viktor de Boer and Maarten van Someren and Bob J. Wielinga ¹

Abstract. The Semantic Web requires automatic ontology population methods. We developed an approach, that given existing ontologies, extracts instances of ontology relations, a specific subtask of ontology population. We use generic, domain independent techniques to extract candidate relation instances from the Web and exploit the redundancy of information on the Web to compensate for loss of precision caused by the use of these generic methods. The candidate relation instances are then ranked based on co-occurrence with a seed set. In an experiment, we extracted instances of the relation between artists and art styles. The results were manually evaluated against selected art resources.

1 INTRODUCTION

The ongoing project of the Semantic Web calls for (semi-)automatic methods for the construction of ontologies (ontology learning) and knowledge bases (ontology population)[3]. In this paper, we describe a method for *relation instantiation*, a subtask of ontology population.

We define a (partly) populated ontology as a set of labeled classes (the domain concepts) C_1, \dots, C_n , hierarchically ordered by a subclass relation. Non-hierarchical relations between concepts are also defined ($R : C_i \times C_j$). We also have a knowledge base containing instances of the ontology concepts. The task of relation instantiation is to identify for a single instance i of C_i for which instances j of C_j , the relation $R(i,j)$ is true given the information in the corpus. In this paper we assume that R is not a one-to-one relation (The instance i is related to multiple instances of C_j). We also assume that we know all instances of C_j and have a method available that recognizes these elements in the documents in our corpus. For a textual corpus such as the Web, this implies that the instances must have a textual label.

2 THE REDUNDANCY METHOD

Current approaches for Information Extraction or Question Answering tasks could also be used for ontology population. However, the performances of methods such as [2] depend on the specific structure or domain of the corpus. We designed our method to be structure- and domain-independent. Also, methods that use some form of supervised Machine Learning assume a large number of tagged example instances to be

able to learn patterns for extracting new instances and this is a serious limitation for large scale use. Our method requires only a small amount of examples that are used as a seed set.

Our approach incorporates generic methods that do not rely on assumptions about the domain or the type of documents in the corpus. By using these general methods for the extraction, we will lose in precision since the general methods are not optimized for a specific corpus or domain. However, since we use more generic methods, we are able to extract information from a greater number of sources. The main assumption behind our method is that because of the redundancy of information on the Web and because we are able to combine information from heterogeneous sources, we can compensate for this loss of precision.

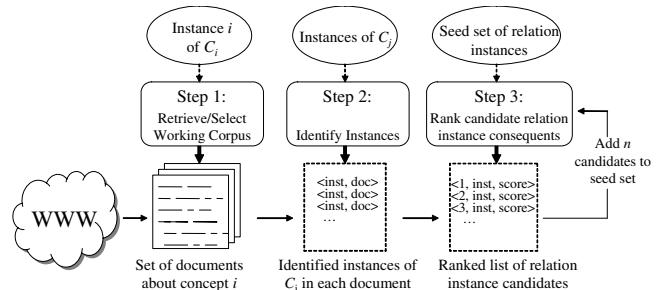

Figure 1. Outline of the method

The method consists of three steps, shown in Figure 1. We first construct a 'working corpus' by feeding the label(s) of the instance i to the Google search engine. The size of this working corpus is a parameter of the method.

In step 2, we identify the instances of the concept C_j in the documents of the working corpus. For this, we use a Named Entity Recognition module and match the results to the instances of C_j in our populated ontology, this yields our candidate relation instances.

In step 3, the method combines the evidence from the different documents to produce a ranking for these candidates. We base this ranking on the assumption that on average in individual web pages, a target relation is either well represented (the web page contains a number of correct right-hand side instances) or not represented (it contains few or none of these instances).

We therefore calculate a Document Score DS for each document. This is the probability that for all candidates in that document the relation R holds, according to the seed set. This is equal to the number of identified instances that are in the

¹ Human-Computer Studies Laboratory, Informatics Institute, Universiteit van Amsterdam, email: {vdeboer,maarten,wielinga}@science.uva.nl

seed set divided by the total number of candidate instances in that document. We then combine all evidence for each of the candidate instances by taking the average of DS over all used documents in the corpus resulting in an Instance Score IS for each candidate instance.

We then add the candidate with the highest value of IS to the seed set and iterate by recalculating all DS and IS , based on the expanded seed set. The method iterates up to a threshold on the number of iterations or a drop in the Instance Scores. In Section 3, we explore the effects of these thresholds.

3 EXTRACTING ART STYLE-ARTISTS RELATION

We tested our method in the cultural heritage domain. We used two well-known art thesauri as our partly populated ontologies: the AAT[4] and the ULAN[5]. In this experiment we extracted the instances of the relation 'has_artist' between `aat:Art Style` and `ulan:Artist`. We tested the method for nine art styles².

We first populated the seed set with three well-known artists associated with that art style. Then in Step 1, 1000 pages were extracted as a working corpus by querying Google with the labels of the art style instances. In Step 2, we used the Person Name Extractor from the tOKO toolkit[1] and matched the results to the ULAN. In Step 3, the DS and IS scores were calculated and for each art style. We evaluated the results of 40 iterations by having two annotators manually score each of the 40 retrieved relation instances as 'correct' or 'incorrect' for each art style. The annotators were allowed to consult a fixed set of encyclopedic web sources. Inter-annotator agreement (Cohen's Kappa) = 0.83. Finally, consensus was reached to calculate precision.

We first illustrate the results for a single art style: 'Neue Sachlichkeit' ('New Objectivity'). Figure 2 shows the IS for the top artists and value of precision for all 40 iterations.

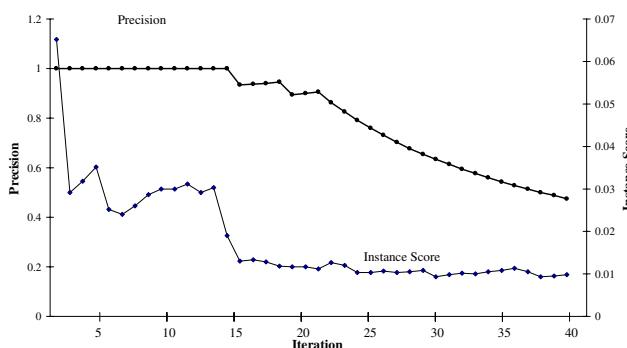

Figure 2. IS and precision for 'Neue Sachlichkeit'

The drop in precision co-occurs with a drop in IS . We can use this drop in IS as a threshold. We stop adding relation instances to the knowledge base if the value of IS of the next candidate instance is less than some drop factor, DF , multiplied by the maximum of the Instance Scores up to that iteration. We also stop adding instances after an absolute maximum number of iterations has been reached (Max). In the above example, setting DF to 0.2 and Max to 40, leads to a precision of 0.933, with 15 correct relations added.

² Art Deco, Art Nouveau, Cubism, Dada, Expressionism, Impressionism, Neo-Impressionism, Neue Sachlichkeit and Surrealism

Table 1. Average precision (prec) and total number of correct extractions (ex) for the nine Art Styles

DF	Max							
	10		20		30		40	
prec	ex	prec	ex	prec	ex	prec	ex	
0	0.856	77	0.806	145	0.722	195	0.650	234
0.1	0.856	77	0.806	145	0.721	193	0.648	228
0.2	0.856	77	0.799	137	0.776	179	0.746	197
0.3	0.865	73	0.842	117	0.830	138	0.810	144
0.4	0.857	62	0.834	96	0.826	114	0.824	120
0.5	0.902	55	0.878	86	0.868	103	0.866	109
0.6	0.924	46	0.896	67	0.882	81	0.880	87

In Table 1, we list both the average precision and the total sum of the number of correct relation instances extracted for the nine art styles for 24 combinations of the two threshold parameters DF and Max . The lowest value for precision is 0.65. This occurs at $DF=0$ (the drop in the Instance Score is not used to set the threshold) and $Max=40$. In that case, for the nine art styles, all 360 (9×40) extractions are added to the knowledge base, of which 234 are evaluated correct. The highest precision, 0.924, is reached at $DF=0.6$ and $Max=10$, with only 46 correct relation instances added to the knowledge base. We observe relatively high values for precision and a tradeoff between precision and number of correct extractions comparable to that of the traditional precision/recall tradeoff.

4 CONCLUSIONS

Considering the method uses very generic methods and intuitive ranking scores, the results are encouraging but also suggest that further processing of the results could improve the relation instantiation. Analysis of the working corpus showed the documents were highly heterogeneous in structure and language. How much redundancy helped is a topic for further research. Improvement in the Person Name Extraction module or combining different Person Name Extractors could improve the extraction. Also, other measures for DS and IS could be considered. An obvious direction for further research is to test this method on other relations in other domains.

Norms with deadlines in Dynamic Deontic Logic

Demolombe Robert¹ and Bretier Philippe² and Louis Vincent³

Abstract.

In this paper we extend the logical framework defined by K. Segerberg about norms and actions to norms that refer to deadlines. We also characterize the circumstances where these norms are violated.

1 Introduction

Interactions between artificial agents who are partially autonomous, or between human agents, are restricted by regulations that define the obligations, forbiddances or permissions they have to fulfil.

There are many papers in the literature about the formalization of regulations, or norms in general. Some norms are about the obligation to do an action. They combine obligations and actions, and there are several proposals for their formalization in the framework of modal logics [9, 10, 8, 5]. However, as far as we know, Dignum et al., in [7, 6], and Broersen et al., in [2, 3], are the only researchers who have taken into account a fundamental feature of obligations to do, which is the notion of **deadline**.

For example, if we just say that it is obligatory for some agent to pay some bill, without specifying any deadline, then the obligation will never be violated. Even if the customer never pays!

This example is clear enough to understand that the deadline is a constitutive component of an obligation to do. The objective of this paper is to present a new definition of obligations to do with deadlines.

2 Segerberg's dynamic deontic logic

Obligations to do raise a particular formalization problem with regard to obligations to be, because formulae in the scope of an obligation must denote a proposition, and actions are denoted by terms (see [9]).

The solution proposed by Segerberg in [10, 9] is to interpret an obligation to do an action as an obligation to have done this action.

His logic is defined by its semantics. The primitive notion is the notion of **point** (also called “**instant**”), which is similar to a possible world in a Kripke model. A **path** is a sequence of points that can be understood as a given evolution of the world.

An **event type** (an *event* for short) is a finite set of paths. Each path can be viewed as a particular realization of the event type.

An **individual action** is a tuple $\langle i, e, p \rangle$, where i denotes an agent, e an event type and p a path. Intuitively, i is the agent who realized the event type e along the path p .

¹ ONERA Toulouse, France, email: Robert.Demolmbe@cert.fr

² France Telecom Research and Development, France, email: philippe.bretier@francetelecom.com

³ France Telecom Research and Development, France, email: vincent.louis@francetelecom.com

A **history** is a sequence of individual actions, which can be finite or infinite, of the form: $\langle i_0, e_0, p_0 \rangle \langle i_1, e_1, p_1 \rangle \dots \langle i_n, e_n, p_n \rangle$

We say that “ i does e in h ”, if p is some path in e and $\langle i, e, p \rangle$ is an individual action of the history h . That is, in formal terms: $\exists h', h''$ such that $h = h' \langle i, e, p \rangle h''$ (h' and h'' may be empty).

We use the following notations:

- ef is the event consisting of e immediately followed by f ,
- pq is the path made up by p immediately followed by q .

We say that the histories h and h' are equivalent, and that is denoted by $h \approx h'$, iff $\exists g, g'^4$

$$h = g \langle i, e_0, p_0 \rangle \dots \langle i, e_{n-1}, p_{n-1} \rangle g' \text{ and} \\ h' = g \langle i, e_0, \dots, e_{n-1}, p_0, \dots, p_{n-1} \rangle g'$$

It is assumed that for any given history there is a definite set of possible continuations. The set of complete continuations of h is denoted by: $cont(h)$. This set represents the set of possible futures when we are at the last point of h .

It is also assumed that for every h the set $cont(h)$ can be partitioned into two categories: the set of continuations that conform to the Norm (also called “ideal histories”), denoted by $norm(h)$, and those that do not.

The formal language is the language of a propositional multi modal logic [4] with the following additional modal operators:

$[H]\phi$: it is historically necessary that ϕ .

$[D]\phi$: it is deontically necessary that ϕ .

$[F]\phi$: it will always be the case that ϕ .

$[P]\phi$: it always was the case that ϕ .

The satisfiability conditions are defined using the relation:

$$(h, g) \models \phi$$

whose intuitive meaning is: ϕ is true at a point which is the last point of the past history h , and the first point of the future history g .

If ϕ is an atomic formula A , we have $(h, g) \models A$ iff the last point of h is in the set of points that interprets A . The satisfiability conditions for logical connectives are defined as usual. For the modal operators we have:

$$(h, g) \models [H]\phi \text{ iff } \forall g' \in cont(h)((h, g') \models \phi)$$

$$(h, g) \models [D]\phi \text{ iff } \forall g' \in norm(h)((h, g') \models \phi)$$

$$(h, g) \models [F]\phi \text{ iff } \forall g_0, g_1(g = g_0 g_1 \Rightarrow (h g_0, g_1 \models \phi))$$

$$(h, g) \models [P]\phi \text{ iff } \forall h_0, h_1(h = h_0 h_1 \Rightarrow (h_0, h_1 g) \models \phi)$$

Actions are represented by terms built up with atomic actions and the constructors of sequence and non deterministic choice.

$|\alpha|$ is used to denote an event type which is the interpretation of the action α .

For each agent i we have the event-to-proposition operator:

$done_i(\alpha) : i$ has just finished doing α .

Its formal semantics is defined by:

$$(h, g) \models done_i(\alpha) \text{ iff } \exists h', e, p(p \in e \wedge e = |\alpha| \wedge h \approx h' \langle i, e, p \rangle)$$

⁴ $\exists g, g'$ abbreviates $\exists g \exists g'$, and $\forall g, g'$ abbreviates $\forall g \forall g'$.

We say that: “ i does α in h ” iff $\exists h', h'', e, p (p \in e \wedge e = |\alpha| \wedge h \approx h' < i, e, p > h'')$.

Now it is possible to introduce the two operators that represent obligation or forbiddance to do an action:

$ob_i(\alpha)$: it is obligatory for agent i to have done action α .

$fb_i(\alpha)$: it is forbidden for agent i to have done action α .

Their satisfiability conditions are:

$(h, g) \models ob_i(\alpha)$ iff $\forall g' \in cont^0(h)$

$\neg(i \text{ does } \alpha \text{ in } g') \Rightarrow \forall f \in norm(hg') (i \text{ does } \alpha \text{ in } f)$

$(h, g) \models fb_i(\alpha)$ iff $\forall g' \in cont^0(h)$

$\forall f \in norm(hg') \neg(i \text{ does } \alpha \text{ in } f)$

where $cont^0(h)$ denotes the set of h finite continuations.

The *until* operator is assigned the intuitive meaning:

$(\text{until } \phi)\psi$: ψ holds from the point where we are until ϕ holds

Its formal definition is⁵:

$(h, g) \models (\text{until } \phi)\psi$ iff $\forall g', g'' (g \approx g'g'' \Rightarrow$

$((hg', g'') \models \psi \vee \exists g_0, g_1 (g' \approx g_0g_1 \wedge (hg_0, g_1g'') \models \phi)))$

If there are several points in g where ϕ holds, $(\text{until } \phi)\psi$ guarantees that ψ holds until the point that is just before the first point where ϕ holds.

The operator $(before \phi)\psi$ is assigned the intuitive meaning:

$(before \phi)\psi$: ψ will hold, and it will hold before ϕ holds.

If ϕ and ψ have several occurrences in the future, $(before \phi)\psi$ guarantees that the first occurrence of ψ will hold before the first occurrence of ϕ . The formal definition of *before* is:

$(before \phi)\psi \stackrel{\text{def}}{=} (\text{until } \psi) \neg \phi \wedge \langle F \rangle \psi$

Then, it can be shown that we have the following valid formulas:

$ob_i(\alpha) \leftrightarrow [H](\text{until } done_i(\alpha))[D] \langle F \rangle done_i(\alpha)$

$fb_i(\alpha) \leftrightarrow [H][F][D][F] \neg done_i(\alpha)$

3 Extension to norms with deadlines

Previous definitions are now extended to norms with deadlines. We define the operator $ob_i(\alpha < d)$ whose intuitive meaning is:

$ob_i(\alpha < d)$: it is obligatory for agent i to have done the action α between the present point and the first occurrence of the proposition d . Its formal definition is:

$ob_i(\alpha < d) \stackrel{\text{def}}{=} [H](\text{until } done_i(\alpha) \vee d)[D](before d)done_i(\alpha)$

We have similar operators for forbiddance and permission. Their formal definitions are:

$fb_i(\alpha < d) \stackrel{\text{def}}{=} [H](\text{until } d)[D](\text{until } d) \neg done_i(\alpha)$

$pmi(\alpha < d) \stackrel{\text{def}}{=} [H](\text{until } d) \langle D \rangle (before d)done_i(\alpha)$

In the case where there is no deadline (i.e. d is equivalent to *false*) we get the same definitions as Segerberg.

Violations.

An obligation of the form $ob_i(\alpha < d)$ has been violated at the present instant t , if there is a past instant t_1 where:

- d has occurred, and

- before t_1 there was an instant t_2 where we had $ob_i(\alpha < d)$, and the action α has never been done between t_2 and the first instant after t_2 where d has occurred.

If $ob.viol(i, \alpha, d)$ is used to denote the formula that characterizes the violation of the obligation $ob_i(\alpha < d)$, we have:

$ob.viol(i, \alpha, d) \stackrel{\text{def}}{=} \langle P \rangle (d \wedge \langle P \rangle (ob_i(\alpha < d) \wedge (\text{until } d) \neg done_i(\alpha)))$

A forbiddance of the form $fb_i(\alpha < d)$ has been violated at the present instant t if there is a past instant t_1 where:

- we had $fb_i(\alpha < d)$, and

- between t_1 and the first occurrence of d , α has been done.

If $fb.viol(i, \alpha, d)$ is used to denote the formula that characterizes the violation of the forbiddance $fb_i(\alpha < d)$, we have:

$fb.viol(i, \alpha, d) \stackrel{\text{def}}{=} \langle P \rangle (done_i(\alpha) \wedge \langle P \rangle (fb_i(\alpha < d) \wedge (before d)done_i(\alpha)))$

In the case of permissions there is no violation. Indeed, a permission does not impose to do an action, it just offers the possibility to do an action without any violation of the norms.

4 Conclusion

We have extended the Segerberg's logical framework to norms with deadlines. This general framework proposes solutions to real needs in practical applications.

Other approaches that can be found in the state of the art.

In [8], Horty and Belnap present a logic where histories have a tree structure which has some similarities with Segerberg's structures. The main difference is that, they use a “*stir*” operator where actions are not explicitly represented.

Dignum et al.[7] have defined a temporal logic with tree structures and a *stir* operator. Norms are formalized according to the Anderson's reductionist approach [1], and there is no explicit representation of ideal histories. Moreover deontic modalities cannot be nested with other modal operators.

In Broersen et al. [2], formulas of the form $O_i(\phi, d)$ mean that it is obligatory for agent i that ϕ holds before the deadline d . But there is no explicit reference to the actions, and we see this operator as a representation of obligation to be. In [3], there is no deontic modality and norms are formalized by their violation à la Anderson.

The logical framework that has been presented could be extended in several directions. The first one is to consider obligations to be with deadlines. Another direction could be to have obligations to have started the performance of an action. Finally, an important and difficult pending problem is to find a complete axiomatics for this logic.

Adaptive Multi-Agent Programming in GTGolog

Alberto Finzi^{1,2} and Thomas Lukasiewicz^{2,1}

Abstract. We present a novel approach to adaptive multi-agent programming, which is based on an integration of the agent programming language GTGolog with adaptive dynamic programming techniques. GTGolog combines explicit agent programming in Golog with game-theoretic multi-agent planning in stochastic games. In GTGolog, the transition probabilities and reward values of the domain must be provided with the model. The adaptive generalization of GTGolog proposed here is directed towards letting the agents themselves explore and adapt these data. We use high-level programs for the generation of both abstract states and optimal policies.

1 INTRODUCTION

We present a novel approach to adaptive multi-agent programming, which is based on an integration of GTGolog [5] with multi-agent reinforcement learning as in [7]. We use high-level programs for both generating abstract states and learning policies over these abstract states. The generation of abstract states exploits the structured representation of the domain in a basic action theory in the situation calculus (SC) [9], along with the high-level control knowledge in a Golog program [9]. A learning process then incrementally adapts the model to the executive context and instantiates the partially specified behavior. To our knowledge, this is the first adaptive approach to Golog interpreting. Differently from classical Golog [9, 3], here the interpreter generates not only complex sequences of actions, but also an abstract state space for each machine state. Similarly to [2, 6], we rely on the SC machinery for state abstraction, but in our system the state generation depends on the program structure. Here, we can take advantage from the deep integration between the SC action theory and Golog programs. Similarly to hierarchical reinforcement learning [4, 1], the choice points of partially specified hierarchical programs are instantiated through reinforcement learning and dynamic programming constrained by the program structure.

2 ADAPTIVE GTGOLOG

In this section, we present AGTgolog for $n \geq 2$ agents. To introduce our framework, we refer to the following scenario inspired by [8].

Example 2.1 We have a game field which is a grid of 9×9 positions, and two agents, a and o , can move one step in the N, S, E, W directions, or remain stationary. Each of them can pick up wood or gold when at a forest or goldmine, respectively, and drop these resources at its base. Each action can fail resulting in a stationary move. A reward is received whenever a unit of wood or gold is brought back to the base of an agent. Any carried object drops when two agents collide. The game is zero-sum, hence, after each move an agent receives

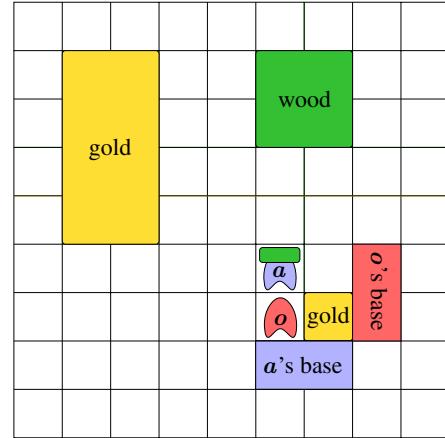

Figure 1. Example Domain

a reward consisting of the reward of its action minus the reward of the adversary action.

Domain Theory of AGTgolog. A *domain theory* of AGTgolog $DT = (AT, ST, OT)$ consists of a basic action theory AT , a *stochastic theory* ST , and an *optimization theory* OT , defined in the SC.

We assume two zero-sum competing agents a and o (called *agent* resp. *opponent*, where the former is under our control, while the latter is not). A *two-player action* is either an action a for agent a , or an action b for agent o , or two parallel actions $a||b$, one for each agent. E.g., $move(a, N)$, $move(o, W)$, and $move(a, N)||move(o, W)$ are two-player actions. The basic action theory AT represents a deterministic dynamic domain through fluent predicates, e.g., $at(q, x, y, s)$ and $holds(\alpha, o, s)$, which are defined by an FOL theory for the initial situation S_0 and *successor state axioms*, e.g.,

$$\begin{aligned} holds(\alpha, o, do(a, s)) \equiv & \quad holds(\alpha, o, s) \wedge \neg dropping(\alpha, a) \wedge \\ & \neg collision(a, s) \vee pickingUp(\alpha, o, a). \end{aligned}$$

It also encodes *action preconditions*, one for each action, e.g.,

$$Poss(pickUpS(\alpha), s) \equiv \neg \exists x (holds(\alpha, x, s)).$$

Given AT , we can specify ST . As usual in the SC [3], stochastic actions are expressed by a finite set of deterministic actions represented by AT . When a stochastic action is executed, then “nature” chooses and executes with a certain probability exactly one of its deterministic actions. E.g., we introduce the stochastic action $moveS(\alpha, m)$ (agent α executes $m \in \{N, S, E, W, stand\}$), associated with the deterministic actions $move(\alpha, m)$ and $move(\alpha, stand)$ representing success and failure, respectively. To encode probabilities in ST (and rewards in OT), we use *state formulas* and *state partitions*. A *state formula* over \vec{x}, s is an SC formula $\phi(\vec{x}, s)$ in which all predicate symbols are fluents, and the only free variables are the non-situation variables \vec{x} and the situation variable s . A *state partition* over \vec{x}, s is a nonempty set of state formulas $P(\vec{x}, s) = \{\phi_i(\vec{x}, s) \mid i \in \{1, \dots, m\}\}$ such that (i) $\forall \vec{x}, s (\phi_i(\vec{x}, s) \Rightarrow \neg \phi_j(\vec{x}, s))$ is valid

¹ Inst. für Informationssysteme, TU Wien, Favoritenstr. 9-11, A-1040 Wien.

² DIS, Università di Roma “La Sapienza”, Via Salaria 113, I-00198 Roma.

for all $i, j \in \{1, \dots, m\}$ with $j > i$, (ii) $\forall \vec{x}, s \bigvee_{i=1}^m \phi_i(\vec{x}, s)$ is valid, and (iii) every $\exists \vec{x}, s \phi_i(\vec{x}, s)$ is satisfiable. For state partitions P_1 and P_2 , we define $P_1 \otimes P_2 = \{\psi_1 \wedge \psi_2 \mid \psi_1 \in P_1, \psi_2 \in P_2, \psi_1 \wedge \psi_2 \neq \perp\}$.

Given a stochastic action a and an associated component n , we specify a state partition $P_{pr}^{a,n}(\vec{x}, s) = \{\phi_j^{a,n}(\vec{x}, s) \mid j \in \{1, \dots, m\}\}$ to group together situations s with common p such that “nature” chooses n in s with probability p , denoted $\text{prob}(a(\vec{x}), n(\vec{x}), s) = p$:

$$\exists p_1, \dots, p_m (\bigwedge_{j=1}^m (\phi_j^{a,n}(\vec{x}, s) \Leftrightarrow \text{prob}(a(\vec{x}), n(\vec{x}), s) = p_j)).$$

In our example, we assume $P_{pr}^{a,n} = \{\top\}$ for each action-component pair, e.g., $\exists p (\text{prob}(\text{pickUpS}(\alpha), \text{pickUp}(\alpha), s) = p)$.

As for the optimization theory OT , for every two-player action a , we specify a state partition $P_{rw}^a(\vec{x}, s) = \{\phi_k^a(\vec{x}, s) \mid k \in \{1, \dots, q\}\}$ to group together situations s with common r such that $a(\vec{x})$ and s assign the reward r to agent a , denoted $\text{reward}(a(\vec{x}), s) = r$:

$$\exists r_1, \dots, r_q (\bigwedge_{k=1}^q (\phi_k^a(\vec{x}, s) \Leftrightarrow \text{reward}(a(\vec{x}), s) = r_k)).$$

In our domain, we define a zero-sum reward function as follows:

$$\begin{aligned} \text{reward}(\alpha, a, s) = r &\equiv \exists r_\alpha (\text{rewAg}(\alpha, a, s) = r_\alpha \wedge \\ &\quad \exists \beta, r_\beta (\text{rewAg}(\beta, a, s) = r_\beta \wedge r = r_\alpha - r_\beta)), \\ \exists r_1, \dots, r_m (\bigwedge_{j=1}^m \phi_j^{\alpha,a}(s) &\Leftrightarrow \text{rewAg}(\alpha, a, s) = r_j). \end{aligned}$$

Here, $\phi_j^{\alpha,a}(\vec{x}, s)$ belongs to $P_{rw}^{\alpha,a}$. Moreover, a utility function associates with every reward v and success probability pr a real-valued utility $\text{utility}(v, pr)$. We assume that $\text{utility}(v, 1) = v$ and $\text{utility}(v, 0) = 0$ for all v . E.g., $\text{utility}(v, pr) = v \cdot pr$.

Syntax of AGTGolog. AGTGolog has the same syntax as standard GTGolog. Given the actions in the domain theory DT , a program p has one of the following forms:

- *Deterministic or stochastic action:* α . Do α .
- *Nondeterministic action choice of a :* $\text{choice}(a : a_1 | \dots | a_n)$. Do an optimal action (for agent a) among a_1, \dots, a_n .
- *Nondeterministic action choice of o :* $\text{choice}(o : o_1 | \dots | o_m)$. Do an optimal action (for agent o) among o_1, \dots, o_m .
- *Nondeterministic joint action choice:* $\text{choice}(a : a_1 | \dots | a_n) \parallel \text{choice}(o : o_1 | \dots | o_m)$. Do any action $a_i \parallel o_j$ with an optimal probability $\pi_{i,j}$.
- *Test action:* $\phi?$. Test the truth of ϕ in the current situation.
- *Action sequence:* $p_1; p_2$. Do p_1 followed by p_2 .
- *Nondeterministic choice of two programs:* $(p_1 \mid p_2)$. Do p_1 or p_2 .
- *Nondeterministic choice of an argument:* $\pi x(p(x))$. Do any $p(x)$.
- *Conditionals, while-loops, and procedures, including recursion.*

E.g., in our example, we define the procedure *tryToPickUp*:

```
proc(tryToPickUp, choice(a: pickUpS(a)|moveS(a, stand))||choice(o: pickUpS(o)|moveS(o, stand))).
```

State Partition Generation. Given an AGTGolog program p , a machine state consists of a subprogram p' of p and a number of steps to go h . A joint state (ϕ, p, h) consists of a state formula ϕ and a machine state (p, h) . Every machine state (p, h) is associated with a state partition, denoted $SF(p, h) = \{\phi_1(\vec{x}, s), \dots, \phi_m(\vec{x}, s)\}$. E.g., for *null program* or *zero horizon* (base case):

$$SF(\text{Nil}, h) = SF(p', 0) = \{\top\}.$$

For *deterministic first program action*, we have:

$$\begin{aligned} SF(a; p', h) = P_{rw}^a(\vec{x}, s) \otimes \{Regr(\phi(\vec{x}, do(a, s)) \wedge Poss(a, s) \mid \\ \phi(\vec{x}, s) \in SF(p', h-1)\} \cup \{\neg Poss(a, s)\} - \{\perp\}. \end{aligned}$$

For $p = \text{tryToPickUp} ; \text{carryToBase}$ and $h = 3$, each program state (e.g., $(p, 3)$ or $(p_1, 2)$, with $p_1 = \text{carryToBase}$) is associated with a suitable state partition, e.g., $SF(p, 3)$ or $SF(p_1, 2)$.

Learning Algorithm. For each joint state σ composed of a machine state (p, h) and a state formula $\phi(\vec{x}, s) \in SF(p, h)$, the learning algorithm generates the best policy $\pi(\sigma)$ for the agent a . The policy is

Algorithm $\text{Learn}(p, h)$

Input: GTGolog program p and finite horizon h .

Output: optimal policy $\pi(\phi, p, h)$ for all $\phi \in SF(p, h)$.

1. $\alpha := 1$;
2. **for each** joint state σ **do** $\langle v, pr \rangle(\sigma) := \langle 1, 1 \rangle$;
3. **repeat**
4. estimate $\phi \in SF(p, h)$;
5. $\text{Update}(\phi, p, h)$;
6. $\alpha := \alpha \cdot \text{decay}$
7. **until** $\alpha < \varepsilon$;
8. **return** $(\pi(\phi, p, h))_{\phi \in SF(p, h)}$.

Figure 2. Algorithm $\text{Learn}(p, h)$

obtained from (p, h) by replacing every single-agent choice in p by a single action, and every multi-agent choice by a collection of probability distributions $\pi(\sigma)$, one over the actions of each agent. We deploy a hierarchical version of Q-learning described in Figure 2.

We initialize the learning rate α (decaying at each cycle according to decay) and the variables $\langle v, pr \rangle(\cdot)$ representing the current value of the v -function in a joint state. At each cycle, the current state $\phi \in SF(p, h)$ is estimated. Then, from the joint state $\sigma = (\phi, (p, h))$, the procedure $\text{Update}(\phi, p, h)$ updates the values $\langle v, pr \rangle(\sigma)$ during an execution of the program p with horizon h . $\text{Update}(\phi, p, h)$ is inductively defined w.r.t. the structure of the program. E.g., if $p = a ; p'$, where a is deterministic and executable in ϕ , then $\text{Update}(\phi, p, h)$ executes a and gets *reward*; upon the $\text{Update}(do(a, \phi), p', h-1)$ execution, we have the updates $\langle v, pr \rangle(\sigma) := \langle (1 - \alpha) \cdot v(\sigma) + \alpha \cdot (\text{reward} + \gamma \cdot v(do(a, \phi), p', h-1)), pr(do(a, \phi), p', h-1) \rangle$ and $\pi(\sigma) := a ; \pi'(do(a, \phi), p', h-1)$. If $p = \text{choice}(a : a_1 | \dots | a_n) \parallel \text{choice}(o : o_1 | \dots | o_m) ; p'$, then the update step is associated with a Nash equilibrium (as in [7]): $(\pi_a, \pi_o) := \text{selectNash}(\{r_{i,j} = \text{utility}(\langle v, pr \rangle(\phi, a : a_i \parallel o : o_j ; p', h)) \mid i, j\})$; where $\langle v, pr \rangle(\sigma) := \sum_{i=1}^n \sum_{j=1}^m \pi_a(a_i) \cdot \pi_o(o_j) \cdot \langle v, pr \rangle(\phi, a : a_i \parallel o : o_j ; p', h)$. E.g., in our domain, we run the learning algorithm to instantiate a policy for the program $p = \text{tryToPickUp} ; \text{carryToBase}$, with horizon 3, i.e., $\text{Learn}(p, 3)$. The agent runs several times p (with horizon 3) playing against the opponent until the learning ends and the variables $\langle v, pr \rangle$ are stabilized for each joint state of the program p .

Formalizing Complex Task Libraries in Golog

Alfredo Gabaldon¹

Abstract. We present an approach to building libraries of *tasks* in complex action languages, such as Golog, for query answering. Our formalization is based on a situation calculus framework that allows probabilistic, temporal actions. Once a knowledge base is built containing domain knowledge including type information and a library of tasks and the goals they can achieve, we are interested in queries about the achievability of goals. We consider cases where, using domain object type and goal information in the KB, a user is able to get specific answers to a query while leaving some of the details for the system to figure out. In some cases where the specifics are missing from the KB, the user is provided with possible alternative answers that are compatible with the incomplete information in the KB. This approach is being explored in the context of a military operations planning domain for decision support.

1 Introduction

Complex activity planning as required in military operations, the construction industry, software development, etc., is usually carried out by expert hand from scratch or by reuse and adaptation of solutions to similar, previous problems. Computer assistance is used for solving the resulting scheduling problem, usually only after the set of activities necessary to achieve the desired goal has been chosen. The activity planning phase is thus time consuming because it is done by hand, and expensive because it requires domain expertise.

We are interested in building libraries of tasks in the situation calculus based action programming languages Golog [4] and its relatives. One motivation is the possibility of mitigating the time and cost overhead in complex activity planning by developing techniques that allow the reuse of libraries of tasks in an (ideally) automatic way. Although domain experts would still be required during the initial construction of such a library, once it contains a substantial amount of knowledge in the form of domain-specific, detailed tasks for achieving a number of goals, the cost incurred in this initial phase would be amortized over the many problems solved by reusing that knowledge. In order to achieve this, the library has to be in a form that can be reused by users who are not necessarily domain experts. For example, we would like the library to allow planning for the construction of a building on a soft clay ground, without consulting with an expert on how to lay foundations on such a ground if the library contains tasks for doing that. In this case, it should be enough to simply specify the type of ground, the type of building, and so on, in order to obtain from the library a detailed construction plan. If some details are missing or under specified, we ultimately would like the library to provide alternative plans, possibly including costs and risks.

Toward this end, we consider formalizing tasks and task execution in a stochastic, temporal version of Reiter's action theories in the sit-

uation calculus [6]. A task is defined by means of a set of axioms in the action theory, together with a Golog program. We also allow the user to specify properties (goals) that tasks are capable of bringing about, so that, given a goal, relevant tasks are executed without explicit invocation. This notion is useful for our purposes of designing a general task library that can be utilized by non expert users. Once this framework is in place, we then consider ways of generalizing goal achievement so that more of the burden required in retrieving information is shifted from the user to the knowledge base that contains the library. In particular, we consider the use of *generalized goals* so that tasks that achieve a very specific goal is also attempted on generalized versions of the specific goal. We also consider a form of generalized query based on *compatible types* of objects so that useful answers are obtained even in the case of incomplete information about domain objects' types. We have implemented this framework in Prolog building on the interpreters of the action programming languages mentioned above. The full version of this paper [3] contains a detailed description of this framework and sample runs obtained from the implementation.

2 Background

As a practical footing for our work, we consider a military operations planning problem described in [1]. Roughly, a problem instance in this domain consists of a description of a set of *tasks*, e.g. "anti-submarine operation", which are similar but more complex than actions in classical planning, together with a description of the initial state, including numerical quantities of available resources. A task description includes a duration, multiple possible outcomes with corresponding probabilities, resource requirements, and other pre-conditions. Also included are statements about goals that tasks can achieve, which are used to invoke relevant tasks as required by a goal. Moreover, some tasks require subgoals to hold prior or during their execution. These last two characteristics of tasks in this application resemble how Hierarchical Task Networks (HTNs) [2] and complex action languages like Golog operate. We appeal to the latter in this work, since these languages are based on a formal, logic foundation that allows stochastic, temporal actions, and is first-order [6].

One of the motivations for building a library of tasks is for using it in decision support. We are thus interested in query answering with respect to the library. For instance, we'd like to be able to issue queries such as: what is the prob. of achieving control of sea region $r2?$, and obtaining answers such as: A1: prob=0.8, executing tasks: aswWsubs,... A2: prob=0.75, executing tasks: aswWfrigates,... corresponding to two available ways of achieving the goal in the query.

3 Executing Tasks and Achieving Goals

As part of the specification of a task as described above, a "body" is defined in the form of a Golog program δ to be executed when the

¹ National ICT Australia and U. of New South Wales, Sydney, Australia, alfredo@cse.unsw.edu.au

task is invoked. A task is executed by 1) checking the arguments are of the right types, 2) substituting the arguments in the body of the task, and 3) executing the body. We formalize the execution of a task as the following Golog procedure:

```
proc execTsk(tsk,  $\vec{x}$ , t)
    typeCheck(tsk,  $\vec{x}$ )? ;
    ( $\exists \delta$ ).task(tsk,  $\vec{x}$ , t,  $\delta$ )? ;
     $\delta$ 
endProc
```

The definition of a task also includes declarations of what goals it can achieve. This allows requests that a goal be achieved without referring to a particular task. This is important for our purpose of designing libraries that can be used by non experts once the background knowledge has been stored in the libraries. For making such requests of achieving a goal, we define a procedure *achieve(goal, \vec{x} , t)*. In general there may be multiple tasks capable of achieving the same goal. For instance, the two tasks mentioned above, *aswWsubs* and *aswWfrigates*, represent two different ways of establishing control of a region of type “sea sub-surface”. Thus the *achieve* procedure is defined so that it non-deterministically chooses a task from among those that can achieve the goal, and executes it.

```
proc achieve(goal,  $\vec{x}$ , t)
    goal( $\vec{x}$ )? |
    ( $\pi tsk$ )[achievesG(tsk,  $\vec{x}$ , goal)? ;
    execTsk(tsk,  $\vec{x}$ , t)]
```

```
endProc
```

Notice that one of the choices for achieving the goal is to do nothing other than successfully test that the goal is already true. (πx) means choose an x , and $\delta_1|\delta_2$ means choose between executing δ_1 and δ_2 .

4 Generalized goals and achieve

A successful execution of a task, as defined above, requires that the parameters be of the correct type for the task. For instance, executing task *aswWsubs* on a region *reg* will only be successful if the knowledge base contains the fact that *reg* is of type *seaSubSurf*. Since we are interested in query answering we consider generalizing our framework so that goals and goal achievement can be organized into a hierarchy based on specificity.

Consider a scenario where a user issuing queries is interested in control of region *reg*, which he knows to be a sea region, but not whether it is a sea surface or a sea sub-surface. Suppose that the user does not know, but the info about the specific type of *reg* is in fact stored in the system. In such a situation, we would nevertheless like to be able to check if the goal *seaRegionCtrlEst* can be achieved for *reg*. The library should be able to invoke an appropriate task for *reg* based on its type, even if the user is not aware of it. However, we need to endow the system with the ability to figure out that, for example, if the more specific goal *seaSubSurfCtrlEst* is achieved, then the more general goal *seaRegionCtrlEst* has also been achieved. The fact that one goal is a generalized version of another cannot be derived from type information alone as it also depends on the nature of the goals. Thus for now we will rely on the knowledge engineer to provide additional information by means of statements of the form: *generalizedG(generalGoal, specificGoal)*. Since tasks that achieve a specific goal also achieve the less specific version of the goal, we can then define a generalization of *achievesG* capturing this relationship between goals by means of these statements and axiom:

$$\text{achievesG}(tsk, \vec{x}, g) \equiv \text{achievesG}_0(tsk, \vec{x}, g) \vee \\ \text{generalizedG}(g, g') \wedge \text{achievesG}_0(tsk, \vec{x}, g').$$

This results in the invocation of specific tasks, if necessary and available, for attempting to achieve a generalized goal. Type information plays a critical role in this.

Consider again the scenario mentioned above, but this time let us assume that the KB does not contain any info on whether *reg* is of type *seaSurf* or *seaSubSurf*. In this case, none of the specific tasks will execute since their type-check tests fail. Nevertheless, if the system knows *reg* is a sea region, then for a query whether control of *reg* can be achieved, we would like to obtain an answer that is more useful than “don’t know”. For instance, if a sea region must be either a *seaSurf* or a *seaSubSurf*, the system could give answers corresponding to these alternatives. For this, we introduce a test to check if the arguments passed to a task are *compatible* with the types required, where *compatible* is defined in terms of possible sub-types. Then we introduce execution of compatible tasks as a procedure *execCompTsk(tsk, \vec{x} , t)* similar to *execTsk(tsk, \vec{x} , t)*, but with a type-compatibility test instead of the strict type-check. Finally, we modify procedure *achieve* so that it tries compatible tasks when no specific task can execute:

```
proc achieve(goal,  $\vec{x}$ , t)
    goal( $\vec{x}$ )? |
    ( $\pi tsk$ )[achievesG(tsk,  $\vec{x}$ , goal)? ; execTsk(tsk,  $\vec{x}$ , t)] |
    [( $\forall tsk'$ )(achievesG(tsk',  $\vec{x}$ , goal)  $\supset$   $\neg$ typeCheck(tsk',  $\vec{x}$ ))? ; \\
    ( $\pi tsk$ )[achievesG(tsk,  $\vec{x}$ , goal)? ; \\
    execCompTsk(tsk,  $\vec{x}$ , t)]]
```

```
endProc
```

5 Conclusions

In this paper we present preliminary ideas on building a knowledge base containing a library of tasks for query answering. We discuss an encoding of stochastic, temporal tasks, and their execution, as complex actions in programming language Golog and its relatives. We consider how such a library can be used together with information about a domain’s object types to handle queries about the achievement of goals. We have also considered how to make the knowledge base more robust by allowing users to obtain useful answers even in cases where queries lack some degree of specificity, and where the knowledge base lacks detailed info about the types of certain domain objects. Much work remains to be done, including a proof of correctness of our implementation and extending the system to handle a larger class of queries.

Automated Deduction for Logics of Default Reasoning

Laura Giordano^{*} and Valentina Gliozzi[§] and Nicola Olivetti[○] and Gian Luca Pozzato^{§ 1}

Abstract. We present a tableau calculus for the rational logic **R** of default reasoning, introduced by Kraus, Lehmann and Magidor. Our calculus is obtained by introducing suitable modalities to interpret conditional assertions, it makes use of labels to represent possible worlds, and it can be used to provide a decision procedure for **R**.

1 INTRODUCTION

The work [4] of Kraus, Lehmann and Magidor (KLM) proposed a formalization of nonmonotonic reasoning that leads to a classification of nonmonotonic consequence relations, determining a hierarchy of stronger and stronger systems. The so called *KLM properties* have been widely accepted as the “conservative core” of default reasoning; in the recent literature it is shown that many different semantics for plausible reasoning are characterized by the axioms of logic **R** (including κ -rankings, parametrized probabilistic structures, ϵ -semantics and possibilistic structures) [1].

In KLM logics, defeasible knowledge is assumed to be represented by a set of nonmonotonic conditionals or assertions of the form $A \succsim B$, whose reading is *normally (or typically) the A's are B's*. The operator “ \succsim ” is nonmonotonic, in the sense that $A \succsim B$ does not imply $A \wedge C \succsim B$. In this paper we focus on logic **R**, whose axiom system includes the rule of *rational monotonicity*: if $A \succsim B$ and $\neg(A \succsim \neg C)$ hold, then one can infer $A \wedge C \succsim B$. This rule allows a conditional to be inferred from a set of conditionals in absence of other information. For instance, a knowledge base K can contain the following set of conditional assertions: *adult* \succsim *work*, *adult* \succsim *taxpayer*, *student* \succsim *adult*, *student* \succsim \neg *work*, *student* \succsim \neg *taxpayer*, whose meaning is that adults typically work, adults typically pay taxes, students are typically adults, but they typically do not work, nor do they pay taxes. In rational logic **R** one can infer the following conditional assertions from the knowledge base K : *adult* \wedge *student* \succsim \neg *work* (giving preference to more specific information), *adult* \succsim \neg *student* (i.e. typical adults are not students). Moreover, if one further knows that *adult* $\not\sim$ *married* (i.e. it is not the case the adults are typically unmarried), one can also infer that *adult* \wedge *married* \succsim *work*. Observe that one cannot infer *student* \succsim *work*.

In this work we extend the investigation of tableau procedures for propositional KLM logics developed in [3] by considering the case of **R**. We present a tableau calculus for **R** which is sound, complete and terminating. Our approach is based on a novel interpretation of **R** into an extension of modal logic **G**. As a difference with [3], here we present a *labelled* tableau system.

2 KLM RATIONAL LOGIC **R**

We briefly recall the semantics of **R**. The language of KLM logics consists just of conditional assertions $A \succsim B$. We consider a richer language allowing boolean combinations of conditional and propositional formulas. Our language \mathcal{L} is defined from a set of propositional variables ATM , the boolean connectives and the conditional operator \succsim . We use A, B, C, \dots to denote propositional formulas, whereas F, G, \dots are used to denote all formulas (even conditionals); Γ, Δ, \dots represent sets of formulas. The formulas of \mathcal{L} are defined as follows: if A is a propositional formula, $A \in \mathcal{L}$; if A and B are propositional formulas, $A \succsim B \in \mathcal{L}$; if F is a boolean combination of formulas of \mathcal{L} , $F \in \mathcal{L}$.

The semantics of **R** is defined by considering possible world structures with a preference relation (a strict partial order) $w < w'$ whose meaning is that w is preferred to w' . Moreover, the preference relation is supposed to be *modular*, i.e. for all w, w_1 and w_2 , if $w_1 < w_2$ then either $w_1 < w$ or $w < w_2$. We have that $A \succsim B$ holds in a model \mathcal{M} if B holds in all *minimal A-worlds* (w.r.t. $<$). This definition makes sense provided minimal *A*-worlds exist (whenever there are *A*-worlds). This is ensured by the *smoothness condition* in the next definition.

Definition 1 (Semantics of **R, Definition 14 in [5])** A rational model is a triple $\mathcal{M} = \langle \mathcal{W}, <, V \rangle$ where: \mathcal{W} is a non-empty set of items called worlds; $<$ is an irreflexive, transitive and modular relation on \mathcal{W} ; V is a function $V : \mathcal{W} \rightarrow \text{pow}(ATM)$, which assigns to every world w the set of atoms holding in that world. We define the truth conditions for a formula F as follows:

- If F is a boolean combination of formulas, $\mathcal{M}, w \models F$ is defined as for propositional logic;

- Let A be a propositional formula; we define $\text{Min}_{<}(A) = \{w \in \mathcal{W} \mid \mathcal{M}, w \models A \text{ and } \forall w', w' < w \text{ implies } \mathcal{M}, w' \not\models A\}$;

- $\mathcal{M}, w \models A \succsim B$ if for all $w' \in \text{Min}_{<}(A)$ then $\mathcal{M}, w' \models B$.

The relation $<$ satisfies the smoothness condition: if $\mathcal{M}, w \models A$ then $w \in \text{Min}_{<}(A)$ or $\exists w' \in \text{Min}_{<}(A)$ such that $w' < w$. We say that a formula F is valid in a model \mathcal{M} ($\mathcal{M} \models F$), if $\mathcal{M}, w \models F$ for every $w \in \mathcal{W}$. A formula is valid if it is valid in every model \mathcal{M} .

Observe that from the modularity of $<$ follows that possible worlds of \mathcal{W} are *clustered* into equivalence classes, each class consisting of worlds that are incomparable to one another, with these classes being totally ordered. In other words the property of modularity determines a *ranking* of worlds so that the semantics of **R** can be specified equivalently in terms of *ranked* models [5].

3 THE TABLEAU CALCULUS FOR **R**

We present $\mathcal{T}\mathbf{R}$, a labelled tableau calculus for rational logic **R**. The calculus makes use of labels to represent possible worlds. We con-

sider a language \mathcal{L}_R and a denumerable alphabet of labels \mathcal{A} , whose elements are denoted by x, y, z, \dots . \mathcal{L}_R extends \mathcal{L} by formulas of the form $\Box A$, where A is propositional, whose intuitive meaning is as follows: $\Box A$ holds in a world w if A holds in all the worlds w' such that $w' < w$, that is to say:

Definition 2 (Truth condition of \square) $\mathcal{M}, w \models \square A$ if for every $w' \in \mathcal{W}$ if $w' < w$ then $\mathcal{M}, w' \models A$.

It is easy to see that \Box has (among others) the properties of the modal system G: the accessibility relation (defined as xRy if $y < x$) is transitive and does not have infinite ascending chains. From definition of $\text{Min}_<(A)$ in Definition 1 above, it follows that for any formula A , $w \in \text{Min}_<(A)$ iff $\mathcal{M}, w \models A \wedge \Box\neg A$. Our tableau calculus comprises two kinds of labelled formulas: (i) *world formulas* $x : F$, whose meaning is that F holds in the possible world represented by x ; (ii) *relation formulas* of the form $x < y$, where $x, y \in \mathcal{A}$, used to represent the relation $<$. We denote by $\alpha, \beta \dots$ world or relation formulas.

We define $\Gamma_{x \rightarrow y}^M = \{y : \neg A, y : \Box \neg A \mid x : \Box \neg A \in \Gamma\}$. The calculus \mathcal{TR} is presented in Figure 1.

We conclude this section by refining \mathcal{TR} in order to ensure termination. In general, non-termination in tableau calculi can be caused by two different reasons: 1. some rules copy their principal formula in the conclusion, so that they can be reapplied over the same formula without any control; 2. rules introducing *new* labels in their conclusion(s) can generate infinitely-many worlds, creating infinite branches. As far as \mathcal{TR} is concerned, one can prove the following Theorem:

Theorem 5 Given a set of formulas Γ , the tableau generated by TR for Γ only contains a finite number of labels.

This excludes the second source of non termination (point 2). Concerning point 1, \mathcal{TR} does not ensure a terminating proof search due to (\sim^+) , which can be applied without any control. We ensure the termination by putting some constraints on (\sim^+) in \mathcal{TR} . It is easy to observe that it is useless to apply the rule on the same conditional formula more than once by using the same label x . Indeed, all formulas in the premise of (\sim^+) are kept in the conclusions, then we can assume, without loss of generality, that two applications of (\sim^+) on x are consecutive. We observe that the second application is useless, since each of the conclusions has already been obtained after the first application, and can be removed. We prevent redundant applications of (\sim^+) by keeping track of labels (worlds) in which a conditional $u : A \vdash B$ has already been applied in the current branch. To this purpose, we add to each positive conditional a list of *used* labels, then we restrict the application of (\sim^+) only to labels not occurring in the corresponding list. Notice that also the rule $(<)$ copies its principal formula $x < y$ in the conclusion; however, this rule will be applied only a finite number of times. This is a consequence of the side condition of the rule application and the fact that the number of labels in a tableau is finite (Theorem 5). Hence the rule $(<)$ does not affect the termination of the calculus.

Theorem 6 (Termination of improved TR) Let Γ be a finite set of formulas, then any tableau generated by TR (modified as described above) is finite.

4 CONCLUSIONS

In this paper we have presented an analytic and terminating tableau calculus \mathcal{TR} for the rational logic \mathbf{R} . The paper is complementary to the work [3], where the other KLM systems are considered. In future research we plan to extend our proof-procedures to first-order KLM logics on the base of the analysis carried on in [2].

Figure 1. The calculus $\mathcal{T}\mathbf{B}$. To save space, rules for \rightarrow and \vee are omitted

Definition 3 (Truth conditions of formulas of TR) Given a model $\mathcal{M} = \langle \mathcal{W}, <, V \rangle$ and a labelled alphabet \mathcal{A} , we consider a mapping $I : \mathcal{A} \mapsto \mathcal{W}$. Given a formula α of the calculus TR , we define $\mathcal{M} \models_I \alpha$ as follows: $\mathcal{M} \models_I x : F$ iff $\mathcal{M}, I(x) \models F$; $\mathcal{M} \models_I x < y$ iff $I(x) < I(y)$. We say that a set Γ of formulas of TR is satisfiable if, for all formulas $\alpha \in \Gamma$, then $\mathcal{M} \models_I \alpha$, for some model \mathcal{M} and some mapping I .

A branch is a set of tableau formulas; a branch is closed if it contains an axiom, otherwise it is open. We say that a tableau is closed if all its branches are closed. The calculus \mathcal{TR} is sound and complete w.r.t. the semantics.

Theorem 4 (Soundness and completeness) Given a set of formulas Γ , there is a closed tableau for Γ iff Γ is unsatisfiable.

Reasoning about motion patterns

Björn Gottfried¹

Abstract. In order to analyse motion patterns for the purpose of making predictions and to explain the behaviour of systems methods are required for dealing with them. Difficulties in verbalising motion patterns for the purpose of communicating spatiotemporal situations, or in order to index spatiotemporal databases, indicate the importance of means which are simple to handle by human users. This paper proposes a set of sixteen atomic motion patterns which form the basis of a relation algebra. The relations are coarse but crisp, they allow imprecise knowledge about motion patterns to be dealt with, and they are easily accessible from the point of view of the user.

1 Atomic motion patterns

We are looking for a small graphical set of motion patterns, which can be obtained by simple observations and which can be drawn as a simple query-sketch, i.e. the representation we are looking for makes clear distinctions, not requiring sophisticated measurement tools. Additionally, motion patterns are to be described in a relative way between objects to avoid working with absolute positions.

In the most simple case we are concerned with two objects, O and P, each of which moves either towards the other one or away from it. An obvious way to represent such distinctions is the orientation grid which has been introduced by [3]. This reference system allows the relative positions between objects to be described with regard to both a left-right dichotomy and a towards-away dichotomy. Fig. 1 shows how this reference system is defined: an oriented reference line (depicted as an arrow) connects the positions of O and P.

Figure 1. Left: Two objects O and P define an arrow which connects them. Right: This arrow defines a two-dimensional reference system.

Then, there are the following possibilities:

- O moves towards P,
- O moves away from P,
- O moves left with respect to P, or
- O moves right with respect to P.

Combining these four relations simultaneously for both O and P we obtain $4^2 = 16$ relations which are depicted in Fig. 2. Each relation represents a motion pattern between two time points, t_0 and t_1 , and shows the way the objects take relative to each other during this time

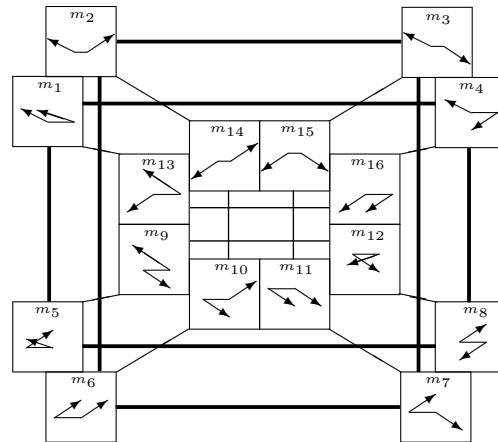

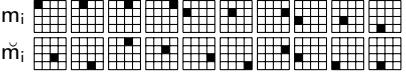

Figure 2. The neighbourhood graph of the 16 atomic motion patterns based on tripartite line tracks [1].

interval. While the two endpoints of the middle line define the initial positions of O and P at t_0 (as shown on the left hand side of Fig. 1), the head of the arrows (in Fig. 2) show their target positions at t_1 . Note that we confine ourselves to those situations in which both O and P are in general position at t_1 , i.e. we represent coarse tendencies. Including those situations in which objects can be observed precisely, so that it is possible to determine that they move exactly to the left or to the right, we obtain 36 relations. Including additionally those situations in which they can be observed to move precisely forward or backward we obtain 64 relations. Since such observations require precise measurement tools and since they are beyond what people can reliably observe it makes sense to deal with them as follows. We assign precise relations to other general relations, namely in the way that precisely forward equals forward to the right, precisely backward equals backward to the left, precisely left equals forward to the left, and precisely right equals backward to the right. However, if such precise distinctions matter they can be included in our formalism without changing any of our assumptions. In any case, we are concerned with a set of jointly exhaustive and pairwise disjoint relations. Similarly, we consider only objects which move and omit stationary objects. But stationary objects can be included in our formalism, extending only the set of atomic relations. Eventually, we include the identity relation, ID, which describes the movement pattern between two objects, such that they start at the same position and take exactly the same way. Graphically, this amounts to consider a single arrow.

Arranging the sixteen relations in a neighbourhood graph their similarity can be described by the conceptual distance among them. Fig. 2 shows this graph in which two relations are connected if they can be transformed into each other by continuously deforming or

moving the patterns without passing through another relation. Also, this graph aids in predicting motion patterns by constraining which motion patterns can occur next, provided that specific motion patterns are given. For instance, m_3 can directly follow m_2 , while m_8 cannot directly follow m_2 without passing other patterns in the meantime. The sixteen patterns form a set of jepd-relations on which a relation algebra can be defined [2]. Its table of converse relations and its composition table are given in Fig. 3 and Fig. 4, respectively. Furthermore, the usual set-theoretic operations apply. This allows the application of constraint based reasoning techniques.

2 An example application

We shall consider an example in which a claim is proved to be wrong in a civil hearing. Accordingly to a number of testimonies, O and P ran into opposite directions, away from each other. At the very same time P and Q separated, walking into different but not opposite directions, i.e. Q walked backwards with respect to P . Eventually, O and R walked towards each other, though on different sides of some object. Is it possible that R and Q is one and the same person, as claimed by a witness?

Formalising these evidences we obtain the following relations:

- $O \circ m_3 P$; though m_{14} would have also be a possible choice. However, one can choose between those relations. But as soon as we

Figure 4. Composition table: each entry shows the composition result in the form of an icon with the sixteen atomic motion patterns, which are arranged accordingly to the icon shown on the left hand side of Fig. 3; each relation that holds is printed in black.

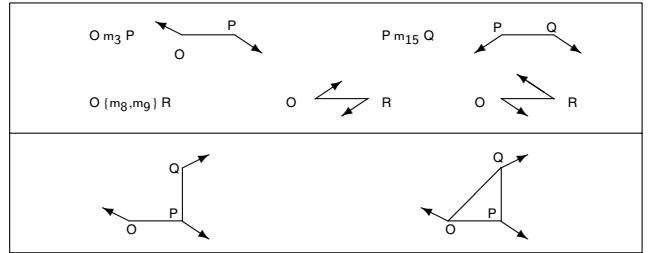

Figure 5. Upper part: graphical depiction of the observed motion patterns; lower part: the combination of $O \circ m_3 P$ and $P \circ m_{15} Q$ (left); in this instance it holds that $O \circ m_3 Q$.

commit ourselves to one of those relations, ensuing choices have to be made accordingly.

- $P \circ m_{15} Q$; here, we have to take m_{15} instead of m_2 since we decided for m_3 before.
- $O \{m_8, m_9\} R$

We assume that R and Q are equal. This especially implies that the relations between O and Q as well as between O and R have to be equal, too. We obtain the relation r between O and Q by composition: $O \circ Q = O \circ m_3 P \circ P \circ m_{15} Q = \{m_1, m_3, m_4, m_{11}, m_{12}, m_{13}, m_{15}, m_{16}\}$ (third row, fourteenth column in Fig. 4). As it holds that $\{m_8, m_9\} \not\subseteq r$, we conclude that R and Q cannot be the same person.

Fig. 5 illustrates this scenario. The assumptions are shown in the upper part of the Figure, while the lower part shows how these assumptions combine graphically. The right hand side of the lower part shows that it is neither possible to realise $O \circ m_8 Q$ nor $O \circ m_9 Q$. We conclude that R and Q are different persons.

3 Pro and con

- Whenever precise information is not available, coarse knowledge about motion patterns is better than to have no information at all.
- Incomplete information can be represented by sets of atomic motion patterns (that is, to mention those which might hold and to exclude those which cannot hold).
- Imprecise information is inherently represented by the atomic relations. Each one represents a range of variations, though perceptually clear distinctions are represented by different relations.
- As for other qualitative representations this approach suffers from a weak composition definition. But 43.75% of the relations possible can be excluded in the average in one inference step, as far as atomic motion patterns are used.
- While a set of sixteen qualitative atomic relations still exhibits a manageable size, including more relations (such as precisely left) the set of atomic relations becomes quite large, and as a consequence more difficult to handle in the context of adequate user interfaces (to observe and to draw precisely left). Note that it is sometimes just because of the difficulties to obtain precise information that such qualitative representations are used at all.

Applying OPRMs to Recursive Probability Models

Catherine Howard¹ and Markus Stumptner²

1 INTRODUCTION

Recursive probabilistic models(RPMs) are described as models where a variable may probabilistically depend on a potentially infinite, but finitely describable, set of variables [1,2]. In a RPM, a variable associated with a particular model entity may probabilistically depend on the same variable associated with a different model entity. Recursive models present two main challenges: how to compactly represent the model and how to perform inference. This paper discusses the application of the Object Oriented Probabilistic Relational Modelling Language (OPRML) to recursive probability models. We introduce the Iterative Junction Tree Construction (IJC) algorithm, a novel inference algorithm for OPRMs, which performs anytime inference to compute an approximate solution to the infinite BN described by a RPM in a finite time. We compare the performance of IJC against the Iterative Structured Variable Elimination (ISVE) algorithm [1] which was proposed for RPMs expressed using PRML. As part of this evaluation, we implemented ISVE, which to our knowledge, has not been previously implemented.

2 REPRESENTATION & REASONING

The OPRML is a typed relational language which is outlined in [3, 4]. Models produced using this language are called Object-Oriented Probabilistic Relational Models (OPRMs) [3, 4]. OPRMs specify a template for the probability distribution³ over a knowledge base (KB), where a knowledge base is defined as consisting of a set of OPRM classes and instances, a set of inverse statements and a set of instance statements. When representing and reasoning with RPMs, we place the following restrictions on the knowledge base:

- There are no inverse statements in the KB
- There are a finite number of named instances in the KB

The first restriction is used in this paper to simplify the discussion and can easily be lifted (see [1]). The second restriction cannot, because, as will be seen in Section 3, in order to reason with RPMs, we approximate the model using a finite network.

The OPRML can represent RPMs can represent recursive models very compactly for example, the OPRM shown in Figure 1 represents a RPM where a person's happiness depends on their Mother's happiness. While this model is simple, it is sufficient to illustrate the key points about representation and reasoning for RPMs.

Once we have the OPRM class specifications for the recursive model, we need an algorithm that will automatically construct the equivalent object oriented probabilistic network

¹Electronic Warfare and Radar Division, Defence Science and Technology Organisation, PO Box 1500, Edinburgh, South Australia, 5111, email: catherine.howard@dsto.defence.gov.au

²Advanced Computing Research Centre, University of South Australia, Adelaide, South Australia, 5095. email: mst@cs.unisa.edu.au

³ As with traditional BN, the probability model specified by a OPRM must be acyclic.

from the information stored in these class specifications and perform inference. Howard and Stumptner [4] present the Knowledge Based Model Construction (KBMC) and Junction Tree Construction (JC) algorithms which automatically construct models from OPRM KBs. However, these algorithms are unsuitable for RPMs because the set of variables in the recursive model is potentially infinite, these model construction algorithms may never terminate.

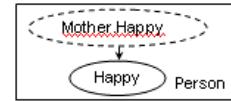

Figure 1. The OPRM for the Happiness model.

The Iterative JC (IJC) algorithm is an anytime algorithm which is an extension of the JC algorithm which addresses this problem. The IJC embodies the solution quality/execution time tradeoff by incrementally building a larger, more complex finite model to *approximate* the infinite network described by the RPM. After each iteration, the model becomes a better and better approximation and as this *approximate model* describes the probability distribution over a finite number of variables, the model construction process will terminate and exact inference can be performed in a finite time.

At design time, the class specifications are used to create the equivalent object oriented probabilistic network for each class in the KB. This network is then translated directly into a 'local' junction tree. An interface clique is created which consists of all nodes in the class's interface, κ . This interface clique is connected into the local junction tree and any loops created during this process are removed. Thus at design time, each class is 'precompiled' into a local junction tree and these local junction trees are stored in a cache.

When the IJC algorithm is executed, the desired order of approximation, n_D , is specified. Then, starting with an order of approximation, n , of one and increasing n by one in each iteration, the algorithm builds an increasing complex model which approximates the infinite network described by the RPM. In each iteration, the model from the previous iteration is built upon by instantiating the required number of generic unnamed instances of the Person class. The number of instances that are required to be added to the model will be specified by the probabilistic dependencies within the class. For example, in the Phenome and Intelligence models, a person's Phenome and Intelligence attributes depend on Phenome and Intelligence attributes of *both* parents, so 2^n generic instances will be added to the model in each iteration (where n is the order of approximation which equals the iteration number), while for the Happiness model, only 1^n instances will be added to the model per iteration.

Whenever a generic unnamed instance, Z , of the Person class is created, the appropriate local rooted junction tree, JT_{RZ} , is instantiated. A root clique for the model is created which contains all the nodes in all the generic unnamed instances' interfaces, κ_Z . Each local instance junction tree is then connected to the root clique, ω_R , to create the 'global junction

tree'. Exact inference can then be performed using this global junction tree using standard junction tree message passing techniques to return the approximate probability distribution over the query variables.

So the n^{th} iteration of the IJC algorithm produces a model which is the n^{th} order approximation to the infinite BN described by the RPM. In our example models, the order of approximation equates to the number of generations of people included in the model. As n (and hence execution time) increases, the algorithm includes more and more generations in the approximate model and returns a better and better approximate solution to the query. IJC is an interruptible anytime algorithm: it can be interrupted at any time and will return the best computed approximation so far. The meta-level control paradigm employed by the IJC algorithm is to allocate the desired order of approximation and allow the algorithm to construct a model of this order, regardless of how long it takes.

3 EXPERIMENTS

Both ISVE and IJC were implemented in MATLAB augmented with the BN Toolbox (BNT) and executed using a Pentium III, 1.2GHz computer.

Figure 2 shows that for small orders of approximation ($n \leq 15$), the IJC performs slightly better than ISVE. However, after this, there is a blowout in the inference time which can be seen clearly in Figure 2a. This blowout is clearly due to inference time as shown in Figure 2d. The inference time is being effected by the major limitation of the IJC algorithm: as the root clique must contain all the interface nodes of all the generic unnamed instances currently in the model, the root clique becomes very large very quickly. If instead of creating a root node, we propagate 'fill ins' between interface nodes in a manner similar to Multiply Sectioned Bayesian Networks, this problem may be ameliorated.

In order to compare the performance of IJC and ISVE, we need to be able to define objective metrics for measuring the quality of the solution provided by the algorithms at any given time. We cannot use the Kullback-Leibler Entropy which is the traditional measure for the quality of an approximate algorithm because as RPMs can potentially include an infinite number of variables, the true probability distribution over the query variables can not be calculated. The behaviour of an anytime algorithm is often described using a performance profile (PP) which describes how the quality of the algorithm output varies as a function of execution time. Figure 3 shows the PP of the ISVE and IJC algorithms for the Happiness model for a query on the Happy attribute where the quality is defined as one minus the normalized rate of change of the probability distribution over the query variable. This figure shows that the quality of both ISVE and IJC are non-decreasing functions of execution time. Figure 3b shows the rate of change in the probability distribution over the query variable for both algorithms. This plot shows that the rate of change of the quality of the solution is large at the early stages of execution and decreases over time. As can be seen from these figures, the IJC algorithm reaches a steady state in a shorter execution time.

Both ISVE and IJC approximate the infinite BN by a finite network which is incrementally built up to the desired order of approximation which is set at run time. Both algorithms then use exact inferencing techniques on these resulting model approximations to obtain a probability distribution over the query variables. ISVE uses a structured form of variable elimination while IJC uses a message passing algorithm. Both

IJC and ISVE take advantage of the structure of the domain by encapsulating information within individual objects so that only a small amount of information needs to be passed between objects. And both algorithms take advantage of reuse.

However, unlike PRMs, the OPRML can be used to represent RPMs without placing any restrictions on the language. We have conducted similar experiments using different domain models and we have found that, as you would expect, the comparative performance of IJC and ISVE is model dependant.

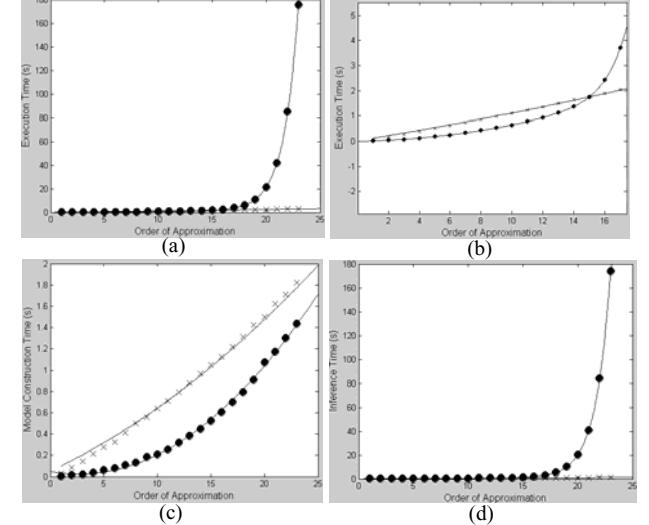

Figure 2. Plots of the IJC (circles) and ISVE (crosses) (a) execution (c) model construction and (d) inference times for the Happiness model. Fig. 2(b) is an expansion of the $n=1$ through to $n=17$ section of plot (a).

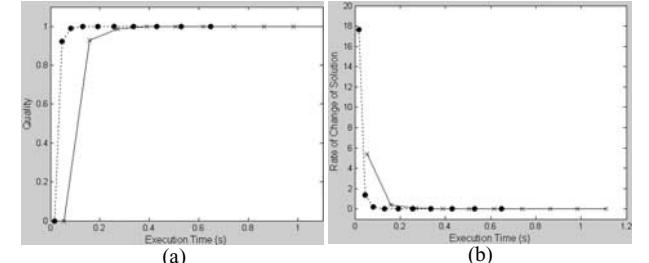

Figure 3. The quality of the IJC (circles) and ISVE (crosses) algorithms for the Happiness model.

Variable forgetting in preference relations over propositional domains

Philippe Besnard¹ and Jérôme Lang¹ and Pierre Marquis²

Abstract. Representing (and reasoning about) preference relations over combinatorial domains is computationally expensive. For many problems involving such preferences, it is relevant to simplify them by projecting them on a subset of variables. We investigate several possible definitions, focusing without loss of generality on propositional (binary) variables.

1 Introduction and background

Decision-making problems are concerned with managing agents' preferences. When the set of alternatives is small, preferences can be represented explicitly, by simply ranking alternatives, and the associated tasks such as optimization or aggregation are computationally easy. However, in many real-world applications, domains have a combinatorial structure. In that case, managing agents' preferences can be an enormous computational burden. This has led to the study of compact preference representation languages.

For some problems it may be relevant to process a preference relation, so as to simplify it and make it more compact, even if this results in a loss of information. Especially, it may be helpful to *project* a preference relation on a subset of the variables. This way of summarizing a preference relation is relevant in particular when some variables are more important than others, or when some variables should be assigned prior to others. Consider for instance a group decision making scenario. Rather than aggregating the whole preference relations before finding out an optimal assignment of variables, which generally is computationally intractable, it may be a good idea to focus on "primary" variables first, project the preference relation on those variables, aggregate them, decide on the values to be assigned to those variables, and only then consider secondary variables.

Projection operations have not been considered much as far as preference relations are concerned, but there is a huge amount of work about projecting (or *marginalizing*) probability distributions (especially when they are represented by Bayesian networks), and more generally valuation functions [6, 3], as well as sets of constraints, and propositional formulas (cf. the forgetting operation [5]). In this paper we define similar projection operations for ordinal preference relations. For the sake of simplicity, we focus on combinatorial domains formed from propositional (i.e., binary) variables.

Let V be a finite set of propositional variables. For any subset X of V , an X -alternative is an element of 2^X , that

¹ IRIT, UPS, 31062 Toulouse, France; {besnard, lang}@irit.fr

² CRIL, U. d'Artois, 62307 Lens, France; marquis@cril.univ-artois.fr

is, an assignment of a binary truth value to each one of the variables in X . X -alternatives are denoted by \vec{x} , \vec{x}' etc. If X and Y are disjoint subsets of V then the concatenation of $\vec{x} \in 2^X$ and $\vec{y} \in 2^Y$ is the $X \cup Y$ -alternative, denoted by $\vec{x}\vec{y}$, assigning values to variables of X (resp. Y) as \vec{x} (resp. \vec{y}) does.

A V -preference relation R is a reflexive and transitive relation over 2^V . The *strict preference* $>_R$ associated with R is the strict order defined by $\vec{v} >_R \vec{v}'$ iff $R(\vec{v}, \vec{v}')$ and not $R(\vec{v}', \vec{v})$. The *indifference relation* \sim_R associated with R is the equivalence relation defined by $\vec{v} \sim_R \vec{v}'$ iff $R(\vec{v}, \vec{v}')$ and $R(\vec{v}', \vec{v})$. If neither $R(\vec{v}, \vec{v}')$ nor $R(\vec{v}', \vec{v})$ holds, then \vec{v} and \vec{v}' are *incomparable* w.r.t. R , denoted by $\vec{v}Q\vec{v}'$. For the sake of notation, when we specify a preference relation explicitly, we omit pairs coming from reflexivity and transitivity. R^* denotes the transitive closure of a relation R over 2^V .

For any V -preference relation R and any partition $\{X, Y, Z\}$ of V , X is preferentially independent from Y given Z w.r.t. R iff for all $\vec{x}, \vec{x}' \in 2^X$, all $\vec{y}, \vec{y}' \in 2^Y$ and all $\vec{z} \in 2^Z$, $R(\vec{x}\vec{y}\vec{z}, \vec{x}'\vec{y}'\vec{z})$ implies $R(\vec{x}\vec{y}'\vec{z}, \vec{x}'\vec{y}'\vec{z})$. If $Z = \emptyset$ then we say that X is preferentially independent from $V \setminus X$ w.r.t. R .

2 Lower and upper projections

Definition 1 (lower and upper projections) Let R be a V -preference relation and $X \subseteq V$. Let $Y = V \setminus X$.

- $R_L^{\downarrow X}$, called the lower projection of R on X , is the binary relation over X defined as follows: $R_L^{\downarrow X}(\vec{x}, \vec{x}')$ holds iff $R(\vec{x}\vec{y}, \vec{x}'\vec{y})$ holds for all $\vec{y} \in 2^Y$;
- $R_U^{\downarrow X}$, called the upper projection of R on X , is the transitive closure of the relation R' over X defined by:
 $R'(\vec{x}, \vec{x}')$ holds iff $R(\vec{x}\vec{y}, \vec{x}'\vec{y})$ holds for some $\vec{y} \in 2^Y$.

When R is complete, $R_U^{\downarrow X}$ is obviously complete as well but $R_L^{\downarrow X}$ may fail to be complete. Other properties are:

Proposition 1 For any V -preference relations R , R' and any $X, Y \subseteq V$:

1. $R_L^{\downarrow X}$ and $R_U^{\downarrow X}$ are X -preference relations;
2. if $R \subseteq R'$ then $R_L^{\downarrow X} \subseteq (R')^{\downarrow X}_L$ and $R_U^{\downarrow X} \subseteq (R')^{\downarrow X}_U$;
3. $(R \cap R')^{\downarrow X}_L = R_L^{\downarrow X} \cap (R')^{\downarrow X}_L$; $(R \cap R')^{\downarrow X}_U \subseteq R_U^{\downarrow X} \cap (R')^{\downarrow X}_U$;
4. $((R \cup R')^*)^{\downarrow X}_U = (R_U^{\downarrow X} \cup (R')^{\downarrow X}_U)^*$;
 $(R \cup R')^{\downarrow X}_L \supseteq (R_L^{\downarrow X} \cup (R')^{\downarrow X}_L)^*$;
5. $(R_L^{\downarrow X})^{\downarrow Y}_L = (R_L^{\downarrow Y})^{\downarrow X}_L$; $(R_U^{\downarrow X})^{\downarrow Y}_U = (R_U^{\downarrow Y})^{\downarrow X}_U$.

Proposition 2 For any V -preference relation R and any $X \subseteq V$, $R_L^{\downarrow X} = R_U^{\downarrow X}$ iff X is preferentially independent from $V \setminus X$ w.r.t. R .

3 Optimistic and pessimistic projections

Definition 2 (optimistic/pessimistic projections) Let R be a V -preference relation and $X \subseteq V$. Let $Y = V \setminus X$.

- $R_{StrongOpt}^{\downarrow X}$, the strong optimistic projection of R on X , is defined by: $R_{StrongOpt}^{\downarrow X}(\vec{x}, \vec{x}') \text{ iff } \exists \vec{y} \forall \vec{y}', R(\vec{x}\vec{y}, \vec{x}'\vec{y}');$
- $R_{WeakOpt}^{\downarrow X}$, the weak optimistic projection of R on X , is defined by: $R_{WeakOpt}^{\downarrow X}(\vec{x}, \vec{x}') \text{ iff } \forall \vec{y}' \exists \vec{y} R(\vec{x}\vec{y}, \vec{x}'\vec{y}');$
- $R_{StrongPess}^{\downarrow X}$, the strong pessimistic projection of R on X , is defined by: $R_{StrongPess}^{\downarrow X}(\vec{x}, \vec{x}') \text{ iff } \exists \vec{y}' \forall \vec{y}, R(\vec{x}\vec{y}, \vec{x}'\vec{y}');$
- $R_{WeakPess}^{\downarrow X}$, the weak pessimistic projection of R on X , is defined by: $R_{WeakPess}^{\downarrow X}(\vec{x}, \vec{x}') \text{ iff } \forall \vec{y} \exists \vec{y}' R(\vec{x}\vec{y}, \vec{x}'\vec{y}').$

The optimistic projections focus on finding some possibility to have \vec{x} dominating \vec{x}' whatever the context for \vec{x}' . The pessimistic projections focus on finding some possibility to have \vec{x}' dominated by \vec{x} whatever the context for \vec{x} .

When R is complete, $R_{StrongOpt}^{\downarrow X}$ and $R_{WeakOpt}^{\downarrow X}$ coincide, as well as $R_{StrongPess}^{\downarrow X}$ and $R_{WeakPess}^{\downarrow X}$, and all four are complete. In this case, $R_{StrongOpt}^{\downarrow X}(\vec{x}, \vec{x}')$ (and equivalently $R_{WeakOpt}^{\downarrow X}(\vec{x}, \vec{x}')$) iff the best alternatives extending \vec{x} are at least as good as the best alternatives extending \vec{x}' , whereas $R_{StrongPess}^{\downarrow X}(\vec{x}, \vec{x}')$ (and equivalently $R_{WeakPess}^{\downarrow X}(\vec{x}, \vec{x}')$) iff the worst alternatives extending \vec{x} are at least as good as the worst alternatives extending \vec{x}' .³

Proposition 3 We have the following inclusions:

- $R_L^{\downarrow X} \subseteq R_{StrongOpt}^{\downarrow X} \subseteq R_{WeakOpt}^{\downarrow X} \subseteq R_U^{\downarrow X};$
- $R_L^{\downarrow X} \subseteq R_{StrongPess}^{\downarrow X} \subseteq R_{WeakPess}^{\downarrow X} \subseteq R_U^{\downarrow X}.$

4 Examples

R_1	R_2	R_3	R_4	R_5
			xy	
xy	$x\bar{y}$	$xy \rightarrow x\bar{y}$	\downarrow	$xy \sim x\bar{y}$
\downarrow	\downarrow		$\bar{x}\bar{y}$	\downarrow
$\bar{x}y$	$\bar{x}\bar{y}$	$\bar{x}y \leftarrow \bar{x}\bar{y}$	$\swarrow \searrow$	$\bar{x}y \sim \bar{x}\bar{y}$
		$\bar{x}y$	\downarrow	
			$\bar{x}y$	

When $R = R_1$: all projections on x coincide and are equal to the preference relation $x > \bar{x}$. All projections of R_1 on y coincide and are equal to the preference relation $yQ\bar{y}$ in which y and \bar{y} are incomparable.

When $R = R_2$: all projections on x are equal to $xQ\bar{x}$. $R_L^{\downarrow \{y\}}$ as well as $R_{StrongOpt}^{\downarrow \{y\}}$ and $R_{StrongPess}^{\downarrow \{y\}}$ are equal to $yQ\bar{y}$, while $R_U^{\downarrow \{y\}}$ as well as $R_{WeakOpt}^{\downarrow \{y\}}$ and $R_{WeakPess}^{\downarrow \{y\}}$ are equal to $y \sim \bar{y}$.

When $R = R_3$: $R_L^{\downarrow \{x\}}$ is equal to $xQ\bar{x}$; $R_U^{\downarrow \{x\}}$ is equal to $x \sim \bar{x}$; $R_{StrongOpt}^{\downarrow \{x\}}$ and $R_{WeakOpt}^{\downarrow \{x\}}$ are equal to $x > \bar{x}$; $R_{StrongPess}^{\downarrow \{x\}}$ is equal to $xQ\bar{x}$, while $R_{WeakPess}^{\downarrow \{x\}}$ is equal to $x \sim \bar{x}$. Things are symmetric for the projections on y .

When $R = R_4$: all projections on x are equal to $x > \bar{x}$. $R_L^{\downarrow \{y\}}$ is equal to $yQ\bar{y}$; $R_U^{\downarrow \{y\}}$ is equal to $y \sim \bar{y}$; the optimistic

projections on y (which coincide because R is complete) are equal to $y > \bar{y}$; the pessimistic projections on y (which coincide, again because R is complete) are equal to $\bar{y} > y$.

When $R = R_5$, all projections on x are equal to $x > \bar{x}$ and all projections on y are equal to $y \sim \bar{y}$.

5 Connection to propositional logic

Let L_V be the propositional language built up from V . When $\varphi \in L_V$, $Var(\varphi)$ denotes the set of propositional variables occurring in φ . We make use of the next two notions, close to the ones considered in [4]: let $\varphi \in L_V$ and $X \subseteq V$, the *strongest necessary condition* of φ on X , denoted by $\exists(V \setminus X).\varphi$, is the logically strongest formula ψ of L_X s.t. $\varphi \models \psi$; the *weakest sufficient condition* of φ on X , denoted by $\forall(V \setminus X).\varphi$, is the logically weakest formula ψ of L_X s.t. $\psi \models \varphi$. $\exists(V \setminus X).\varphi$ is also known as the *forgetting* of $V \setminus X$ in φ .

A V -preference relation is *bipartite* iff there exists $G \subseteq 2^V$ such that for all $\vec{v}, \vec{v}' \in 2^V$, then $R(\vec{v}, \vec{v}')$ holds iff $\vec{v} \in G$ or $\vec{v}' \in 2^V \setminus G$; a *characteristic formula* θ_R of a bipartite V -preference relation R is a propositional formula whose set of models is exactly G (in symbols, $Mod(\theta_R) = G$). Note that if R is bipartite, it is complete and then strong and weak projections coincide.

Proposition 4 Let R be a bipartite V -preference relation and a characteristic formula θ_R of it. Let $X \subseteq V$ and $Y = V \setminus X$. Then

- $R_{WeakOpt}^{\downarrow X} = R_{StrongOpt}^{\downarrow X}$ is the bipartite relation whose characteristic formula is $\exists(V \setminus X).\theta_R$.
- $R_{WeakPess}^{\downarrow X} = R_{StrongPess}^{\downarrow X}$ is the bipartite relation whose characteristic formula is $\forall(V \setminus X).\theta_R$.

6 Conclusion and perspectives

This paper is meant to pave the way towards simplifying and decomposing preference relations over combinatorial structures. It is still a preliminary work and raises many questions. One of the most salient issues that we did not investigate is about computing the various notions of projection when the initial preference relation is represented in a *compact representation language*. The long version of the paper also includes a section on the various possible notions of *independence* of a preference relation from a set of variables.

³ These criteria are reminiscent of those used in qualitative decision theory (see e.g., [1, 2] – with the slightly different interpretation that X -alternatives represent possible decisions and elements of $(V \setminus X)$ -alternatives represent possible states of the world).

Two Orthogonal Biases for Choosing the Intensions of Emerging Concepts in Ontology Refinement

Francesca A. Lisi and Floriana Esposito¹

1 INTRODUCTION

Ontology Refinement is the adaptation of an existing ontology to a specific domain or the needs of a particular user [5]. In this paper we consider the problem of finding subconcepts of a known concept C_{ref} , called *reference concept*, in the existing ontology Σ in the light of new knowledge coming from a data source Π . We assume that a concept C consists of two parts: an *intension* $int(C)$ and an *extension* $ext(C)$. The former is an expression belonging to a logical language \mathcal{L} whereas the latter is a set of objects that satisfy the former. More formally, given

- a reference concept $C_{ref} \in \Sigma$,
- a data set $\mathbf{r} = \Sigma \cup \Pi$,
- a language \mathcal{L}

our **Ontology Refinement problem** is to find a directed acyclic graph (DAG) \mathcal{G} of concepts C_i such that (i) $int(C_i) \in \mathcal{L}$ and (ii) $ext(C_i) \subset ext(C_{ref})$. Note that C_{ref} is among both the concepts defined in Σ and the symbols of \mathcal{L} . Furthermore $ext(C_i)$ relies on a notion of satisfiability of $int(C_i)$ w.r.t. \mathbf{r} . Note that \mathbf{r} includes Σ because in Ontology Refinement, as opposite to other forms of Ontology Learning such as Ontology Extraction (or Building), it is mandatory to consider the existing ontology and its existing connections.

A **Knowledge Representation and Reasoning (KR&R) framework** that turns out to be suitable for our problem is the one offered by the *hybrid system* $\mathcal{AL}\text{-log}$ [2]. It allows for the specification of both relational and structural data: the former is based on DATALOG [1], the latter on \mathcal{ALC} [8]. The integration of the two logical formalisms is provided by the so-called constrained DATALOG clause, i.e. a DATALOG clause with variables possibly constrained by concepts expressed in \mathcal{ALC} . Within this KR&R framework, the data set \mathbf{r} is represented as a $\mathcal{AL}\text{-log}$ knowledge base \mathcal{B} and the language \mathcal{L} contains expressions, called $\mathcal{O}\text{-queries}$, of the form

$$Q = q(X) \leftarrow \alpha_1, \dots, \alpha_m \& X : C_{ref}, \gamma_1, \dots, \gamma_n,$$

relating individuals of C_{ref} to individuals of other concepts (*task-relevant concepts*) also occurring in Σ . Thus, for a concept C , $int(C)$ is an \mathcal{O} -query $Q \in \mathcal{L}$ and $ext(C)$ is the set $answerset(Q, \mathcal{B})$ of correct answers to Q w.r.t. \mathcal{B} . The DAG \mathcal{G} is structured according to the *subset relation* between concept extensions.

As a **solution approach** to the problem, we follow a recent trend in Cluster Analysis: using *frequent (association) patterns* as candidate clusters [10]. A frequent pattern is an intensional description, expressed in a language \mathcal{L} , of a subset of a given data set \mathbf{r} whose cardinality exceeds a user-defined threshold (*minimum support*). Note

that patterns can refer to multiple levels of description granularity (*multi-grained patterns*). In any case, a frequent pattern highlights a regularity in \mathbf{r} , therefore it can be considered as the clue of a data cluster. In our context these clues are called *emerging concepts* because they are concepts whose only extension is determined. We propose to discover emerging concepts by following the approach of [3] to frequent pattern discovery at l , $1 \leq l \leq maxG$, levels of description granularity and k , $1 \leq k \leq maxD$, levels of search depth. It adapts [6] to the case of a pattern space of \mathcal{O} -queries organized according to the quasi-order $\succeq_{\mathcal{B}}$ (\mathcal{B} -subsumption).

Since multiple patterns can have the same set of supporting individuals, an **open issue** is to determine the intension for each emerging concept. As a solution to this issue we propose the criterion of choice illustrated in the next Section.

2 THE CHOICE CRITERION

The choice criterion for concept intensions has been obtained by combining two orthogonal biases: a language bias and a search bias. A *bias* concerns anything which constrains the search for theories [7]. In particular, *language bias* has to do with restrictions on the clauses in the search space whereas *search bias* has to do with the way a system searches its space of permitted clauses. In our context, the language bias allows the user to define conditions on the form of \mathcal{O} -queries to be accepted as concept intensions. E.g., it is possible to state which is the minimum level of description granularity and whether (all) the variables must be ontologically constrained or not. The search bias allows the user to define a preference criterion based on \mathcal{B} -subsumption. More precisely, it is possible to state whether the *most general description* (*m.g.d.*) or the *most specific description* (*m.s.d.*) w.r.t. $\succeq_{\mathcal{B}}$ has to be preferred. Since $\succeq_{\mathcal{B}}$ is not a total order, it can happen that two patterns P and Q , belonging to the same language \mathcal{L} , can not be compared w.r.t. $\succeq_{\mathcal{B}}$. In this case, the m.g.d. (resp. m.s.d.) of P and Q is the union (resp. conjunction) of P and Q . The two biases are combined as follows. For each frequent pattern $P \in \mathcal{L}$ that fulfills the language bias specification, the procedure for building the DAG \mathcal{G} from the set $\mathcal{F} = \{\mathcal{F}_k^l \mid 1 \leq l \leq maxG, 1 \leq k \leq maxD\}$ checks whether a concept C with $ext(C) = answerset(P)$ already exists in \mathcal{G} . If one such concept is not retrieved, a new node C with $int(C) = P$ and $ext(C) = answerset(P)$ is added to \mathcal{G} . Note that the insertion of a node can imply the reorganization of the DAG to keep it compliant with the subset relation on extents. If the node is already present in \mathcal{G} , its intension is updated according to the search bias specification.

As an illustration, we report the results of two experiments conducted on the $\mathcal{AL}\text{-log}$ knowledge base \mathcal{B}_{CIA} that has been obtained

¹ Dipartimento di Informatica, Università degli Studi di Bari, Via Orabona 4, 70125 Bari, Italy, email: {lisi, esposito}@di.uniba.it

by adding DATALOG facts² extracted from the on-line 1996 CIA World Fact Book³ to an \mathcal{ALC} ontology Σ_{CIA} concerning the concepts Country, EthnicGroup, Language, and Religion. The parameter settings are: $C_{\text{ref}} = \text{MiddleEastCountry}$, $\max D = 5$, $\max G = 3$, $\min sup^1 = 20\%$, $\min sup^2 = 13\%$, and $\min sup^3 = 10\%$. Both experiments start from the same set \mathcal{F} of 53 frequent patterns out of 99 candidate patterns and require the descriptions to have all the variables ontologically constrained by concepts from the second granularity level on. When the m.g.d. criterion is adopted, the procedure of graph building returns twelve concepts among which:

- $\mathcal{C}'_2 \in \mathcal{F}_3^2$
 $q(A) \leftarrow \text{speaks}(A, B) \&$
 $A:\text{MiddleEastCountry}, B:\text{AfroAsiaticLanguage}$
 $\{\text{IR, SA, YE}\}$
- $\mathcal{C}'_3 \in \mathcal{F}_3^2$
 $q(A) \leftarrow \text{speaks}(A, B) \&$
 $A:\text{MiddleEastCountry}, B:\text{IndoEuropeanLanguage}$
 $\{\text{ARM, IR}\}$
- $\mathcal{C}'_4 \in \mathcal{F}_5^2$
 $q(A) \leftarrow \text{speaks}(A, B), \text{believes}(A, C) \&$
 $A:\text{MiddleEastCountry},$
 $B:\text{AfroAsiaticLanguage}, C:\text{MonotheisticReligion}$
 $\{\text{IR, SA}\}$
- $\mathcal{C}'_6 \in \mathcal{F}_3^3$
 $q(A) \leftarrow \text{believes}(A, 'Druze') \& A:\text{MiddleEastCountry}$
 $\{\text{IL, SYR}\}$
- $\mathcal{C}'_7 \in \mathcal{F}_3^3$
 $q(A) \leftarrow \text{believes}(A, B) \&$
 $A:\text{MiddleEastCountry}, B:\text{JewishReligion}$
 $\{\text{IR, IL, SYR}\}$
- $\mathcal{C}'_8 \in \mathcal{F}_3^3$
 $q(A) \leftarrow \text{believes}(A, B) \&$
 $A:\text{MiddleEastCountry}, B:\text{ChristianReligion}$
 $\{\text{ARM, IR, IRQ, IL, JOR, RL, SYR}\}$
- $\mathcal{C}'_9 \in \mathcal{F}_3^3$
 $q(A) \leftarrow \text{believes}(A, B) \&$
 $A:\text{MiddleEastCountry}, B:\text{MuslimReligion}$
 $\{\text{BRN, IR, IRQ, IL, JOR, KWT, RL, OM, Q, SA, SYR, TR, UAE}\}$

organized in the DAG $\mathcal{G}'_{\text{CIA}}$. They are numbered according to the chronological order of insertion in $\mathcal{G}'_{\text{CIA}}$ and annotated with information of the generation step. From a qualitative point of view, concepts \mathcal{C}'_2 ⁴ and \mathcal{C}'_9 well characterize Middle East countries. Armenia (ARM), as opposite to Iran (IR), does not fall in these concepts. It rather belongs to the weaker characterizations \mathcal{C}'_3 and \mathcal{C}'_8 . This proves that our procedure performs a 'sensible' clustering. Indeed Armenia is a well-known borderline case for the geo-political concept of Middle East, though the Armenian is usually listed among Middle Eastern ethnic groups. Modern experts tend nowadays to consider it as part of Europe, therefore out of Middle East. But in 1996 the on-line CIA World Fact Book still considered Armenia as part of Asia.

When the m.s.d. criterion is adopted, the intensions for the concepts \mathcal{C}'_4 , \mathcal{C}'_6 and \mathcal{C}'_7 change as follows:

- $\mathcal{C}'_4 \in \mathcal{F}_5^2$
 $q(A) \leftarrow \text{speaks}(A, B), \text{believes}(A, C) \&$
 $A:\text{MiddleEastCountry},$
 $B:\text{ArabicLanguage}, C:\text{MuslimReligion}$
 $\{\text{IR, SA}\}$
- $\mathcal{C}'_6 \in \mathcal{F}_3^3$
 $q(A) \leftarrow \text{believes}(A, 'Druze'), \text{believes}(A, B),$
 $\text{believes}(A, C), \text{believes}(A, D) \&$
 $A:\text{MiddleEastCountry}, B:\text{JewishReligion},$
 $C:\text{ChristianReligion}, D:\text{MuslimReligion}$
 $\{\text{IL, SYR}\}$
- $\mathcal{C}'_7 \in \mathcal{F}_3^3$
 $q(A) \leftarrow \text{believes}(A, B), \text{believes}(A, C), \text{believes}(A, D) \&$
 $A:\text{MiddleEastCountry}, B:\text{JewishReligion},$
 $C:\text{ChristianReligion}, D:\text{MuslimReligion}$
 $\{\text{IR, IL, SYR}\}$

In particular \mathcal{C}'_6 and \mathcal{C}'_7 look quite overfitted to data. Yet overfitting allows us to realize that what distinguishes Israel (IL) and Syria (SYR) from Iran is just the presence of Druze people.

3 CONCLUSIONS AND FUTURE WORK

Our approach to Ontology Refinement takes an ontology as input and returns subconcepts of one of the concepts in the ontology. This is done by discovering strong associations between concepts in the input ontology. The idea of applying association rules in Ontology Learning has been already investigated in [4]. Yet there are several differences: [4] is conceived for Ontology Extraction instead of Ontology Refinement, uses generalized association rules (bottom-up search) instead of multi-level association rules (top-down search), adopts propositional logic instead of First Order Logic (FOL). Also our work has contact points with Vrain's proposal [9] of a top-down incremental but distance-based method for conceptual clustering in a mixed object-logical representation. For the future we plan to extensively evaluate our approach. Experiments will show, among the other things, how emerging concepts depend on the minimum support thresholds set for the stage of frequent pattern discovery.

Computing possible and necessary winners from incomplete partially-ordered preferences

M. S. Pini*, F. Rossi*, K. B. Venable*, T. Walsh**¹

1 INTRODUCTION

There are many situations where we wish to represent and reason with preferences. We consider here how to combine the preferences of multiple agents despite incompleteness and incomparability in their preference orderings. An agent's preference ordering may be incomplete because, for example, we are in the middle of eliciting their preferences. It may also contain incomparability since, for example, we might have multiple criteria we wish to optimize.

To combine preferences, we use *social welfare functions*, which map a *profile*, that is, a sequence of partial orders (one for each agent), to a partial order (the result). For example, the Pareto social welfare function orders A before B iff every agent orders A before B , else if there is some disagreement between agents declares A and B to be incomparable.

Since agents' preferences may be incomplete, we consider all the possible ways they can be completed. In each possible completion, we may obtain different optimal elements (or *winners*). This leads to the idea of *possible winners* (those outcomes which are winners in at least one possible completion) and *necessary winners* (those outcomes which are winners in all possible completions) [5].

Possible and necessary winners are useful in many scenarios including preference elicitation [3]. In fact, elicitation is over when the set of possible winners coincides with that of the necessary winners [4]. In addition, as we argue later, preference elicitation can focus just on the incompleteness concerning those outcomes which are possible and necessary winners. We can ignore completely all other outcomes.

Whilst computing the sets of possible and necessary winners is in general a difficult problem, we identify sufficient conditions where we can obtain the necessary winners and an upper approximation of the set of possible winners in polynomial time. Such conditions concern either the language for stating preferences, or general properties of the preference aggregation function.

2 FROM THE COMBINED RESULT TO WINNERS

We would like to compute efficiently the set of possible and necessary winners, as well as to determine whether a given outcome is a possible or a necessary winner. In general, even if the social welfare function is polynomially computable, incompleteness in the profile may require us to consider an exponential number of completions. As observed in [5], determining the possible winners is in NP, and the necessary winners is in coNP.

¹*: Department of Pure and Applied Mathematics, University of Padova, Italy. Email: {mpini,frossi,kvenable}@math.unipd.it. **: NICTA and UNSW, Sydney, Australia. Email: tw@cse.unsw.edu.au

We consider therefore a compact representation of all the completions that is polynomial in size. This necessarily throws away information by compacting together results into a single combined result. Given a social welfare function f and a possibly incomplete profile ip , we consider a complete binary graph, whose nodes are the outcomes, and whose arcs are labeled by non-empty subsets of $\{<, >, =, \bowtie\}$, where \bowtie represents incomparability. Label l is on the arc between outcomes A and B if there exists a completion in which A and B are related by l in the result. We call this structure the *combined result* of f and ip and we denote it with $cr(f, ip)$. We first consider how to compute the possible and necessary winners given the combined result. We will then consider how to compute the combined result.

Consider the arc between an outcome A and an outcome B in the combined result. Then, if this arc has the label $A < B$, A is not a necessary winner, since there is an outcome B which is better than A in some result. If this arc *only* has the label $A < B$, then A is not a possible winner since we must have $A < B$ in all results. Moreover, consider all the arcs between A and every other outcome C . Then, if no such arc has label $A < C$, then A is a necessary winner. Notice, however, that, even if none of the arcs connecting A have just a single label $A < C$, then we cannot be sure that A is a possible winner: A could be better than some outcomes in every completion, but there might be no completion where it is better than all of them. We define the following algorithm to compute the necessary winners and a superset of the possible winners.

Algorithm 1: Necessary and possible winners

```

Input:  $\Omega$ : set of outcomes;  $f$ : preference aggregation function;
 $ip$ : incomplete profile;
Output:  $P, N$ : sets of outcomes;
 $P \leftarrow \Omega$ ;
 $N \leftarrow \Omega$ ;
foreach  $O \in \Omega$  do
    if  $\exists O' \in \Omega$  such that  $(O < O') \in cr(f, ip)$  then
         $N \leftarrow N - O$ ;
    if  $\exists O' \in \Omega$  such that  $(O < O') \in cr(f, ip)$  and  $(OrO') \notin cr(f, ip)$  for  $r \in \{=, >, \bowtie\}$  then  $P \leftarrow P - O$ ;
return  $P, N$ ;

```

If NW is the set of necessary winners and PW is the set of possible winners, Algorithm 1 obtains $N = NW$ and $P = PW^*$, which is a superset of the set of possible winners, in time quadratic in the number of outcomes. This is optimal as the combined result we are starting from is itself quadratic in size. PW^* can be larger than the set of possible winners for two reasons. First, since we consider one arc at a time, we may not recognize completions which violate tran-

sitivity. Second, we start from the combined result where we have already thrown away some information.

The first reason for approximation (that is, non-transitivity) can be eliminated. In fact, given an outcome O , we eliminate $O < O'$ from the label of each arc connecting O in the combined result, and test whether the new structure, which we call the *possibility structure* of outcome O (or $\text{poss}(O)$) is consistent with transitivity. This test is equivalent to testing the consistency of a set of branching temporal constraints [2], which is NP-hard. Fortunately, however, there are many classes of branching temporal constraint problems which are tractable [2], and these are likely to occur when combining preferences. For example, one tractable class is defined by restricting the labels to the set $\{<, >, =\}$. That is, we do not permit incomparability (\bowtie) in the result. Another tractable case is when we combine preferences using the Pareto social welfare function.

3 TRACTABLE COMPUTATION OF POSSIBLE AND NECESSARY WINNERS

Unfortunately, a naive computation of the combined result requires applying the social welfare function to an exponential number of completions. We identify here some properties often held by preference aggregation functions which allow us to compute an upper approximation to the combined result in polynomial time. This upper approximation can then be used to compute possible and necessary winners again in polynomial time. Let us denote the set of labels of an arc between A and B in the combined result as $\text{rel}(A, B)$.

The first property we consider is *independence to irrelevant alternatives (IIA)*. A social welfare function is said to be IIA if, for any pair of outcomes A and B , the ordering between A and B in the result depends only on the relation between A and B given by the agents. Many preference aggregation functions are IIA, and this is a desirable property related to the notion of fairness in voting theory [1].

Given a function which is IIA, to compute the set $\text{rel}(A, B)$, we just need to ask each agent its preference over the pair A and B , and then use f to compute all possible results between A and B . However, if agents have incompleteness between A and B , f has to consider all the possible completions, which is exponential in the number of such agents.

Assume now that f is also *monotonic*. We say that an outcome B improves with respect to another outcome A if the relationship between A and B does not move left along the following sequence: $>, \geq, (\bowtie \text{ or } =), \leq, <$. A social welfare function f is monotonic if, given any two profiles p and p' and any two outcomes A and B , if passing from p to p' B improves with respect to A in one agent i and $p_j = p'_j$ for all $j \neq i$, then in passing from $f(p)$ to $f(p')$ B improves with respect to A .

To compute $\text{rel}(A, B)$ assuming IIA and monotonicity, we just need to consider the agents' preferences over the pair A and B . However, because of monotonicity, we don't need to consider all possible completions for all agents with incompleteness between A and B , but just two completions: $A < B$ and $B > A$. Function f will return a result for each of these two completions, say AxB and AyB , where $x, y \in \{<, >, =, \bowtie\}$. Since f is monotonic, the results of all the other completions will necessarily be between x and y in the ordering $>, \geq, (\bowtie \text{ or } =), \leq, <$.

By taking all such relations, we obtain a superset of $\text{rel}(A, B)$, that we call $\text{rel}^*(A, B)$. In fact, monotonicity of f assures that, if we consider profile $A < B$ and we get a certain result, then considering profiles where A is in a better position w.r.t. B (i.e., $A > B$, $A = B$,

or $A \bowtie B$), will give an equal or better situation for A in the result.

Notice that we have obtained the set $\text{rel}^*(A, B)$ in time polynomial in the number of agents as we only needed to consider two completions. Under the IIA and monotonicity assumptions, we can thus obtain in polynomial time a labeled graph similar to the combined result, but with possibly more labels on the arcs. Then, we can apply the same reasoning as in the previous section to this labeled graph. In fact, we can show that the additional labels do not change the necessary and possible winners computed by the algorithm. So, under the IIA and monotonicity assumptions, we can obtain NW and PW^* in polynomial time.

4 PREFERENCE ELICITATION

One use of necessary and possible winners is in eliciting preferences. At each stage in preference elicitation, there is a set of possible and necessary winners. When $NW = PW$, preference elicitation can be stopped since we have enough information to declare the winners, no matter how the remaining incompleteness is resolved [4]. At the beginning, NW is empty and PW contains all outcomes. As preferences are declared, NW grows and PW shrinks. At each step, an outcome in PW can either pass to NW or become a loser.

In those steps where PW is still larger than NW , we can use these two sets to guide preference elicitation and avoid useless work. In fact, to determine if an outcome $A \in PW - NW$ is a loser or a necessary winner, it is enough to ask agents to declare their preferences over all pairs involving A and another outcome, say B , in PW . Any outcome outside PW is a loser, and thus is dominated by at least one possible winner.

If the preference aggregation function is IIA, then all those pairs (A, B) with a defined preference for all agents can be avoided, since they will not help in determining the status of outcome A . Moreover, IIA allows us to consider just one profile when computing the relations between A and B in the result, and assures that the result is a precise relation, that is, either $<$, or $>$, or $=$, or \bowtie . In the worst case, we need to consider all such pairs. To determine all the winners, we thus need to know the relations between A and B for all $A \in PW - NW$ and $B \in PW$.

During preference elicitation, we can also use the consistency test defined in the previous section to test the consistency of the preferences of each agent. In particular, if the agent declares outcomes to be ordered or incomparable, testing the consistency of the agents' preferences is tractable. If the consistency test is successful, we can exploit the information deduced by the consistency enforcement to avoid asking for preferences which are implied by previously elicited ones. If instead we detect inconsistency, then we can help the agent to make their preferences consistent by providing one or more triangles where consistency fails.

What's a head without a body?

Christian Anger¹ and Martin Gebser¹ and Tomi Janhunen² and Torsten Schaub^{1,3}

Abstract. Concepts in Answer Set Programming (ASP) are normally defined in terms of atoms. We show that the treatment of atoms and bodies (of rules) as equitable computational objects may yield exponential speed-ups, even for standard ASP-solvers such as *smodels*. To this end, we give simple transformations providing solvers with access to both kinds of objects and show that some families of examples can be solved exponentially faster after they have been transformed. We prove that these transformations may yield exponentially smaller search spaces.

1 SIMULATING HEADS AND BODIES

For a detailed introduction to Answer Set Programming (ASP), we refer the reader to the literature (cf. [3]) and confine ourselves to formalities essential to our contribution: Given an alphabet \mathcal{P} , a *logic program* is a finite set of rules, r , of the form $p_0 \leftarrow p_1, \dots, p_m, \text{not } p_{m+1}, \dots, \text{not } p_n$ where $n \geq m \geq 0$ and $p_i \in \mathcal{P}$ is an *atom* for $0 \leq i \leq n$. Let $\text{head}(r) = p_0$ be the *head* of r and $\text{body}(r) = \{p_1, \dots, p_m, \text{not } p_{m+1}, \dots, \text{not } p_n\}$ be the *body* of r . The set of atoms occurring in a logic program Π is given by $\text{atom}(\Pi)$. The set of bodies in Π is $\text{body}(\Pi) = \{\text{body}(r) \mid r \in \Pi\}$. An *answer set* of a logic program Π is a model of Π that satisfies a certain “stability criterion” (cf. [3]).

We consider the following systems: (i) *smodels* [7], as an atom-based ASP-solver, assigning truth values to atoms only; (ii) *dlv* [5], also atom-based, yet designed for handling disjunctive logic programs; (iii) *nomore++* [1], pursuing a hybrid approach, wherein truth values are assigned to both atoms and bodies; (iv) a restriction of *nomore++* to assignments to bodies only, indicated by *nomore++^B*.⁴ All systems incorporate techniques such as propagation and lookahead in their solving procedures [1, 7].

Inspired by structural normal form translations [2], we give two simple transformations introducing new symbols for bodies and atoms, respectively. This allows standard ASP-solvers to access the underlying structures and implicitly incorporate them in their solving procedures. To this end, we extend the alphabet \mathcal{P} of a program Π by adding a new atom α_a for each $a \in \text{atom}(\Pi)$ and a new atom β_B for each $B \in \text{body}(\Pi)$. We then define a transformation over the extended alphabet:

$$\mathcal{T}_B(\Pi) = \left\{ \begin{array}{lcl} \beta_B & \leftarrow & B \\ \text{head}(r) & \leftarrow & \beta_B \end{array} \mid r \in \Pi, B = \text{body}(r) \right\}$$

This enables ASP-solvers branching on atoms, like *smodels*, to indirectly incorporate bodies as computable objects in their solving procedures. Vice versa, a different transformation over the extended

¹ Universität Potsdam, Postfach 90 03 27, D–14439 Potsdam, Germany

² Helsinki University of Technology, P.O. Box 5400, FI-02015 TKK, Finland.

³ Affiliated with Simon Fraser University, Canada.

⁴ To distinguish full-fledged *nomore++* in (iii) from this restricted variant, we sometimes add superscript $a + B$, yielding *nomore++^{a+B}*.

alphabet enables body-based systems (such as *nomore++^B*) to indirectly incorporate atoms:

$$\mathcal{T}_a(\Pi) = \left\{ \begin{array}{lcl} \alpha_a & \leftarrow & \text{body}(r) \\ a & \leftarrow & \alpha_a \end{array} \mid r \in \Pi, a = \text{head}(r) \right\}$$

As an example, consider program Π along with its transforms:

$$\begin{aligned} \Pi &= \left\{ \begin{array}{lcl} a & \leftarrow & b, \text{not } c \\ a & \leftarrow & d, \text{not } e \end{array} \right\} \\ \mathcal{T}_B(\Pi) &= \left\{ \begin{array}{lcl} \beta_{\{b, \text{not } c\}} & \leftarrow & b, \text{not } c \\ a & \leftarrow & \beta_{\{b, \text{not } c\}} \\ \beta_{\{d, \text{not } e\}} & \leftarrow & d, \text{not } e \\ a & \leftarrow & \beta_{\{d, \text{not } e\}} \end{array} \right\} \\ \mathcal{T}_a(\Pi) &= \left\{ \begin{array}{lcl} \alpha_a & \leftarrow & b, \text{not } c \\ \alpha_a & \leftarrow & d, \text{not } e \\ a & \leftarrow & \alpha_a \end{array} \right\} \end{aligned}$$

To begin with, we empirically underpin our claim that treating atoms and bodies as equitable computational objects may yield exponential speed-ups by some experimental results. As common in proof complexity [4], we need an infinite family of logic programs witnessing an exponential behavior in the best-case. For this, we consider the following programs Π_B^n and Π_a^n for $n \geq 0$:

$$\begin{aligned} \Pi_B^n &= \left\{ \begin{array}{l} r_0 : x \leftarrow \text{not } x \\ r_1 : x \leftarrow \text{not } a_1, \text{not } b_1 \\ \vdots \\ r_n : x \leftarrow \text{not } a_n, \text{not } b_n \\ r_{n+1} : a_1 \leftarrow \text{not } b_1 & r_{n+2} : b_1 \leftarrow \text{not } a_1 \\ \vdots \\ r_{3n-1} : a_n \leftarrow \text{not } b_n & r_{3n} : b_n \leftarrow \text{not } a_n \end{array} \right\} \\ \Pi_a^n &= \left\{ \begin{array}{ll} r_0 : x \leftarrow c_1, \dots, c_n, \text{not } x & \\ r_1 : c_1 \leftarrow \text{not } a_1 & r_2 : c_1 \leftarrow \text{not } b_1 \\ \vdots & \vdots \\ r_{2n-1} : c_n \leftarrow \text{not } a_n & r_{2n} : c_n \leftarrow \text{not } b_n \\ r_{2n+1} : a_1 \leftarrow \text{not } b_1 & r_{2n+2} : b_1 \leftarrow \text{not } a_1 \\ \vdots & \vdots \\ r_{4n-1} : a_n \leftarrow \text{not } b_n & r_{4n} : b_n \leftarrow \text{not } a_n \end{array} \right\} \end{aligned}$$

None of these programs has an answer set, that is, all of them are *unsatisfiable*. Importantly, this can be determined *linearly*. In both programs, the source of unsatisfiability lies in r_0 . For Programs Π_B^n , this can be found out linearly by assigning “true” to bodies of the form $\{\text{not } a_i, \text{not } b_i\}$ ($1 \leq i \leq n$) and by subsequent propagation. For *smodels*, transformation \mathcal{T}_B makes these bodies indirectly accessible. With Programs Π_a^n , assigning “false” to an atom c_i ($1 \leq i \leq n$) leads to a conflict by propagation. For *nomore++^B*, transformation \mathcal{T}_a makes these atoms indirectly accessible. The programs are composed in such a way that lookahead on the crucial structures (bodies and atoms, respectively) is able to de-

termine the optimal choices and thus ensures that the minimal number of choices is obtained.⁵ Unlike this, detecting the unsatisfiability of Π_B^n with the atom-based *smodels* strategy requires exponentially many choices. The same holds for Π_a^n with *nomore++^B*'s strategy. The *dlv* system employs a slightly different lookahead strategy with fewer lookahead operations, which is why it is unable to identify the best choices for the given program classes. We give *d lv* results purely for the record.

We have implemented the above transformations and run benchmarks on a number of instances of Π_B^n and Π_a^n and their transforms. The implementation is available at [6]. Results of these benchmarks are given in Table 1 and 2. All tests were run on an AMD Athlon 1.4GHz PC with 512MB RAM. We limited memory to 256MB and time to 900s. All results are given in terms of number of choices⁶ and seconds (in parentheses), reflecting the average of 10 runs. The application of a translation is indicated by T_B or T_a , respectively, otherwise a hyphen indicates no such application. We see that the application of transformation T_B leads to an exponential speed-up for *smodels* on Π_B^n , while T_a exponentially speeds up *nomore++^B* on Π_a^n . On the other hand, a superfluous transformation (as in the case of $T_a(\Pi_a^n)$ when running *smodels*) seems not to hurt the performance significantly. In terms of choices, the hybrid approach of *nomore++^{a+B}* lets it perform optimally on both Π_B^n and Π_a^n .

Table 2. Results for family $\{\Pi_a^n\}$.

Finally, let us show that our observation is not accidental and formally prove that the availability of both atoms and bodies may lead to exponentially smaller search spaces than obtainable in either restricted case. To this end, we apply well-known concepts from *proof complexity* [4] and show that there are infinite witnessing families of programs for which even the best-case complexity is exponential. To

⁵ With lookahead disabled, propagation does not suffice to detect unsatisfiability. Thus, linearly many choices must be made.

⁶ The choices of *d lv* are omitted since they rely on a different concept.

be more precise, we show that minimal refutations for Π_B^n and Π_a^n , i.e. proofs that the respective programs have no answer sets, require exponentially many choices in the cases of Π_B^n with *smodels* and Π_a^n with *nomore++^B*, while a linear number of choices is required for the transformed programs.

Theorem 1 *There is an infinite family $\{\Pi^n\}$ of logic programs such that the minimal number of choices made by *smodels* for determining the unsatisfiability of Π^n is $O(2^n)$ and of $T_B(\Pi^n)$ is $O(n)$.*

Theorem 2 *There is an infinite family $\{\Pi^n\}$ of logic programs such that the minimal number of choices made by *nomore++^B* for determining the unsatisfiability of Π^n is $O(2^n)$ and of $T_a(\Pi^n)$ is $O(n)$.*

In neither case is it possible to simulate this behavior polynomially, as witnessed by families $\{\Pi_B^n\}$ and $\{\Pi_a^n\}$, respectively. Finally, we note that the hybrid approach pursued by *nomore++^{a+B}* gives a best-case complexity of $O(n)$ for both classes of programs: A hybrid approach can polynomially simulate both uniform approaches.

2 DISCUSSION

We have shown that the integration of bodies as explicitly referable objects into atom-based ASP-solvers may have a great computational impact. The same holds for purely body-based (or rule-based) approaches, when introducing special atoms. Considering bodies rather than more complex formulas is motivated by the fact that they allow for replacing rules in characterizing computational concepts (see below) and by applying an “input strategy” (similar to *linear resolution*). Very simple transformations allow for exponential reductions of the best-case complexity on witnessing families of logic programs. That is, any uniform ASP-solver even equipped with the optimal heuristics will be unable to solve all witnessing programs in polynomial time. This is only possible by means of a genuinely hybrid approach, as realized in *nomore++*, or via respective transformations.

Our discovery is insofar surprising as standard ASP-solvers, such as *smodels*, rely already on twofold data structures but somehow stop “halfway”: The abstract *smodels* algorithm [7] relies on atoms (in branching and assigning truth values). However, underlying propagation and its implementation must also take rules (or bodies) into account. Consequently, the primary data structure of *smodels* is an “atom-rule graph.” Furthermore, propagation takes advantage of the concept of “active” rules, that is, rules whose bodies are not false [7]. Although bodies are vital objects in *smodels*’ propagation, they are ignored when branching.

Irrelevant Updates of Nonmonotonic Knowledge Bases

Ján Šefránek and Jozef Šiška¹

1 INTRODUCTION

The second postulate of Katsuno and Mendelzon, 2[KM] hereafter, characterizes irrelevant updates: if ψ implies μ , then $\psi \diamond \mu$ is equivalent to ψ , where ψ is a knowledge base, μ is an update and \diamond is an update operator [3].

We show that the postulate has to be modified, if nonmonotonic assumptions are considered. Our characterization of irrelevant updates is based on a dependency framework [5], which provides an alternative semantics of multidimensional dynamic logic programming (MDyLP). MDyLP [4] can be viewed as a logical idealization of nonmonotonic knowledge bases (NMKB).

Unwanted generation of new models caused by cyclic or tautological updates has been a serious problem of MDyLP for a time. Recently, the problem has been solved for dynamic logic programs in [1] and for the general MDyLP in [2]. The solution of [1] is based on Refined Extension Principle with ambition to express features essential for a “right” semantics of logic program updates. Unfortunately, the principle has not been extended to the general case of MDyLP and the trivial semantics assigning empty set of models to each dynamic logic program satisfies the principle, see [2].

We believe that the role of nonmonotonic assumptions (and dependencies on assumptions) is crucial for understanding the semantic problems of NMKBs and also for understanding unwanted generation of models.

2 DEPENDENCY FRAMEWORK

We assume a language \mathcal{L} with a set of atoms \mathcal{A} . In general, a language of the dependency framework contains a set of assumptions. In this extended abstract are assumptions represented by a set of negative literals $\mathcal{D} = \{\text{not } A \mid A \in \mathcal{A}\}$, where *not* is a default negation. The set of literals is $\text{Lit} = \mathcal{A} \cup \mathcal{D}$.

Definition 1 A dependency relation is a set of pairs $\{(L, W) \mid L \in \text{Lit}, W \subseteq \text{Lit}, L \notin W\}$.

$Xs \subseteq \mathcal{D}$ is called a sound set of assumptions (SSOA) w.r.t. the dependency relation \ll iff the set $Cn_{\ll}(Xs) = \{L \in \text{Lit} \mid L \ll Xs\} \cup Xs$ is non-empty and consistent.

It is said that a SSOA Xs is total (TSSOA) iff for each $A \in \mathcal{A}$ holds either $A \in Cn_{\ll}(Xs)$ or $\text{not } A \in Cn_{\ll}(Xs)$. The set of all (T)SSOAs w.r.t. \ll is denoted by $(T)SSOA(\ll)$. \square

Each NMKB consisting of rules can be mapped into the dependency framework. We will present a mapping of generalized logic programs (programs hereafter) and multidimensional dynamic logic programs (multiprograms hereafter) into the dependency framework.

A program consists of a set of rules of the form $L_0 \leftarrow L_1, \dots, L_k$, where L_i is a literal. L_0 is denoted by $\text{head}(r)$ and $\{L_1, \dots, L_k\}$ by $\text{body}(r)$, if a rule r is considered. A multiprogram is a set of programs together with a preference relation – a partial order on the set of programs. If there are some conflicts between programs, they are solved according to the preference relation – information from the less preferred programs is rejected.

Definition 2 A literal L depends on a set of literals W , $L \notin W$, with respect to a program P ($L \ll_P W$) iff there is a sequence of rules $\langle r_1, \dots, r_k \rangle$, $k \geq 1$, and $\text{head}(r_k) = L$, $W \models \text{body}(r_1)$, for each i , $1 \leq i < k$, $W \cup \{\text{head}(r_1), \dots, \text{head}(r_i)\} \models \text{body}(r_{i+1})$.

It is said that the dependency relation \ll_P is generated by the program P . \square

Notice that a literal cannot depend on itself (also in a context of other literals). Next theorem shows that a semantics of the dependency framework based on TSSOAs is equivalent to stable model (answer set) semantics of logic programs.

Theorem 3 X is a TSSOA w.r.t. \ll_P iff $Cn_{\ll_P}(X)$ is a stable model of P . Let S be a stable model of P . Then there is $X \subseteq \mathcal{D}$, a TSSOA w.r.t. \ll_P such that $S = Cn_{\ll_P}(X)$. \square

Next example illustrates Theorem 3 and it also shows that dependencies in multiprograms are well defined. Only the most simple multiprograms of the form $\langle P, U \rangle$, where U is more preferred (updating) program are considered here because of the limited space. However, the results are extendable to the general case.

Example 4 $P = \{a \leftarrow \text{not } b; b \leftarrow \text{not } a\}$, $U = \{\text{not } b \leftarrow \text{not } a\}$.

There are two TSSOAs w.r.t. \ll_P : $Xs_1 = \{\text{not } b\}$, $Xs_2 = \{\text{not } a\}$. $Cn_{\ll_P}(Xs_1) = \{\text{not } b, a\}$, $Cn_{\ll_P}(Xs_2) = \{\text{not } a, b\}$. Note that both TSSOAs generate (all) stable models of P .

$P \cup U$ is a program and it generates a dependency relation. Observe that $a \ll_{P \cup U} \{\text{not } a\}$, but $(a, \{\text{not } a\}) \notin (\ll_P \cup \ll_U)$. \square

Proposition 5 Let $\langle P, U \rangle$ be a multiprogram. Then $\ll_{P \cup U}$ is well defined. It holds $(\ll_P \cup \ll_U) \subseteq \ll_{P \cup U}$, but the converse inclusion does not hold.

Multiprograms contain in general conflicts. Example 6 illustrates notions connected to conflicts and solutions of conflicts.

Example 6 Dependency relation $\ll_{P \cup U}$ from Example 4 contains conflicts $C_1 = \{(b, \{\text{not } a\}), (\text{not } b, \{\text{not } a\})\}$ and $C_2 = \{(a, \{\text{not } a\})\}$.

A solution of a conflict is a set of dependencies which should be rejected (ignored) in order to remove the conflict. $D =$

¹ Comenius University, Bratislava, Slovakia, email: [sefranek,siska]@fmph.uniba.sk

$\{(not\ b, \{not\ a\})\}$ is a minimal solution of C_1 . However, it is more suitable to reject less preferred dependencies. Hence, $D' = \{(b, \{not\ a\})\}$ is a more suitable solution of C_1 than D . A solution of a conflict is called a good solution of it if there is not a more suitable solution. D' is the good solution of C_1 .

We intend to define the semantics of a multiprogram (with the dependency relation \ll) as a subset of \ll , which provides a coherent view on the multiprogram – i.e. there is a TSSOA w.r.t. the subset. In our example the set of assumptions $\{not\ a, not\ b\}$ is a TSSOA w.r.t. $View = \ll_{P \cup U} \setminus \{(b, not\ a)\}$ and $\{not\ b\}$ is a TSSOA w.r.t. $\ll_{P \cup U}$. \square

Definition 7 (Semantics of multiprograms) A dependency relation \ll is called *coherent* iff there is a TSSOA w.r.t. \ll .

Semantics of multiprograms (of the form $\langle P, U \rangle$) is a mapping Σ which assigns to $\langle P, U \rangle$ the set of all pairs of the form $(Z, View)$, where $View$ is a coherent subset of $\ll_{P \cup U}$ and Z is a TSSOA w.r.t. $View$.

3 IRRELEVANT UPDATES

2[KM] is adapted for multiprograms of the form $\langle P, U \rangle$ as follows: if $P \models_{SM} U$, then $TSSOA(P \cup U) = TSSOA(P)$, where $P \models_{SM} U$ means that U is satisfied in all stable models of P . Unfortunately, 2[KM] is not acceptable literally for multiprograms (and for NMKBs), see Examples 10 and 11. 2[KM] should be modified for NMKBs in order to catch the role of nonmonotonic assumptions.

Convention 8 Let $\langle P, U \rangle$ be a multiprogram. We would call U an *irrelevant update* of P iff $TSSOA(\ll_{P \cup U}) = TSSOA(\ll_P)$. \square

We are aiming to find sufficient and necessary conditions of $TSSOA(\ll_{P \cup U}) = TSSOA(\ll_P)$ and to define irrelevant updates in terms of those conditions.

First, consider the condition $P \models_{SM} U$. It is a necessary condition of an irrelevant update. On the other hand, if $P \not\models_{SM} U$, then update U is a relevant one.

Proposition 9 If $P \not\models_{SM} U$, then $TSSOA(\ll_P) \not\subseteq TSSOA(\ll_{P \cup U})$. If $TSSOA(\ll_{P \cup U}) = TSSOA(\ll_P)$, then $P \models_{SM} U$. If $P \models_{SM} U$, then $TSSOA(\ll_P) \subseteq TSSOA(\ll_{P \cup U})$.

Unfortunately, Examples 10 and 11 show that $TSSOA(\ll_{P \cup U}) \subseteq TSSOA(\ll_P)$ does not hold in general, if $P \models_{SM} U$.

Example 10

$$P = \{a \leftarrow not\ b\} \quad U = \{b \leftarrow not\ a\}$$

$P \models_{SM} U$, but U introduces a new assumption $not\ a$, which is false in all stable models of P and generates a new stable model of $P \cup U$.

Example 11 $P = \{a_1 \leftarrow not\ b_1; b_1 \leftarrow not\ a_1; a_2 \leftarrow not\ b_2; not\ b_2 \leftarrow not\ a_2\}$, $U = \{b_2 \leftarrow not\ a_2\}$.

The set of assumptions $\{not\ a_2\}$ is a SSOA w.r.t. \ll_U and $Cn_{\ll_P}(\{not\ a\}) \cup Cn_{\ll_U}(\{not\ a\})$ is inconsistent. The inconsistency can be overridden if we prefer $b_2 \ll_U \{not\ a_2\}$ over $not\ b_2 \ll_P \{not\ a_2\}$. Hence, $\{not\ a_2\}$ generates new stable models: $\{not\ a_2, not\ b_1\}$ and $\{not\ a_2, not\ a_1\}$ are TSSOAs w.r.t. $\ll_{P \cup U} \setminus \{(not\ b_2, not\ a_2)\}$. \square

We proceed to the definition of irrelevant updates. An update U of P is irrelevant if $P \models_{SM} U$ and there is no set of assumptions, which is sound w.r.t. \ll_U , some literals are dependent on it, it is not falsified, not satisfied in P (in order to gain something new w.r.t. $P \models_{SM} U$), and which generates a new model (by extending the set of reasonable assumptions, see Example 10, or by solving a conflict, see Example 11).

Definition 12 An assumption $not\ A$, where $A \in \mathcal{A}$, is *falsified* in a dependency relation \ll iff $A \ll \emptyset$, $not\ A \not\ll \emptyset$ and \emptyset is a SSOA w.r.t. \ll .

A set of assumptions $Xs \subseteq \mathcal{D}$ is falsified in \ll iff it contains a literal falsified in \ll . \square

Definition 13 (Irrelevant update) Let $\langle P, U \rangle$ be a multiprogram, P be coherent and $P \models_{SM} U$.

It is said that U is an irrelevant update of P iff there is no $Xs \subseteq \mathcal{D}$ such that:

- $Xs \in SSOA(\ll_U)$ and $Cn_{\ll_U}(Xs) \setminus Xs \neq \emptyset$,
- Xs is not falsified in $\ll_{P \cup U}$,
- Xs is false in each stable model of P ,
- there is $Bss \subseteq \mathcal{D}$ s.t. $Xs \subseteq Bss$ and $Bss \in TSSOA(\ll_{P \cup U})$ or
 - $Cn_{\ll_P}(Xs) \cup Cn_{\ll_U}(Xs)$ is inconsistent,
 - there is $View \subseteq \ll_{P \cup U}$ and $Bss \subseteq \mathcal{D}$ such that $Xs \subseteq Bss$ and $Bss \in TSSOA(View)$ \square

Observe that the condition $Cn_{\ll_U}(Xs) \setminus Xs \neq \emptyset$ eliminates unsupported cyclic updates. A nondeterministic algorithm for computation of TSSOAs is presented in [5].

Theorem 14 If U is an irrelevant update of P , then

$$TSSOA(\ll_{P \cup U}) = TSSOA(\ll_P).$$

4 CONCLUSIONS

Main contributions of this work are as follows:

- analysis and definition of irrelevant updates,
- an adaptation of 2[KM] for updates of NMKB,
- we show that irrelevant updates do not generate new models and that models of the original program are preserved after an irrelevant update.

Decision making in large-scale domains: a case study¹

Mikhail Soutchanski and Huy Pham² and John Mylopoulos³

Abstract.

Planning under uncertainty attracted significant attention in AI and in other fields. To overcome computational problems associated with Markov Decision Processes (MDPs) in large scale domains researchers often take advantage of structural properties and look for approximately optimal solutions. DTGolog, a decision-theoretic agent programming language based on the situation calculus, was proposed to ease some of the computational difficulties by using natural ordering constraints on execution of actions. Using DTGolog, domain specific constraints on the set of available policies can be expressed in a high-level program and this program helps to reduce significantly computation required to find a policy optimal in this set. Our paper explores whether the DTGolog framework can be used to evaluate different designs of a decision making agent in a large real-world domain. Each design is understood as combination of a template (expressed as a Golog program) for available policies and a reward function. To evaluate and compare alternative designs we estimate the probability of goal satisfaction for each design. As a domain, we choose the London Ambulance Service (LAS) case study that is well known in software engineering, but remains unknown in AI. In our paper we demonstrate that DTGolog can be applied successfully to quantitative evaluation of alternative designs in terms of their ability to satisfy a system goal with a high probability. We provide a detailed axiomatization of the domain in the temporal situation calculus with stochastic actions. The main advantage of this representation is that neither actions, nor states require explicit enumeration. We do an experimental analysis using an on-line implementation of DTGolog coupled with a simulator that models real time actions of many external agents.

1 Introduction and Motivation

There is a significant amount of work done in AI related to planning under uncertainty when a certain high level goal must be satisfied with a high probability [7, 1, 10, 9, 16]. Most of the proposed approaches are related to solving a decision-theoretic planning problem in relatively small domains (with less than 10^9 states). However, there are many practical domains where the task of designing a decision making agent (that guarantees goal satisfaction with a sufficiently high probability) is difficult due to a very large number of the state features and (ground) actions with uncertain effects. In these domains, the main problem is that state of the art planners cannot scale up to compute (or approximate) an optimal policy due to extremely

large size of the state space. Even the task of computing the value of a single policy can be prohibitively difficult in these domains. The second common problem is that in some domains the goal of interest is characterized in terms of quality of an on-going process driven by external agents. To deal with the first problem (scalability), one can try to use a logical representation that avoids explicit state and action enumeration. In addition, one can try to elaborate alternative designs of a decision making agent by goal-means analysis, e.g., using goal regression, a mechanism well studied in AI [15, 12]. By careful refining a goal that must be (at least partially) satisfied into sub-goals, and then by identifying sub-tasks to solve and primitive actions that must be executed to solve these sub-tasks, it is possible to ease to some degree the computational burden of designing such an agent. Indeed, a gradual refinement process can identify useful sequences, loops, conditional or recursive structures of actions that provide together important constraints on the set of policies that need to be considered, and as a consequence, significantly reduce the number of potential policies that ever need to be analyzed. One can imagine also that such analysis can identify where search between alternative actions must concentrate: this can be indicated by nondeterministic choices between alternatives. In realistic domains, this refinement process can lead to different designs depending on how stakeholder goals will be captured in this process. Because this can lead to a variety of designs that need precise evaluation, the problem of designing a decision making agent can be reduced to quantitative evaluation of those different designs of an agent which have been elaborated during the goals-means refinement process. To deal with the second problem (representation of an ongoing interaction with external agents), one can build a simulator of exogenous actions and evaluate all identified alternative designs with respect to the same simulator (see [11] for details).

We discuss an expressive framework that provides a tool for reasoning about different designs. This framework, a decision-theoretic extension of Golog (DTGolog), was first introduced in the context of designing efficient controllers for mobile robots [2, 13]. Later, it was extended to the multi-person games [4], was successfully adapted to program robots playing soccer [3], and was also extended to incorporate qualitative preferences to personalize Web services [5].

To the best of our knowledge, there were no attempts to use the DTGolog framework as a tool for evaluation of alternative designs of a decision making agent functioning in a large-scale domain characterized by on-going interaction with many external agents. All previous approaches applied DTGolog to the task of computing a policy in a finite horizon decision-theoretic planning problem. We would like to fill this gap and do extensive analysis of DTGolog with an application to a real case study. In particular, we explore a well-known case study (LAS-CAD) that received a significant attention in the software engineering literature, but remains unknown to the AI community [14, 6, 8]. It is an excellent example of a problem with probabilistic goals. This case study comes from an investigation into a failed software development project. We suggest this case study as a grand challenge for research on planning under uncertainty.

We try to keep our presentation as generic as possible to indicate how our modeling framework can be applied or extended to other decision-making environments. In particular, we clearly show the main features of DTGolog model that can be applied to other domains as well: actions, fluents, precondition axioms, successor-state axioms, initial database, transition probabilities, rewards, Golog procedures for expressing natural constraints on decision making. We illustrate all these main features of the specification framework using the case study.

The main contributions of our paper are the following. First, we developed an extensive logical formalization of a non-trivial domain. Second, we demonstrated that DTGolog is well suited to the task of evaluation of alternative designs of a decision making agent. Third, we did experimental analysis of three different designs of a decision making agent using the same simulator for a fair comparison. Each design is understood as a combination of a Golog program and a reward function. We use two different reward functions to show that preferences of stakeholders can be captured differently in the model. We also intentionally use two Golog programs to show that different decision making designs can be represented using this approach.

The interested reader can consult [12] for background on the temporal situation calculus, stochastic actions and Golog, [1] for background on MDPs, and [13] and papers mentioned above for background on DTGolog. The full version of this paper also includes background material necessary to understand this paper.

2 Discussion and Conclusion

We considered applicability of DTGolog to the task of evaluation of alternative designs of a decision making agent. We choose a domain where the state space has well beyond $30^{300} \cdot 2^{300}$ states (3 grid-worlds 10×10 with at least 1 request anywhere and 30 cars located anywhere). Consequently, it is doubtful that even state-of-the art MDP solvers (such as SPUDD) can solve the decision-theoretic planning problem in this domain and can be used for comparison with DTGolog. Moreover, our task was not solving the decision-theoretic planning problem (exactly or approximately), but evaluating alternative designs. DTGolog was previously used only to compute (approximately optimal) policies for finite horizon planning problems, but we consider a process-oriented problem that continues indefinitely (as long as new exogenous requests arrive). In this setting, we are interested whether DTGolog is a tool that can be used for quantitative evaluation of alternative designs of a resource allocating agent, where each design is determined by a Golog program and a reward function. We demonstrate that alternative designs can be compared by using a simulator in addition to an on-line DTGolog interpreter. We show that domain dependent constraints on the set of policies can range from a purely deterministic program (no decision making at all) to a Golog program with a limited number of decision points. In the latter case, a finite horizon planning can be accomplished by the off-line DTGolog interpreter. It might be surprising that some of our designs are non-deterministic Golog program where non-determinism is resolved at run time to make the best decision (with respect to program constraints). However, we believe this is important, because resolving this non-determinism at design time can be problematic due to the huge size of the state space.

The large number of choices and the large number of actions with uncertain outcomes present computational challenges that have to be addressed in future work. The most important direction for future research is overcoming computational challenges of the DTGolog framework: using sampling to deal with large branching factor (in

the version of directed value iteration that provides semantics for a DTGolog interpreter [2]) and using progression to deal with long situations [12]. Our research goal is a more advanced framework to handle models that are large enough to be of use in software design applications such as this one. In 2004, the real LAS-CAD system included about 30 regions, about 400 vehicles and was the largest public ambulance system in the world.⁴

Towards a logic of agency and actions with duration

Nicolas Troquard¹Laure Vieu²

Abstract. As far as we know, there is no multi-agent system allowing to talk both about choices of agents or groups of agents, strategies, and about sufficiently rich actions. This paper aims at offering a path towards a new more expressive logical framework by mixing a STIT-like logic of agency with a PDL-like logic of action. We present the syntax and ontological motivations, and we highlight the expressivity of the resulting framework on an example.

1 Introduction

Many domains, e.g., agent interaction or social law modeling, require a good framework for time, agency and action. Time is the basis to express dynamic properties and indeterminacy of the future, agency deals with what agents can bring about and actions are the various ways to bring about some state of affairs. As far as we know, there is no multi-agent system allowing to represent these three domains with sufficient expressivity. In particular, we intend to cover actions that have a duration, and that can be categorized on the basis of properties such as expected effects, temporal or participant structure.

Some existing logics answer to some extent such needs. Concerning pure action, the well-known Propositional Dynamic Logic (**PDL**) is a natural candidate. Nevertheless, it is not suitable neither for group action nor for individual and group agency. The logic of “Seeing To It That” (**STIT**) is a logic of agency embedded in a branching-time framework [1]. This is a logic about choices and strategies for individuals and groups. The core idea of logics of agency is that *acting* is best described by what an agent brings about: at some time, an agent *chooses* to constrain that some proposition is true. However, in some circumstances, not being able to explicitly refer to *actions* remains a weakness. One expresses sentences of the form “Mary sees to it that the coyote is dead” but not “Mary shoots at the coyote” or “Mary poisons the coyote”, i.e., the manner of bringing a state of affairs is out of concern. In addition, in **STIT**, it is generally considered that Mary’s acting does not take time: actions cannot be suspended half-way and one cannot express that an action starts while another is going on. This last point has already been overcome in [3] with the operator *istit*, but this logic still doesn’t involve actions explicitly.

It appears that we need a richer logical system, for reasoning about time, agency and actions with duration. One research avenue is to capitalize on strength of both **PDL** and **STIT**. The aim of this paper is to investigate this avenue, offering an expressive logical framework to support time, agency (for individuals and groups) and actions with duration and other properties, for modeling interactions between agents.

2 Description and justification of the framework

Within the limits of this extended abstract, we give the language of the new logic and describe some elements of its semantics intertwined with ontological justifications. Possible axioms or theorems are proposed in formulas labelled **(n)**. Models have been fully characterized but axiomatization proper is still work in progress.

Language. $\mathcal{A}ct$ is the set of actions, and $\mathcal{A}ct_\lambda := \{\alpha_\lambda \mid \alpha \in \mathcal{A}ct\}$ is the set of continuations of those actions. $\mathcal{A}tm$ is the set of atomic propositions. $\mathcal{A}gt$ is the set of agents. By notational convention, $\alpha \in \mathcal{A}ct$, $\alpha_\lambda \in \mathcal{A}ct_\lambda$, $\beta \in \mathcal{A}ct \cup \mathcal{A}ct_\lambda$, $p \in \mathcal{A}tm$, $a \in \mathcal{A}gt$ and $A \subseteq \mathcal{A}gt$. A formula can have the following syntactic form:

$$\begin{aligned} \varphi &\triangleq \perp \mid p \mid \neg\varphi \mid \varphi \vee \varphi \mid \varphi \mathcal{S} \varphi \mid \varphi \mathcal{U} \varphi \\ &\quad \mid \Box \varphi \mid [\beta : a] \varphi \mid [\overline{\alpha : a}] \varphi \mid Stit_A \varphi \end{aligned}$$

A model is a tuple $\mathcal{M} = \langle W, <, R_\square, R_{ACT}, agent, v \rangle$, where W is a set of indexes, partially ordered by the strict temporal precedence $<$. Non comparable indexes are grouped into moments by the equivalence relation R_\square . $R_{ACT}(\beta)$ is a function associating an index w to the index where the performance at w of β ends, $agent$ is a function associating to each action its agent, v is the valuation function.

As in **STIT**, \mathcal{S} and \mathcal{U} are the standard since and until temporal operators. Future and past operators are defined as usual: $\mathbf{F}\varphi \equiv \top \mathcal{U} \varphi$ and $\mathbf{P}\varphi \equiv \top \mathcal{S} \varphi$. $\Box \varphi$ stands for historical necessity of φ (φ is true at every index of the moment). \square is an *S5* modal necessity (**1**). Possible readings of $Stit_A \varphi$ are “the group A sees to it that φ ” or “the group A ’s current choice ensures φ whatever other agents do”.

As in **PDL**, $[\beta : a]$ means that a starts performing action β and that φ holds afterwards. $[\overline{\alpha : a}] \varphi$ means that α has just finished and that φ was true before. By tradition, \Diamond will be used as abbreviation for $\neg \Box \neg$ and similarly for $[\beta : a]$ and $[\beta : a]$.

We will illustrate the logic by the example on Figure 1.

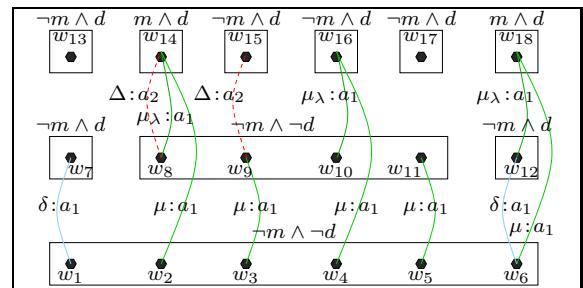

Figure 1. The two cooks. a_1 and a_2 have to prepare a meal. m stands for “the main course is done” and d for “the dessert is done”. δ and Δ are actions of (resp.) a_1 and a_2 cooking the dessert, while μ is the action of a_1 cooking the main course. Boxes are moments containing indexes.

Time. As in **STIT**, our logic assumes a branching time on moments, linear in the past: at each moment, an agent can make different choices, that is, decide to execute different actions bringing about different futures. Maximal linear sets of moments are called

histories; indexes can be seen as moment-history pairs. Models do not constrain all moments to be temporally comparable; an extension could be to do so, adding coincidence of moments through the notion of *instant* as in [1].

Actions. All actions take time ($[\beta : a]\varphi \rightarrow \mathbf{F}\varphi$ (2)). Actions in the present logic are operators thus not properly speaking “events performed by an agent” since events, when they are acknowledged as citizens of the world, are conceived of as concrete individuals, uniquely situated in time and space [2]. These operators correspond to *types*, not tokens, as a given action may occur repeatedly. They are though of a very restricted sort of types. The agent, as well as all other participants, are fixed. The only remaining parameter is time.

Actions correspond to achievements and accomplishments [5], thus two occurrences of the same action cannot overlap ($[\alpha : a]\mathbf{P}[\overline{\alpha : a}]\varphi \rightarrow \mathbf{P}[\overline{\alpha : a}]\varphi$ (3) and $\langle\alpha : a\rangle\top \wedge \mathbf{F}[\alpha : a]\varphi \rightarrow [\alpha : a]\mathbf{F}[\alpha : a]\varphi$ (4) are expected to be valid). Each occurrence runs linearly ($\langle\beta : a\rangle\varphi \leftrightarrow [\beta : a]\varphi$ (5), $\langle\overline{\alpha : a}\rangle\varphi \leftrightarrow [\overline{\alpha : a}]\varphi$ (6), $[\alpha : a][\overline{\alpha : a}]\varphi \rightarrow \varphi$ (7) and $\varphi \wedge \langle\alpha : a\rangle\top \rightarrow [\alpha : a]\overline{[\alpha : a]}\varphi$ (8) are assumed to be valid).

At a same index, more than one action can be performed, by the same or another agent. In the above example, at w_6 , a_1 performs μ and δ ($w_6 \models \langle\mu : a_1\rangle\top \wedge \langle\delta : a_1\rangle\top$).

An action is simply executed or not at an index, but it can unfold into different courses at different indexes of a same moment: in agreement with the STIT approach, actions are not deterministic. In particular, the duration of an action may be left unspecified. That is, not only different occurrences may have different lengths, but the possibly different courses of the same action occurrence may have different lengths on different histories. Action duration can for instance be influenced by the availability of resources. It is also influenced by the fact that actions may be suspended before completion, for reasons external or internal to the agent [3]. Since actions may abort, starting an action does not imply obtaining some expected result: $[\alpha : a]\varphi \rightarrow \square[\alpha : a]\varphi$ is not valid. This means that in our approach, actions are not simply characterized by preconditions and results; we rather focus on the decision of the agent to perform an event of some sort.

Continuation of an action, completed actions. Assuming that actions have a duration and can abort before completion allows to assume that the agent has control over the execution of an action. At each moment during the execution, the agent can decide to keep on performing it or not. On the other hand, in a STIT framework with several agents, agents share the set of indexes, and as a result, whenever an agent makes a choice, all other agents too. This appears too demanding, as simply continuing what has been initiated before is not really a new choice. For both these reasons, we introduce particular actions representing the *continuation of an action*. Introducing in an explicit manner continuations of an action is actually a good way to formalize the notion of *control* on the action [4]. We follow Searle in holding that actions end when the bodily movement is finished, i.e., all actions are totally under control and thus continued up to their end ($\langle\alpha : a\rangle\top \rightarrow \langle\alpha_\lambda : a\rangle\top \wedge \langle\overline{\alpha : a}\rangle\top$ (9) is assumed to be valid). Of course, if a continuation is available, it means that the corresponding action has started before ($[\alpha_\lambda : a]\varphi \rightarrow \mathbf{P}[\alpha : a]\varphi$ (10)). Continuations of a given occurrence of an action do not have a unique starting point, as they are repeated till the end of the action, but they all run till the same ending point (cf. Formula 9).

Since actions can abort, when an action ends, it is not necessarily completed. We thus introduce propositions $\text{comp}(\alpha) \in \text{Atm}$, one for each action α , that reads “action α is completed”. An action α is completed when it has just ended and no continuation is possible; an action aborts if it ends but some continuation is still possible. In

our example, action μ is aborted in w_9 and w_{11} and completed in w_{14}, w_{16} and w_{18} . This notion of completion may be used to express that completed actions do have specific effects; categories of actions could then be introduced on the basis of effects of completed actions. However, one may also want to allow for completed but failed actions, just as in w_{16} , where m doesn’t hold.

Not doing anything. As observed before, STIT’s requiring that if an agent makes a choice at a moment, all other agents too, is too demanding, and needs to be fixed not only for action continuations. In fact, agents may remain simply passive when others really choose to act. To express this, we introduce a set of propositions $\lambda(a) \in \text{Atm}$, one for each agent a , that reads “the agent a remains passive”. An agent a remains passive when it does not perform an action nor a continuation. In the example, agent a_2 remains passive everywhere but w_8 and w_{10} ($w_8 \models \neg\lambda(a_2)$).

Choices and groups agency. We can analyze the combination of choice and action. In multi-agent systems, and particularly in STIT, an agent’s choice is understood as choosing to bring about a state of affairs. In the present work, we handle choice as choosing to perform a set of actions. To deal with agency we still use the *Stit* operator. *Stit* is an *S5* modal operator (11). Moreover, if $A \subseteq B$ then $\text{Stit}_A\varphi \rightarrow \text{Stit}_B\varphi$ (12). We have the interesting property that if a performs α , a sees to it that it performs α , which can be stated by $\langle\alpha : a\rangle\top \leftrightarrow \text{Stit}_a\langle\alpha : a\rangle\top$. Similarly, it is also true that $\lambda(a) \leftrightarrow \text{Stit}_a\lambda(a)$. In the example, at the moment of w_1 , agent a_1 has three choices, corresponding to performing action δ , performing action μ or performing both ($w_2 \models \text{Stit}_{a_1}\langle\mu : a_1\rangle\top \wedge \diamond\text{Stit}_{a_1}\neg\langle\mu : a_1\rangle\top$).

Concerning cooperation, at w_8 none of a_1 and a_2 can see to it that both the main course and the dessert are cooked ($\neg\diamond\text{Stit}_{a_1}(m \wedge d) \wedge \neg\diamond\text{Stit}_{a_2}(m \wedge d)$) but they can cooperate for that ($w_8 \models \text{Stit}_{\{a_1, a_2\}}(m \wedge p)$); it is achieved by means of a_1 continuing to perform μ and a_2 executing Δ .

3 Conclusion

In this work, we have introduced actions with duration, action continuations, and explicit choices of remaining passive in the language of a STIT-like framework. By doing so, we have also cured an annoying feature of STIT which is that when an agent makes a choice, other agents too. Moreover, choices in STIT are arbitrary partitions of moments; we made the notion of choice clearer by constructing choices over sets of actions.

Besides working out a full axiomatization, extensions include: less restricted types of action, expected results, action temporal structure, composing operators and strategies for individuals and groups.

5. Model Based Reasoning

This page intentionally left blank

Better Debugging through More Abstract Observations

Wolfgang Mayer and Markus Stumptner¹

1 INTRODUCTION

Recent years have seen considerable developments in modelling techniques for automatic fault location in programs. However, much of this research was focussed on exploiting a single property of programs or their execution, introducing increasingly complex observation models to keep diagnosis sets manageable. While this has helped somewhat to improve results, it has also led to an increased burden on the users, which have to answer increasingly complex questions posed by the debugging tool to obtain good results. As a result, an increasing number of questions cannot be answered or are answered incorrectly, leading to poor debugging result.

Instead, we propose to combine assertions about multiple abstract properties of program executions to battle the complexity inherent to specification of program behaviour. Assertions are very simple and cannot contribute much individually, but in combination with an automatic model refinement approach provide a powerful tool to diagnose complex faults in programs.

The use of model-based reasoning approaches for localising faults in various software systems has grown to encompass a variety of systems and languages [4, 11, 8, 1]. Work on model-based debugging of has long limited itself to treating user queries in the same fashion as test vectors. That means the debugger indicated a point during program execution that it was considering (e.g., a particular statement), and then queried whether particular values in the program state at some point during execution were correct or not. In the extreme case it asked the user to provide a correct answer for an incorrect value. In the debugging literature the user's contribution to the debugging process is usually referred to as an "oracle", illustrating the depth of knowledge that the user is expected to possess about the actual workings of the program on a given test case.

Answering these oracle queries posed by the system could be surprisingly difficult, potentially needing the *correct* program behaviour to be hand-simulated up to that point. In [9] it was postulated that for interactive debugging, queries based on high level descriptive predicates, being closer to the definitions used in declarative languages, would be both more powerful and easier for the debugger user to apply.

2 MODEL-BASED DEBUGGING

The key idea of *Model-based Software Debugging (MBSD)* is to compile the program into a set of models which reflect (ab-

stract) properties about the program's behaviour. Further, a set of test cases is assumed to be given, where some or all of the tests exhibit incorrect results. Comparing the differences between the program's behaviour when executed on all test cases and the result and assertions specified by the test cases, possible explanations can be inferred using a variant of Reiter's consistency-based diagnosis framework [10].

Previously, a model based on the well-known interval abstraction [2] to approximate the actual behaviour of the program was proposed. When using only this model, certain faults can be located, but for programs predominantly dealing with nested loops and heap data structures, the number of possible explanations is larger than desirable in practice. Analysis of the results has revealed that many of the unwanted results can be removed by strengthening the reasoning engine to detect inconsistencies more often.

The following section proposes a set of abstract properties that help to strengthen the MBSD framework by asserting aspects of program executions that are orthogonal to the ones derived using the interval abstraction. Through interactions between the different properties, the model's structure and fault assumptions can be refined iteratively.

3 DEBUGGING WITH ABSTRACT PROPERTIES

While there are no intrinsic requirements on the abstractions used to query users, we propose the following collection of properties. We do not claim that these are sufficiently complete to effectively debug any fault or program. Rather, abstractions that are simple to decide for a user without detailed knowledge about the program have been selected such that synergies between abstractions and (abstract) program executions allow for effective debugging.

Formally, all abstractions can be modelled as Predicate Abstraction [5] or lattices [2]. Space limitations preclude us from providing formal definitions and we present textual descriptions only.

Read- and write-only. Observations that all (or a particular subset of) elements of a data structure used as input to a loop or a method call are either only read or updated only. Read-only assertions detect conflicts if the program attempts to modify the structure. Write-only access is used to decouple the previous values of the data structure from the updated values, leading to smaller conflicts in case the update operation is included in a fault candidate.

¹ Advanced Computing Research Centre, University of South Australia. [mayer,mst]@cs.unisa.edu.au

A likely scenario is a user looking at a program execution stopped at a breakpoint in a debugger, looking for a reason why a data structure was updated incorrectly. Noticing that some part of the data structure has changed compared to the last time the program was stopped, but shouldn't have been modified according to the intended operation of the program, the user opens a dialog box, selecting the structure in question, and asserting "should not change between b_1 and b_2 " (assume for now that b_i denote the two breakpoints). The automatic debugger incorporates the assertion into the specification of the program's intended behaviour and eliminates all explanations contradicting the new partial specification. This process is repeated until a the true cause of the update has been isolated.

Region reachability. Statements that should be executed always (or never, at least or at most once) are identified to remove paths that would otherwise contribute to spurious explanations.

While precise specifications of the program's control flow represented as for example linear logic or finite state automata may be difficult to provide for a casual user, developers typically have a vague idea of the intended control flow of a program. Simple observations along the lines of "there shouldn't be an uncaught exception when executing this test case" or "this alternative must not be executed" are easy to determine and to assert. The debugger can utilise this specification to build refined representations of the program's control flow, which may reduce loss of information in other abstractions.

Exhaustive Traversal. Elements of arrays and dynamic data structures are often processed such that either all of them are read or updated. If the underlying data structure is monotonic, this allows to bound the number of iterations a loop is executed, which in turn allows to eliminate spurious diagnoses through improved modelling.

Similar to the previous property, it may be known to the developer that for example each element of a data structure must contribute to a computation, whereas the exact computation is unknown. Specifying that a loop should iterate over the entire structure is easy to do, allowing the debugger to relate the size of the data structure and the number of loop iterations. Subsequently, this information can be used refine the model by e.g. unrolling the loop. Note that this is achieved without writing formal specifications.

Variable (in)dependence. While the precise computations performed by a program may not be known, the flow of and dependencies between values computed is typically much easier to establish. Dependencies between variables can be utilised to infer missing statements or uses of wrong variables [6]. Dependency information could also be used to chose a suitable abstraction for dependent variables. For example using a relational model for local dependent variables may reduce spurious values (and fault candidates) compared to a purely non-relational approach.

Subproblem independence. Loops can be modelled more precisely if it is known that computations in different iterations are independent of each other [7]. Many common algorithms dealing with arrays and lists perform computations that could be carried out independently. If it is known that this is the case

for a particular loop, the loop can be "parallelised", leading to independent control and data flow in distinct iterations, which in turn allows the debugger to compute more precise explanations.

Loop specific invariants. Loops based on counters or other induction variables can often be bounded if monotonicity of the induction variable is assumed. While these properties can often be inferred automatically [3] in case the statements in the loop are assumed correct, in case fault assumptions are present, this may not be possible. Simple program analysis techniques combined with user-specified abstract invariants, such as monotonicity, may help to bound the number of iterations and dependences between variables.

4 Outlook

We have presented an approach to semi-automatic debugging that builds on prior model-based debugging work and extends it by a formal framework to incorporate high-level observations. These use a fixed library of predicates that are expressed in terms of the Abstract Interpretation framework in terms of trace segments. This allows for simpler but powerful user interaction, leading to a more precise approximation of the common grounds between intended and actual program behaviour. While ideas have been shown promising result on a set of toy problems, an implementation that can handle every-day programs is still outstanding. Suitable strategies for displaying and interacting with the users, in particular how to present the findings of our semi-automatic debugger and how to pose queries to the user also remains for further investigation.

Logic Profiling for Multicriteria Rating on Web Pages

Alessandra Mileo¹

Abstract. I want to propose a general framework for user-oriented and content-based recommender systems aimed at providing preferential multicriteria rating on Web Pages and automatic user's profile generation and updating through logic programming techniques.

1 Introduction

The World Wide Web (WWW) is constituted by a large, distributed set of heterogeneous documents that is constantly changing, making it harder for a visitor to locate interesting pages exploring all possible paths where pertinent information can be found.

Some of the solutions to this problem proposed so far were mainly based on machine learning techniques [4, 5], sometimes tracing the whole user's browsing behavior to update the profile [3], and generally content-based. Several limitations of these systems showed that multicriteria rating, multidimensionality and flexibility are needed in order to improve the understanding of users and items [1].

2 User's Profile Generation

In my approach, user's browsing behavior, is represented by a set of meaningful user's actions traced in a log file during browsing, and extracted in form of logic predicates when the user asks the system for suggestions on links of a page. User's profile is related to i)sources and ii)reasons to recommend a link.

Interests on sources are represented by a set of pages Url_i (in form of URL addresses) that are interesting to the user. These pages can be a subset of all pages that are included among the *favourites* links in the browser menu and are written as a set of facts of the form $fav(Url_i)$. When a user asks for suggestions, the initial profile is enriched with new facts derived from the *recent* user's browsing behavior. Which actions should be considered meaningful and consequently used to update the profile is a crucial issue, as a user may perform several kinds of actions mostly irrelevant in determining user's preferences in a specific context. Thus, I decided to select a reduced set of actions among those traced in the log file, and rewrite them as logic predicates to be used in the inference process.

The filtering mechanism considers meaningful:

- i. to visit an Url with frequency N for an average dwell time D : $vis(Url, N, D)$;
- ii. to add/remove an Url to/from the list of favourites at time T : $add(Url, Time) / rem(Url, Time)$;
- iii. to follow/discard a suggestion with a frequency N : $foll(Url, N) / disc(Url, N)$.

Any other action is filtered out.

¹ Dipartimento di Informatica e Comunicazione, Università degli studi di Milano. Email: mileo@dico.unimi.it

Preferences on reasons are defined by the user in form of an ordering relation on the reasons for which a page can be recommended.

Each *reason for recommendation* is associated to a function $f_i(P_0, P_j)$ representing a relation among the current page the user is visiting, P_0 , and each of the pages linked by P_0 , namely P_1, \dots, P_j .

In preliminary tests I considered three reasons to recommend a link: f_1 is related to a similarity metric, f_2 expresses how a page is correlated with interesting *sources* and f_3 combines both criteria. According to the ordering relation, each function f_i is associated to a value $p(f_i) \in \{1..i\}$ that will be used for ranking.

3 Updating Profile by Adapting Rules

The formal setting I propose for profile update is that of Answer Set Programming (ASP). ASP is based on the *stable models* semantics for Logic Programs proposed by Gelfond and Lifschitz [2] and it can be seen as bringing together concepts and results from Logic Programming, Default Reasoning and Deductive Databases.

The intuition is that of using automated commonsense (non-monotonic) reasoning to update user's interests by revising the logic program (adding new facts and rules according to information from the log file) and by modifying numerical thresholds in logic rules.

Parameters update allows to adapt the learning process to different users as well as to a user that changes his/her interests.

A page Url_j is classified as being either *interesting* or *uninteresting*. In particular, Url_j is interesting if the log file traced that it has been added to the list of favourites during browsing². Thus, Url_j is interesting either by default (it is in the list of favourites) or if:

- i) Url_j has a frequency N of visits, average dwell time $D > \epsilon$, or
- ii) recommended Url_j has been visited with frequency $N > Min_f$,

When a page is inferred to be uninteresting, the default mechanism detects an *exception to default*. This may happen in three cases:

- i) Url_j has a frequency N of visits, and average dwell time $D < \epsilon$;
- ii) suggested Url_j is ignored with a frequency $N > Min_d$;
- iii) Url_j is removed by favourites at time T , not added again later.

Values for ϵ (expressed in milliseconds), Min_f (real) and Min_d (real) are initially fixed by the system as equal to the minimum value extracted from the log file, and then revised on the basis of how user reacts to suggestions.

4 Computing suggestions

The process of computing suggestions and adding them to a Web Page consists of four phases:

² Supposing a sort of coherence of the search, the log file is cleaned each time the user closes the browser, or manually types a different url address into it, thus moving in a new search context.

1. *Clustering*: page P_0 and pages P_j ($j = 1..m$) pointed by P_0 at the first level of depth, are clusterized on the basis of a similarity function $s(P_0, P_j)$ (e.g. cosine similarity);
2. *Preferred Ranking*: page P_0 and pages P_j are given a weight $W_j = |WC_j| + |WI_j|$ where:

$$WC_j = \{Url_i \mid Url_i \text{ is in the same cluster as } P_j\}$$

$$WI_j = \{Url_i \mid Url_i \text{ points to/is pointed by } P_j\}$$

3. Computing similarities:

- $f_1(P, P_j)$ is equal to the value of the similarity function $s(P_0, P_j)$ if P_0 and P_j are in the same cluster, zero otherwise;
- $f_2(P, P_j)$ is equal to $|WC_j|$ if P_0 and P_j are in the same cluster, zero otherwise;
- $f_3(P, P_j)$ is equal to $W_j - W_0$ if $W_j > W_0$, zero otherwise.

Values of f_i are disposed in a similarity matrix $S \in N^{j \times i}$ where the j -th row corresponds to page P_j , the i -th column corresponds to correlation functions f_i , and each element s_{ji} in the matrix is the result of $f_i(P, P_j)$.

S is multiplied by a *correlation matrix* $C \in R^{i \times i}$ which is a diagonal matrix where each element d_{ii} on the diagonal, corresponds to the weight of f_i according to preferences on reasons expressed by the ordering relation.

By this operation, a *weighted similarity matrix* $S_w \in N^{j \times i}$ is obtained. Each row in S_w is associated a value r_j which is a linear combination of the elements in the j -th row. This value is then used to rank pages.

4. *Adding suggestions*: once r_j has been computed for each page P_j , results are presented to the user by associating symbols to urls in P_0 or by showing an ordered list of the urls of P_0 , accessible by clicking on the correspondent link.

Example 1 Suppose user U is browsing page P_0 , pointing to four pages P_j , $j = 1..4$. Interesting sources are Url_i , $i = 1..4$.

Suppose $s(P_i, P_i) = 1$, $s(P_0, P_3) = 0.92$, $s(P_0, Url_4) = 0.87$, $s(P_1, Url_1) = 0.7$, $s(P_1, Url_2) = 0.8$, $s(P_2, Url_3) = 0.9$, $s(P_3, Url_4) = 0.78$ ³. Values are placed in the correlation matrix S ; weights and links are illustrated in Figure 1.

Suppose we expressed the order $f_1 \succ f_3 \succ f_2$, thus $p(f_1) = 3$, $p(f_3) = 2$ and $p(f_2) = 1$ are placed on the diagonal of matrix C .

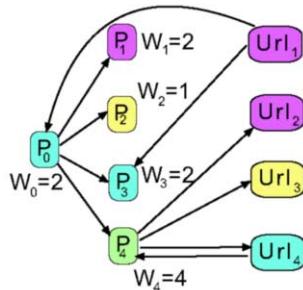

Figure 1. Example 1: preferred ranking

Matrix S_w is given by $S \cdot C$ as follows:

$$S_w = \begin{pmatrix} 0 & 0 & 0 \\ 0 & 0 & 0 \\ 0.92 & 1 & 0 \\ 0 & 0 & 2 \end{pmatrix} \begin{pmatrix} 3 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 2 \end{pmatrix} = \begin{pmatrix} 0 & 0 & 0 \\ 0 & 0 & 0 \\ 2.76 & 1 & 0 \\ 0 & 0 & 4 \end{pmatrix}$$

The ranking value r_j for page P_j is a linear combination of elements of the j -th row of S_w , i.e. $r_j = \sum_{i=1}^3 s_{ji}$, thus $r_1 = r_2 = 0$, $r_3 = 2.76 + 1 = 3.76$, and $r_4 = 4$.

Note that P_3 is less preferred than P_4 despite its being in the same cluster as P_0 . This is due to the combination of two factors: first, correlation between P_0 and P_3 is not as substantial as the increment of interestingness the user could get in visiting page P_4 ; second, function f_3 combining interestingness of a page and similarity metric, is not much less preferred by the user than f_1 , based on similarity only; as a consequence, due to the preferential nature of the multicriteria framework, page P_3 is slightly less preferred than P_4 because browsing through it results in a significant increment of interestingness for the user, although P_3 is more similar to P_0 than P_4 . A different order on functions f_i would affect this result.

5 Conclusions and Future Work

Although no prototype is available for complete validation yet, preliminary tests on a few log file instances showed that classical machine learning approaches mentioned in the introduction, could give better solutions only when a continuative browsing activity of different users is taken into account. My alternative approach considers the profile as user- and interaction-oriented, in that only recent browsing activity of the user who is running the system is detailed and used for profile update. In this case the cost of using a reasoning system at run-time is not too much to pay for the benefits that may be gained, as we can get acceptable recommendations even after a few user's interactions, by combining rating criteria.

Non intrusiveness is granted by the fact that initial user's interests are extracted almost automatically: no complex statistical information, or features selection are needed.

Correlation functions could potentially be n^4 ; this would generate a n -dimensional matrix expressing the preferential order on functions f_i , thus allowing multicriteria rating by a linear combination of the final results of each criterion.

Nonetheless, more detailed experimental results are needed to evaluate effectiveness of this approach and provide significant empirical data. This aspects will be detailed in a future full paper, where also further extensions of the framework will be investigated, such as i) ordering rules applied to infer interestingness of a page and ii) quantifying interestingness at some degree of a page.

⁴ This number is limited by the space available and may affect performances, but $n > 2$ already allow to apply multicriteria rating.

³ Similarity results for the remaining combination of pages are lower than a fixed minimum, so they are considered equal to zero.

An Empirical Analysis of the Complexity of Model-Based Diagnosis

Gregory Provan¹

Abstract. We empirically study the computational complexity of diagnosing systems with real-world structure. We adopt the structure specified by a small-world network, which is a graphical structure that is common to a wide variety of naturally-occurring systems, ranging from biological systems, the WWW, to human-designed mechanical systems. We randomly generate a suite of digital circuit models with small-world network structure, and show that diagnosing these models is computationally hard.

1 Diagnostic Inference for Complex Systems

The problem of model-based diagnosis (MBD) consists of determining whether an assignment of failure status to a set of mode-variables is consistent with a system description and an observation (e.g., of sensor values). This problem is known to be NP-complete. However, this is a worst-case result, and some NP-complete problems are known to be tractable for particular problem classes. For example, graph colouring, which is NP-complete, has empirically been shown to have run-times that depend on the graph structure [2].

We are interested in the average-case complexity of MBD algorithms on problem instances with real-world structure. At present, it is not known whether MBD is computationally difficult for the “average” real-world system. There has been no systematic study of the complexity of diagnosing real-world problems, and few good benchmarks exist to test this.

We empirically study the complexity of diagnostic inference within a model-based framework using a suite of randomly-generated problem instances, each of which possesses typical real-world properties. Our experimental results show that problems with real-world structural properties are computationally more difficult than problems with regular or random structure, such as would be generated by a typical random-problem generator.

This article makes two main contributions. First, it describes a technique to generate diagnosis models with real-world structural properties. This approach circumvents the difficulty of assembling a large suite of test problems (benchmark models), given that most large diagnosis models tend to be proprietary. It also enables us to control model parameters (and hence analyse specific parameters). Second, we show empirically that diagnosing models with real-world structure is computationally hard. This provides the first clear experimental demonstration of this computational intractability.

2 The Structure of Real-World Problems

Several recent theoretical studies and extensive data analyses have shown that a variety of complex systems, including biological [6],

social [6], and technological [1, 5] systems, share a common underlying structure, which is characterised by a *small world graph*. A small-world graph (SWG) is a complex network in which (a) the nodes form several loosely connected clusters, and (b) every node can be reached from every other by a small number of hops or steps.

We can measure whether a network is a small world or not according to two graph parameters: clustering coefficient and characteristic (mean-shortest) path length [6]. The clustering coefficient, C , is a measure of how clustered, or locally structured, a graph is; this coefficient is an average of how interconnected each agent’s neighbors are. The characteristic path length, L , is the average distance between any two nodes in the network, or more precisely, the average length of the shortest path connecting each pair of nodes.

Several recent studies of technological systems have shown that they all possess small-world topology [1, 5]. In these studies, each technological system is described in graph-theoretic terms, and the underlying topology of the system graph G is studied. For example, for the electronic circuits studied in [5], the vertices of G correspond to electronic components (gates, resistors, capacitors, diodes, etc.), and the edges of G correspond to the connections (or wires) between the components. These circuits comprise both analog and ISCAS’89/ITC’89 benchmark circuits, and all display C and L parameters that are typical of SWG topologies.

3 Model-Based Diagnosis

We can characterise a MBD problem using the triple $\langle COMPS, SD, OBS \rangle$ [7], where:

- $COMPS = \{C_1, \dots, C_m\}$ describes the operating modes of the set of m components into which the system is decomposed.
- SD , or system description, describes the function of the system. This model specifies two types of knowledge, denoted $SD = (\mathcal{S}, \mathcal{B})$, where the system structure, \mathcal{S} , denotes the connections between the components, and the system behaviour, \mathcal{B} , denotes the behaviour of each component.
- OBS , the set of observations, denotes possible sensor measurements, which may be control inputs, outputs or intermediate variable-values.

We adopt a propositional logic framework for our diagnostic models. Component i has associated mode-variable C_i ; C_i can be functioning normally, denoted as $[C_i = OK]$, or can take on a finite set of abnormal behaviours.

MBD inference assumes initially that all components are functioning normally: $[C_i = OK]$, $i = 1, \dots, m$. Diagnosis is necessary when $SD \cup OBS \cup \{[C_i = OK] | C_i \in COMPS\}$ is proved to be inconsistent. Hypothesizing that component i is faulty means switching from $[C_i = OK]$ to $[C_i \neq OK]$. A (minimal) diagnosis is thus a

¹ Computer Science Department, University College Cork, Cork, Ireland, email: g.provan@cs.ucc.ie

(minimal) subset $C' \subseteq COMPS$ such that: $SD \cup OBS \cup \{[C_i = OK] | C_i \in COMPS \setminus C'\} \cup \{[C_i \neq OK] | C_i \in C'\}$ is consistent.

4 Benchmark Model Random Generator

We study a suite of electronic circuits that are constructed from simple gates. The inference complexity of other classes of model with comparable structures will be similar, since it is the system topology (graph width) that is the primary determinant of complexity and the type of constraint defining the system description is only a secondary determinant of complexity [3].

We generate diagnostic models in a three-step process.

1. generate the graph structure G underlying each model;
2. assign components to each node in G for system Ψ ;
3. generate the system description (and fault probabilities) for Ψ .

Generate Graph Structure for G : We generate a small-world-graph (SWG) using the approach of Watts and Strogatz [9]. This approach generates a graph G with a pre-specified degree of randomness that is controlled by a probability $p \in [0, 1]$. $p \approx 0$ corresponds to a regular graph, and $p \approx 1$ corresponds to an Erdos-Renyi random graph; SWGs occur roughly in the range $.01 \leq p \leq .8$, as has been determined by empirically comparing the C and L parameters of generated graphs and actual networks [6]. As noted earlier, a node in G corresponds to a system component, and an edge linking nodes i and j in G corresponds to a wire between components i and j . We randomly assign a set O of nodes to be observable inputs and outputs, choosing $|O|$ based on system size, i.e., $|O| = 0.15n$.

Assign Components to graph G : For our experiments, we use a set of digital comparator components. Given a topology graph G , we associate to each node in G a component, based on the number of incoming arcs for the node. Given a SWG node with i inputs and o outputs, we assign a component, denoted $\Psi_Z(i, o, \mathcal{B}, w)$ where \mathcal{B} defines the behavioural equations of component Z , and w the weights assigned to the failure modes of Z . For example, a j -of- k gate will output t if at least j out of the k inputs are t . Given a node that has q possible components that are suitable, we randomly select a component with probability $\frac{1}{q}$. For example, the single-input nodes correspond to single-input gates (NOT, buffer), and the dual-input nodes correspond to dual-input gates (AND, OR, NAND, NOR, XOR).

Generate the System Description: Given the selected gate, we then generate its normal-mode equations (and potentially failure-mode equations). We randomly select the mode type (of the k possible failure modes) for any gate-model with probability $\frac{1}{k}$. We assign weights to failure-mode values by assuming that normal behaviour is highly-likely, i.e., $Pr\{C_i = OK\} \approx 0.99$, and faulty behaviour is unlikely, i.e., $Pr\{C_i \neq OK\} \approx 0.01$.

5 Experimental Analysis

Given a set of diagnosis models, we studied the inference complexity of each model Ψ by assigning observations (OBS) and then measuring the inference complexity for computing a minimal diagnosis given (Ψ, OBS) .

We have adopted the causal network approach [3] for our experiments. We generated models containing 50, 60, 70 and 80 components for 103 different values of p ranging from 0 to 1.0, to cover the full range of regular, small-world and random graph structures. We used as our measure of inference complexity the sum of all clique-tables in the causal network model, which is a typical complexity measure for this type of model.² Figure 1 shows our results, where

each data point is the average of 300 runs. The plot for each model of size n has the same shape; the shape occurs since regular graphs (p near 0) are computationally simple, small-world graphs are computationally hard (with a complexity peak near $p \approx 0.7$), and random graphs ($p \approx 1$) also are hard, but less hard than the computational peak in the small-world region. The correlation of cluster-size and inference complexity presented here is consonant with the analysis of clique sizes (and corresponding complexity of probabilistic inference), using ISCAS'85 benchmark circuits [4].

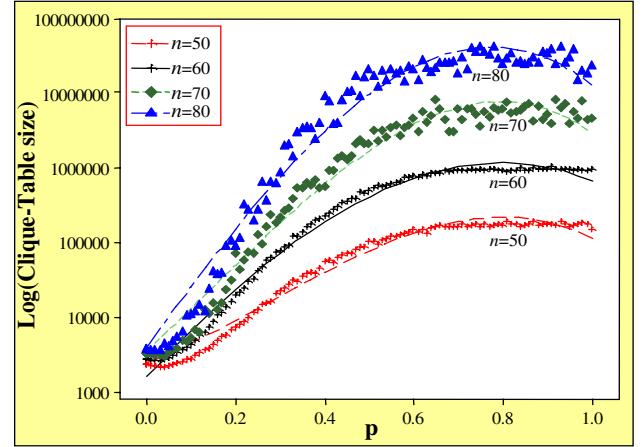

Figure 1. Results of diagnosing SWG-structured digital circuits. Each curve shows a model containing n components.

6 Conclusion

This article has empirically shown that MBD problems with a topology typical of real-world systems, i.e., with a SWG structure, are computationally hard. In fact, over the space of topologies ranging from regular to random, the SWG structure is the computationally least tractable for MBD, a property shared with other inference tasks, such as graph colouring, timetabling and quasi-group analysis [8].

This article has also described a method for generating diagnostic models that have real-world topology and can be tailored to different domains. We have generated models of systems composed of digital circuits, but can generalise this approach to any domain where systems can be composed from a library of components. This method circumvents the problems with using random-graphs for experiments, and provides an alternative to developing suites of hand-built models for benchmarking.

Meta-clustering Gene Expression Data with Positive Tensor Factorizations

Liviu Badea¹ and Doina Tilivea¹

1 INTRODUCTION AND MOTIVATION

Although clustering is probably the most frequently used tool for data mining gene expression data, existing clustering approaches face at least one of the following problems in this domain: a huge number of variables (genes) as compared to the number of samples, high noise levels, the inability to naturally deal with overlapping clusters and the difficulty in clustering genes and samples simultaneously. *Fuzzy k-means* or *Nonnegative Matrix Factorization (NMF)* [1] could be used to produce potentially overlapping clusters, but these approaches are affected by a significant problem: the *instability* of the resulting clusters w.r.t. the initialization of the algorithm. This is not surprising if we adopt a unifying view of clustering as a constrained optimization problem, since the fitness landscape of such a complex problem may involve many different local minima into which the algorithm may get caught when started off from different initial states. And although such an instability seems hard to avoid, we may be interested in the clusters that keep reappearing in the majority of the runs of the algorithm. Note that combining clustering results is more complicated than combining classifiers, as it involves solving an additional so-called *cluster correspondence* problem, which amounts to finding the best matches between clusters generated in different runs. The cluster correspondence problem itself could be solved by a suitable *meta-clustering algorithm*.

2 TWO-WAY METACLUSTERING WITH PTF

In this paper we make the simplifying assumption that the overlap of influences (biological processes) is *additive* $X_{sg} \approx \sum_c A_{sc} \cdot S_{cg}$ (1)

where X_{sg} is the expression level of gene g in data sample s , while the expression level of g in s due to biological process c is multiplicatively decomposable into the expression level A_{sc} of the biological process (cluster) c in sample s and the membership degree S_{cg} of gene g in c . Since expression levels and membership degrees cannot be negative: $A_{sc} \geq 0$, $S_{cg} \geq 0$, our clustering problem (1) can be viewed as a *nonnegative factorization* and could be solved using Lee and Seung's seminal *Nonnegative Matrix Factorization (NMF)* algorithm [1]. Such a factorization can be viewed as a "soft" clustering algorithm allowing for *overlapping clusters*, since we may have several significant S_{cg} entries on a given column g of S (a gene g may "belong" to several clusters c).

Allowing for cluster overlap alleviates but does not completely eliminate the instability of clustering, since the NMF algorithm produces different factorizations (biclusters) $(A^{(i)}, S^{(i)})$ for different

initializations, so meta-clustering the resulting "soft" clusters might be needed to obtain a more stable set of clusters.

In this paper, we show that a generalization of NMF called Positive Tensor Factorization (PTF) [2] is precisely the tool needed for meta-clustering "soft", potentially overlapping *biclusters* obtained by NMF object-level clustering. This unified approach solves in an elegant manner both the clustering and the cluster correspondence problem. More precisely, we first run NMF as object-level clustering r times: $X \approx A^{(i)} \cdot S^{(i)}$. (To allow the comparison of membership degrees S_{cg} for different clusters c , we scale the rows of $S^{(i)}$ to unit norm by taking advantage of the scaling invariance of the factorization.) Next, we *meta-cluster* the resulting *biclusters* $(A^{(i)}, S^{(i)})$. This is in contrast with as far as we know all existing (*one-way*) meta-clustering approaches, which take only one dimension into account and fail whenever two clusters correspond to very similar sets of genes, while differing along the sample dimension. The following *Positive Tensor Factorization (PTF)* of the biclusters $(A^{(i)}, S^{(i)})$ represents a *two-way* meta-clustering:

$$A_{s(ic)} \cdot S_{(ic)g} \approx \sum_{k=1}^{n_e} \alpha_{(ic)k} \cdot \beta_{sk} \cdot \gamma_{kg} \quad (2)$$

where k are metacluster indices. (To simplify the notation, we merged the indices i and c into a single index (ic) .)

The columns β_k of β and the corresponding rows γ_k of γ make up a *base set of bicluster prototypes* $\beta_k \gamma_k$, out of which all biclusters of all individual runs can be recomposed, while α encodes the (*bi*)*cluster-metacluster correspondence*. Instead of a perfect bicluster correspondence, we settle for a weaker one (2) in which the rows of α can contain several significant entries, so that all biclusters $A_c^{(i)} \cdot S_c^{(i)}$ are recovered as *combinations* of bicluster prototypes $\beta_k \gamma_k$. The nonnegativity constraints of PTF meta-clustering are essential for obtaining sparse factorizations. (Experimentally, the rows of α tend to contain typically one or only very few significant entries.) The factorization (2) can be computed using the following multiplicative update rules:

$$\begin{aligned} \alpha &\leftarrow \alpha * \frac{(A^T \cdot \beta) * (S \cdot \gamma^T)}{\alpha \cdot [(\beta^T \cdot \beta) * (\gamma \cdot \gamma^T)]} \\ \beta &\leftarrow \beta * \frac{A \cdot [\alpha * (S \cdot \gamma^T)]}{\beta \cdot [(\alpha^T \cdot \alpha) * (\gamma \cdot \gamma^T)]} \quad \gamma \leftarrow \gamma * \frac{[\alpha * (A^T \cdot \beta)]^T \cdot S}{[(\alpha^T \cdot \alpha) * (\beta^T \cdot \beta)]^T \cdot \gamma} \end{aligned}$$

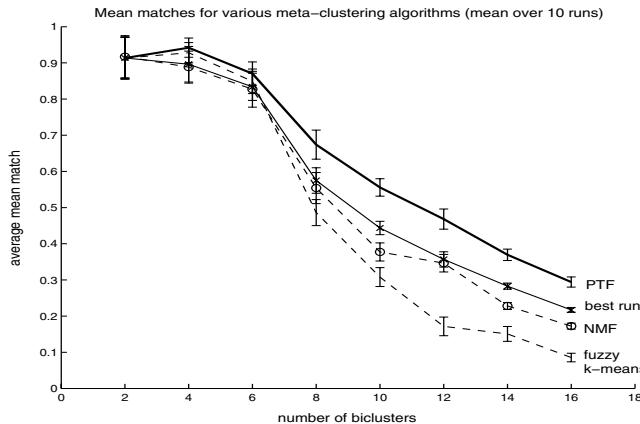

where '*' and '—' denote element-wise multiplication and division of matrices, while '.' is ordinary matrix multiplication.

After convergence of the PTF update rules, we make the prototype gene clusters directly comparable to each other by normalizing the rows of γ to unit norm, as well as the columns of α such that $\sum_{i,c} \alpha_{(ic)k} = r$ and then run NMF initialized with (β, γ) to produce the final factorization $X \approx A \cdot S$.

¹ AI group, National Institute for Research and Development in Informatics, 8-10 Averescu Blvd. Bucharest, Romania. E-mail: badea@ici.ro.

3 EVALUATION ON SYNTHETIC DATA

We evaluated our algorithm on synthetic datasets that match as closely as possible real microarray data. Clusters were modelled using a hidden-variable model $X = A \cdot S + \epsilon$, in which each hidden variable A_c corresponds to the cluster of genes influenced by A_c . We sampled the hidden variables from a log₂-normal distribution with parameters $\mu=2$, $\sigma=0.5$, while the influence coefficients S_{cg} between hidden and observable variables were sampled from a uniform distribution over the interval [1,2]. Finally, we added log₂-normally distributed noise ϵ with parameters $\mu_{noise}=0$, $\sigma_{noise}=0.5$. We chose problem dimensions of the order of our real-world application: $n_{samples}=50$, $n_{genes}=100$, number of genes (respectively samples) per cluster 30 (respectively 15). We compared 4 meta-clustering algorithms (fuzzy k-means, NMF, PTF and the best run) over 10 object-level NMF clustering runs. (Other object level clustering methods perform very poorly and are not shown here). Although all algorithms produce quite low relative errors (under 16%, except for fuzzy k-means which misbehaves for large numbers of clusters), they behave quite differently when it comes to recovering the original clusters. In a certain way, the match of the recovered clusters with the original ones is more important than the relative error. Defining the *match* between two sets of possibly overlapping clusters is nontrivial. For each cluster C_1 from clustering 1, we determine the single cluster C_2 from clustering 2 into which it is best included, i.e. the one with the largest $|C_1 \cap C_2|/|C_1|$. We proceed analogously for the clusters C_2 from clustering 2. Then, for each cluster C_1 (from clustering 1), we determine its match $|C_1 \cap C_2|/|C_1 \cup C_2|$ with the union C_2 of clusters from clustering 2, for which C_1 is the best including cluster (as determined in the previous step). Similarly, we determine matches for clusters C_2 from clustering 2. The average match of the two clusterings is then the mean of all these matches (for all C_1 and all C_2).

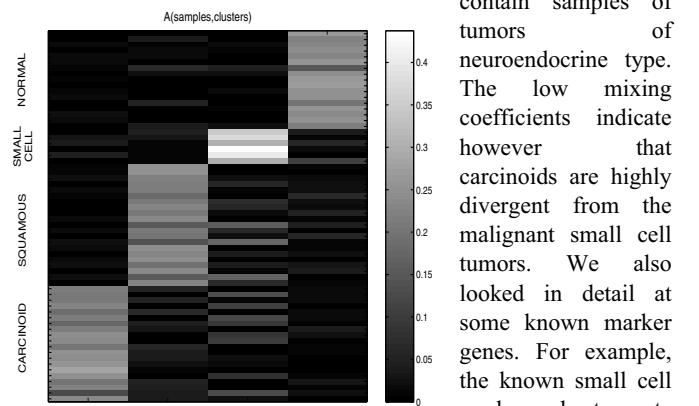

The Figure above shows that PTF consistently outperforms the other meta-clustering algorithms in terms of recovering the original clusters. Note that since clusters were generated randomly, their overlap increases with their number, so it is increasingly difficult for the meta-clustering algorithm to discern between them, leading to a decreasing match. We also observed an inverse correlation between bicluster overlap and matches (Pearson correlation coefficient -0.92). Among all *object-level* clustering algorithms tried (k-means, fuzzy k-means and NMF), only NMF behaves consistently well.

4 METACLUSTERING A LUNG CANCER GENE EXPRESSION DATASET

In the following we show that metaclustering is successful at biclustering a large lung cancer dataset from the Meyerson lab [3], containing 186 lung tumor samples (139 adenocarcinomas, 21 squamous cell lung carcinomas, 6 small cell lung cancers, 20 pulmonary carcinoids) and 17 normal lung samples. For testing our metaclustering algorithm, we first selected a subset of genes (251) that are differentially expressed between the classes (using a SNR measure). More precisely, we selected the genes with an average expression level over 100 and $|SNR| > 2$ for at least one of the classes. Since adenocarcinoma subclasses are poorly understood at the molecular level, we discarded the adeno samples from the dataset and used the histological classification of samples provided in the supplementary material to the original paper [3] as a gold standard for the evaluation of the biclustering results. To eliminate the bias towards genes with high expression values, all genes were scaled to equal norms. Since nonnegative factorizations like NMF cannot directly account for gene down-regulation, we extended the gene expression matrix with new “down-regulated genes” $g' = pos(mean(g_{normal}) - g)$ associated to the original genes g , where $mean(g_{normal})$ is the average of the gene over the *normal* samples and $pos(\cdot)$ is the step function. We then used our PTF metaclustering algorithm to factorize the extended gene expression matrix into 4 clusters with 20 NMF runs.

The algorithm recovered the sample clusters with high accuracy, as can be seen in the following Figure. Note that the overlap between the small cell and carcinoid sample clusters (columns 3 and 1 of A in the Figure) has a biological interpretation: both

1 is *specific* to the small cell cluster, while keratin 5 is specific to the squamous cluster. On the other hand, known proliferative markers like *PCNA* (proliferating cell nuclear antigen), *MCM2* and *MCM6* are *common* to the small cell and squamous clusters, as expected. Overall, our metaclustering algorithm proved quite robust at rediscovering the known histological classification of the various lung cancer types in the Meyerson dataset.

Identifying Inter-Domain Similarities through Content-Based Analysis of Hierarchical Web-Directories

Shlomo Berkovsky¹, Dan Goldwasser¹, Tsvi Kuflik¹ and Francesco Ricci²

Abstract. Providing accurate personalized information services to the users requires knowing their interests and needs, as defined by their User Models (UMs). Since the quality of the personalization depends on the richness of the UMs, services would benefit from enriching their UMs through importing and aggregating partial UMs built by other services from relatively similar domains. The obvious question is how to determine the similarity of domains? This paper proposes to compute inter-domain similarities by exploiting well-known Information Retrieval techniques for comparing textual contents of the Web-sites, classified under the domain nodes in Web-directories. Initial experiments validate feasibility of the proposed approach and raise open research questions.

1 INTRODUCTION

Providing accurate personalized services to the users requires modeling their preferences, interests and needs. This data is referred in the literature as the User Model (UM) [3]. Typically, service providers build and maintain proprietary UMs, tailored to the domain of the service and UMs representation, dictated by the personalization technique being exploited. Since the quality of the provided personalization heavily depends on a richness of the UMs, different services would benefit from enriching their UMs through importing and aggregating partial UMs, i.e., the UMs built by other, possibly related, services. This will bootstrap the UMs of the services where no UMs exist and enrich already existing UMs, leveraging the quality of the provided personalization [1].

One of the major issues that should be resolved to facilitate proper aggregation of partial UMs is "*Which services can provide valuable partial UMs?*". Considering a wide variety of application domains, we conjecture that in addition to the services from the same application domain, also the services from other (relatively similar) domains can provide valuable partial UMs. However, this inherently brings a question of "*Which application domains are considered as similar domains?*".

This work proposes an automatic approach for devising inter-domain similarities through content-based analysis of the Web-sites, classified under the application domains. Such classifications can be found in various human-edited Web-directories, e.g., Google Directory (<http://directory.google.com>), Yahoo! Directory (<http://dir.yahoo.com>), or Open Directory (<http://dmoz.org>). In Web-directories, the Web-sites are classified under application domains, which are recursively partitioned to more specific sub-domains, and so forth. Since Web-directories are edited manually by human experts, we assume that classification of the Web-sites under domains and sub-domains is correct and that large enough set of Web-sites, classified under a certain domain, can be considered as a reliable representative of the domain contents.

Hence, we base inter-domain similarity computation on a comparison of the textual contents of the Web-sites contained in each domain. For this, we first model the contents of the classified domain Web-sites using well-known Information Retrieval (IR) in-

dexing technique of TF-IDF [4]. It allows representing a domain as a ranked vector of terms (derived from the classified Web-sites), where domain-specific terms are assigned higher weights. Then, inter-domain similarity is computed using a cosine similarity metric [4], where the similarity of two vectors is computed as the cosine of the angle between them in a multi-dimensional space. Initial experimental results, conducted over two Web-directories validate the feasibility of the proposed inter-domain similarity computation approach and raise open questions for future research.

The issue of computing similarity over a hierarchical domains structure is elaborately discussed in [2]. That paper presents, analyzes and experimentally compares a set of similarity metrics over a hierarchical tree of domains, while focusing on exploiting the hierarchical structure as an indicator for the similarity values. Conversely, in this work we aim at computing domains similarity through content-based analysis of the Web-sites, classified to the nodes of Web-directories, whereas hierarchical structure of the directories can serve as a heuristic limitation for the search process.

2 ANALYZING DIRECTORIES' CONTENTS

We suggest calculating inter-domain similarity basing on the textual contents of the Web-sites classified under the domain node in a Web-directory. The proposed approach is based on an inherent assumption that the textual contents reliably represent the domain. Although this assumption is not always true (in addition to the textual contents, nowadays Web-sites contain various graphical, audio and video objects, and use dynamic Web-technologies to generate their contents), we believe that large enough number of classified Web-sites will provide an accurate domain representation and a stable basis for the similarity computation.

To represent textual contents of the Web-sites classified under domains of a Web-directory, we propose to exploit well-known IR indexing techniques. For the indexing, stop-words (such as *and*, *to*, *the*, etc...) and HTML tags are filtered-out, the terms are lemmatized to their basic grammatical forms, and weighted according to their domain-related TF-IDF values, assigning higher weights to domain-specific terms (i.e., terms that are frequent in the domain Web-sites only) [4]. As a result, a ranked vector of weighted domain terms, representing the contents of the Web-sites under a given application domain, is obtained. For example, consider a vector of the top terms in *football news* domain, shown in Table 1. It can be clearly seen that the list reliably represents football terms.

Table 1. Top-ranked terms in football news domain

term	score	high	senator	gameface	rumor	league	archive
weight	462.56	397.14	353.94	320.38	251.88	128.31	103.16

After the domain representative vectors are constructed, inter-domain similarity can be easily computed using one of the existing similarity metrics. In this work, we used cosine similarity metrics, defining the similarity between two vectors as the cosine of the angle between them in a multi-dimensional space:

¹ University of Haifa, Haifa, Israel

² ITC-irst, Trento, Italy

$$\text{sim}(V_x, V_y) = \frac{V_x \cdot V_y}{\|V_x\|_2 \times \|V_y\|_2}$$

where \cdot denotes the dot product between the vectors, and $\|V_i\|_2$ denotes the 2-norm of the vector (i.e., the square root of the sum of the squares of the vector elements). The result of the cosine similarity computation is a single scalar, reflecting the similarity of the respective domains, based on their textual contents.

To obtain the required inter-domain similarity values, the above process of similarity computations should be repeated for all the possible pairs of domains. However, compound structure of nowadays Web-directories and high number of the existing domains, make this task expensive and pose a need for heuristically limiting the search space. We propose to exploit the inherent hierarchical structure of the Web-directories for this purpose. Since the Web-directories are organized as linked hierarchical structures, the search (and similarity computations) may be heuristically limited to a set of relatively close nodes only. For example, a search for the domains, similar to *Arts*→*Movies*→*Genres*→*Drama*, may be limited to other movies genres *Arts*→*Movies*→*Genres*→*, other sub-domains of movies *Arts*→*Movies*→*, and more abstract higher-level domain of visual arts *Art*→*Visual Arts*→*.

3 EVALUATION AND FUTURE RESEARCH

We have implemented a prototype system for inter-domain similarity computations. To obtain the contents of the domain Web-sites, we exploited a simple Web-crawler, configured to download the sites' textual contents only. The contents of the domains were represented using IR indexing techniques employed by Lucene, open-source search engine (<http://lucene.apache.org>). The experiments were conducted over Google Directory and Open Directory.

The first experiment was designed to validate the proposed approach for devising inter-domain similarity values. For this, we downloaded the contents of a small set of application domains and computed their pair-wise inter-domain similarities using the above two Web-directories. The pairs of domains whose similarity was computed were: (a) *Arts*→*Television*→*News*→*News on the Internet* vs. *Arts*→*Television*→*News*→*Sports* (b) *Arts*→*Television*→*News* vs. *Sports*→*Football*→*NCAA*, and (c) *Computers*→*Hardware*→*Storage* vs. *Sports*→*Football*→*NCAA*. Note that these domains were selected as their similarity classification can be easily done by a common sense. Pair (a) is a relatively similar one, since the nodes are siblings and many news Web-sites have a dedicated sports section. Pair (b) is similar to some extent only. Despite the fact that the nodes are distinct in Web-directories, news domain does contain some NCAA news items, however, it contains also many other news topics. Pair (c) is highly dissimilar, as the terminology used in hardware storage devices' domain and in NCAA football is very different. Table 2 summarizes the experimental results.

Table 2. Inter-domain similarities in different Web-directories

	(a)	(b)	(c)
Google Dir.	0.3826	0.2676	0.1416
Open Dir.	0.4205	0.1879	0.1103

Experimental results validate feasibility of the proposed approach, as the similarity values for pair (a) are higher than for pair (b), which, in turn, is higher than for pair (c). However, the results raise a question regarding the stability of the proposed approach with the number of the Web-sites that are indexed. Both Google Directory and Open Directory are structured as highly connected graphs, where each domain comprises a set of sub-domains, whereas the sub-domains of different domains may be interlinked. Since a Web-site may be classified to one of the sub-domains of a

given domain, the second experiment was designed to check the impact of indexing and computing TF-IDF representation of a larger set of Web-sites, rather than the sites classified directly under the node of a given domain. We compared three expansion policies: (i) considering also the Web-sites classified under the sub-domain nodes of a given domain, (ii) considering also the Web-sites pointed by the outgoing links from the Web-sites classified under the node of a given domain, i.e., increasing the depth of the search on the Web, and not in the Web-directory, and (iii) integrating (i) and (ii). These policies were employed on the above three pairs of domains and the similarity computations were repeated for a larger set of Web-sites. Table 3 summarizes the results.

Table 3. Inter-domain similarities using different expansion policies

	(a)	(b)	(c)
Google Dir.	(i) 0.3555	0.4279	0.2709
	(ii) 0.3632	0.2275	0.1829
	(iii) 0.4189	0.3874	0.2888
Open Dir.	(i) 0.2703	0.4929	0.1045
	(ii) 0.3354	0.2164	0.0841
	(iii) 0.3279	0.3372	0.1232

The impact of policy (i) can be defined as negative, as the similarity of the of similar domains in pair (a) decreases, while the similarity of less similar pair (b) and (c) increases. We hypothesize that this can be explained by the fact that indexing the Web-sites of the sub-domain nodes inserts a decent noise to the TF-IDF vectors, as also less similar Web-sites are indexed and graph structure of Web-directories brings in sub-domains, which are actually sub-domains of other dissimilar domains. The same observation is true also for policy (ii) as the similarity of (a) decreases, while the similarity of (b) and (c) increases. However, the impact of (ii) is significantly weaker, and (a) is still more similar than (b), which is more similar than (c). This allows us to conclude that indexing the Web-sites pointed by the outgoing links inserts less noise than indexing the Web-sites classified under the sub-domains of a given domain. The impact of (iii) is unclear and it depends on the specific application domain and additional Web-sites that are indexed.

Although the experiments initially validate the feasibility of the proposed inter-domain similarity computation approach, elaborate experiments and analysis are still required. In the future, we plan to analyze statistical properties of the domains for concluding regarding the conditions and domains, where the proposed approach is applicable. We plan to study the use of the graph structure of Web-directories for heuristically limiting the similar domains search. For this, we will check the correlation between the vicinity of nodes in the Web-directories' graph and their content-based similarity. Also, we plan to check the feasibility of the above heuristics in sparse application domains with a small number of classified Web-sites.

As these questions are answered, we plan to investigate the task of aggregating the partial UMs. We believe that the proposed similarity computation approach can be a stable basis for a dynamic user modeling mechanism, facilitating efficient provision of accurate personalization services.

Calibrating Probability Density Forecasts with Multi-objective Search

Michael Carney and Pádraig Cunningham¹

Abstract. The two objectives when estimating the conditional density function in a regression problem are to maximise *sharpness* (the density rewarded to the actual observation), while maintaining *calibration* (the empirical validity of the probability estimates). In this paper we outline a process of optimisation that maximises both these objectives simultaneously to make better probabilistic predictions.

1 INTRODUCTION

Regression is a supervised learning problem where the fundamental task is to predict some *continuous* variable. Formally, the regression problem is the process of estimating the parameters for a model given a set of training data $\{(\mathbf{x}_i, t_i)\}_{i=1}^m$, where the target variable is $t_i \in \mathbb{R}$. Typically, to solve this problem point forecasting methods are used to estimate, $\langle t_i | \mathbf{x}_i \rangle$, the conditional mean of the target given an input pattern. Density forecasting is an important subfield of regression that tackles the practical problem of uncertainty in predictions by attempting to estimate, $p(t_i | \mathbf{x}_i)$, the conditional probability density of the target. This is useful because prediction users are generally sensitive to the possible variance around a prediction. Furthermore, with a correctly specified density forecast they can make the *optimal* decision under uncertainty.

The most common approach to parameter estimation of regression models is maximum likelihood. Density forecasting is not an exception, using a generalisation of maximum likelihood called negative log-likelihood (*NLL*). The convenience of this approach is that the traditional optimisation techniques such as *conjugate gradient* can be used with minimal adaptations. However, on closer examination of this approach, it can be shown that certain aspects of the problem of density forecasting are not addressed and so this technique can lead to poor, sub-optimal, and often misleading models.

In this paper we introduce a new multi-objective approach to optimisation of density forecasting models. We outline a broad framework, based on a multi-objective evolutionary algorithm (MOEA), that can be used to optimise most density forecasting models.

2 GOALS OF DENSITY FORECASTING

The *NLL* addresses the goal of sharpness by rewarding models based on the density of the prediction at the target. The formula for *NLL* is:

$$NLL_i = -\log(p(t_i | \mathbf{x}_i)) \quad (1)$$

Optimising a model using *NLL* is an attempt to find the set of model parameters that maximise the probability density at the target. This approach produces accurate estimates of the conditional

density function in situations where the underlying data generating process (DGP) is known or can be approximated well by the distribution assumed by the model. In circumstances where the DGP is very complex, or the incorrect assumptions are made about the underlying distribution, or over-fitting is an issue, the *NLL* performs poorly, particularly in terms of calibration. Demonstrations of these effects are shown in [3].

Calibration refers to the property that if a predicted density function suggests P percent probability of occurrence, the event truly ought to have probability P of occurring. [6] shows that in classification calibration can be achieved simply; however, in regression the problem is somewhat more difficult and a straightforward post training transformation does not work. In regression, evaluation of calibration is dependent on the assumption that you are attempting to find the model that correctly describes the DGP. In the case where the correct DGP is described, the set of cumulative densities at the targets will be uniform. Therefore, to determine calibration you must carry out the following transformation;

$$z_i = \int_{-\infty}^{t_i} p(u | \mathbf{x}_i) du \quad (2)$$

where z_i is the cumulative of the predicted density at the target t_i . This is known as the Probability Integral Transform (PIT). Diebold et al. [4] show that the z series should be $\{z_i\}_{i=1}^m \stackrel{iid}{\sim} U[0, 1]$.

Typically, it is a histogram of the z values that is displayed (see Fig 2), and the calibration of the model is assessed visually. However, we suggest that a ranking of density models can be obtained by determining the goodness-of-fit of the z values to the uniform distribution. We compared a number of goodness-of-fit tests and concluded that the Anderson-Darling (A^2) [1] test for uniformity was the most robust among the most common tests for uniformity [3]. The A^2 test is negatively oriented returning a 0 in the case where a model is perfectly calibrated. The formula for A^2 is;

$$A^2 = -m - \frac{1}{m} \sum_{j=1}^m (2j-1)[\log(z_j) + \log(1-z_{m-j})] \quad (3)$$

and the z values are sorted in ascending order.

3 OPTIMISATION FRAMEWORK

In the preceding sections we have mentioned two quality scoring metrics for density forecasting, A^2 and *NLL* (calibration and sharpness). Therefore, implicitly we have described a multi-objective optimisation problem. The preferable approach to solve a multi-objective search problem is to use an *a posteriori* MOEA. In the context of

¹ Trinity College Dublin, Ireland, email: firstname.surname@cs.tcd.ie

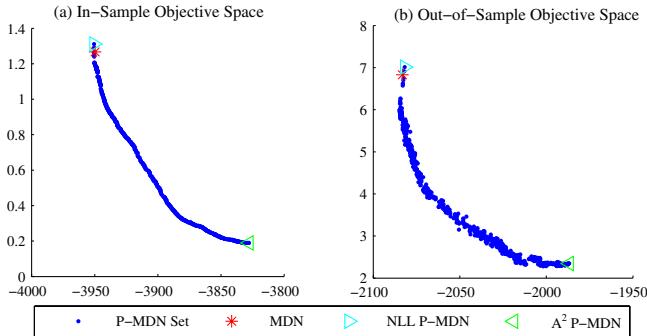

Figure 1. In and out-of-sample objective spaces of Pareto-MDN

MOEA's, *a posteriori* means that the optimisation process maintains an archive of optimal trade-off (non-dominated) solutions, known as the Pareto front, throughout training and the user selects the model that best optimises their goals from the resulting Pareto front of solutions.

Before optimisation the modeler must: (1) Determine a vector representation for the parameters of the density forecasting model. (2) Be able to calculate the A^2 and NLL score for the model's predicted densities. (3) Decide on a mutation and selection strategy for the evolutionary algorithm. Then optimisation can proceed as normal. For further information on the MOEA algorithm, see [3].

Pareto Mixture Density Network A Mixture Density Network (MDN) [2] is a particular class of neural network adapted to produce density forecasts. MDNs represent the conditional density function by a weighted mixture of Gaussians known as a Gaussian Mixture Model (GMM). MDNs are generally optimised using a conjugate gradient technique, however, like most neural networks they can also be optimised using an evolutionary algorithm. Recently, Fieldsend et al. introduced a technique for multi-objective optimisation of neural networks [5]. We have adapted this to fit our framework by using an MDN as the underlying model and setting the objective functions to the NLL and A^2 scores. We use an Evolutionary Strategy (ES) for optimisation of the MDN [5]. This results in objective function and network architecture optimisation. For a full description of the Pareto-MDN see [3].

4 CASE STUDY: FINANCIAL DATA

In this case study, we analyse the performance of an MDN model on estimating the conditional density of foreign exchange data with the purpose of determining a measure of Value-at-Risk. The data is comprised of 1,501 examples of daily price observations for the DeutscheMark/British Pound foreign exchange rate, from April 1985 to January 1992. We transform the daily prices into a log returns series by $r_i = \log(\frac{p_{i+1}}{p_i})$, where p_i is the price at interval i . The return series was separated into a training set of the first 1,000 observations and a test set comprised of the last 500 observations.

The MDN was given 6 hidden units and outputs were represented by a 2 component GMM. An initial model was trained on the data using a standard optimisation technique, in this case we use a Scaled Conjugate Gradient (SCG) method. We use this model as our initial starting position in parameter space for our evolutionary algorithm. We carried out 10,000 iterations of the ES algorithm resulting in a set of 736 non-dominated individuals. Figure 1 shows the in-sample and

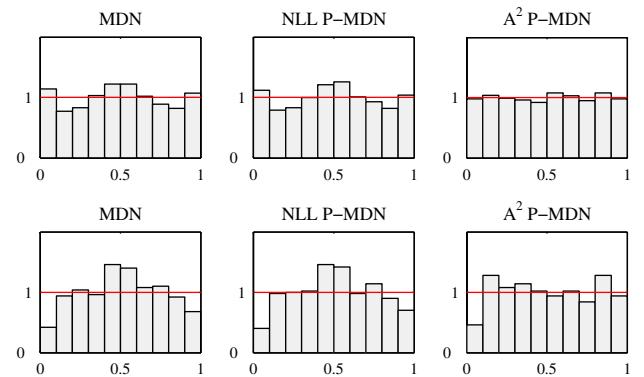

Figure 2. PIT histograms for the training (top row) and test data (bottom).

out-of-sample objective spaces for all individuals in the final Pareto set. Each point on the objective space represents the error scores obtained by one of the Pareto set models. We have highlighted some models of interest, the *MDN* model our benchmark model trained using SCG. *NLL P-MDN* is the model from the Pareto set that has the best in-sample *NLL* score and *A² P-MDN* is the model with best *A²* score.

The Spearman rank correlation coefficient between the in-sample and out-of-sample *NLL* is 0.8589 and *A²* is 0.9848. This suggests little over-fitting of the models to the data on either objective function.

Figure 2 displays the PIT histograms of the z values for the models identified in the objective space. The model with best calibration is *A² P-MDN* in and out-of-sample. The *MDN* and *NLL P-MDN* models show over-confidence in-sample and under-confidence out-of-sample. The effect of this improvement means that for financial applications such as risk management, where rare events are significant, better and more accurate estimates of risk can be reported.

5 CONCLUSIONS

We have introduced and evaluated a multi-objective approach to density forecasting that improves calibration. This is a general method that can be applied to any density forecasting model that can be appropriately parameterised. For example, in [3] we apply this approach to a GARCH model.

Term-Weighting in Information Retrieval using Genetic Programming: A three stage process

Ronan Cummins and Colm O'Riordan ¹

1 Introduction

This paper presents term-weighting schemes that have been evolved using genetic programming in an adhoc Information Retrieval model. We create an entire term-weighting scheme by firstly assuming that term-weighting schemes contain a global part, a term-frequency influence part and a normalisation part. By separating the problem into three distinct phases we reduce the search space and ease the analysis of the schemes generated by the process.

Evolutionary computation techniques are proving to be a viable alternative to other standard analytical methods in many areas of IR. Genetic Programming (GP) [2] is an automated searching algorithm inspired by biological evolution. GP has been shown to be an effective approach to learning term-weighting schemes in IR [5]. Firstly, we evolve weighting schemes in a global domain which promote the best terms to use in distinguishing documents. Then, using a suitable global scheme, we evolve term-frequency influence schemes which uses the within-document term-frequency to correctly weight the term-frequency factor. Finally, we evolve normalisation schemes based on the best performing combined global and term-frequency scheme. This framework is an extension of work carried out in [1]. Most term-weighting schemes combine these three aspects to weight query terms and thus score a document in relation to a query.

2 Experimental Framework

The global (gw_t) and normalised term-frequency (ntf) weighting schemes are evolved in a term-weighting function which scores a document (d) in relation to a query (q) as follows:

$$score(d, q) = \sum_{t \in q \cap d} (ntf \times gw_t \times qtf) \quad (1)$$

where qtf is the actual term-frequency of term t in the query. It can be seen that both BM25 [3] and the pivoted normalisation scheme [4] fit this type of model. Tables 1, 2 and 3 show the terminals sets and some GP parameter details for the experiments. The set of functions used for all experiments is $F = \{\times, +, -, /, log, square, square-root\}$. We use an elitist GP strategy and 4% mutation for all experiments. Mean average precision (MAP) is used as the fitness function in all experiments. All solutions are limited to a depth of 6.

2.1 Document Test Collections

The training set for the global problem consisted of 35,000 OHSUMED documents from 1998 and the 63 topics. The training set

for the term-frequency influence problem consisted of 32,000 document from the LATIMES collection and 37 medium topics. The training set for the normalisation problem consisted of the same 32,000 documents from the LATIMES collection but we used 12 short, 13 medium and 12 long topics for this problem as it has been suggested that query length may have an impact on normalisation. We tested the solutions for generality on collections from TREC disks 4 and 5 to test our schemes. Table 4 details the collections and lengths of short (title), medium (title and description) and long (title and description and narrative) queries. Standard stop-words are removed and remaining words are stemmed.

2.2 Benchmark Term-Weighting

The full BM25 and pivoted normalisation scheme with default values are used as benchmarks for the entire schemes. The default term-frequency influence value of $k_1 = 1.2$ and normalisation influence value of $b = 0.75$ is used for BM25 while the slope (s) set to 0.2 is used for the pivoted normalisation scheme (Piv). We use the BM25 ($BM25_{b=0}$) and pivoted normalisation scheme ($Piv_{s=0}$) with no normalisation (i.e. assuming all documents are of equal length) as benchmarks for the global schemes combined a term-frequency influence factor. We use the idf scheme as found in the BM25 (idf_{rsj}) and pivoted normalisation scheme (idf_{piv}) as benchmarks for the global part of the scheme. We use the actual within-query term-frequency scheme (qtf) with all schemes as in (1).

2.3 Term-Weighting Scheme

One of the best evolved global schemes is as follows:

$$gw_t = \frac{cf^2\sqrt{cf}}{df^3} \quad (2)$$

The best evolved term-frequency factor, based on the global scheme, is as follows:

$$\log\left(\frac{10}{\sqrt{(0.5/tf) + 0.5}}\right) = \log\left(\sqrt{\frac{200.tf}{1+tf}}\right) \quad (3)$$

We assume the term-frequency factor is normalised (ntf) as follows:

$$ntf = \log\left(\sqrt{\frac{200.\frac{tf}{n}}{1+\frac{tf}{n}}}\right) \quad (4)$$

where n is some normalisation factor. One of the best evolved normalisation schemes is as follows:

$$n = \sqrt{\log(qtl)} \times \log(qtl) \times \frac{l}{l_{avg}} \quad (5)$$

Queries of length one were given the same normalisation as queries of length two during testing as $n = 0$ when $qtl = 1$. This occurred as there was no query of length one in the training set for the normalisation problem.

3 Discussion and Conclusions

It is worth noting that none of the randomly created solutions were as good as the best solution from the final generation. We can see for the global weighting problem that the evolved solution presented has a higher MAP on all topic lengths and collections. The increase over the idf type schemes is quite large for medium and long queries. For the term-frequency influence problem (assuming no normalisation), we can see that the MAP of the evolved solution ($tf.gw_t$) is higher than the benchmarks on most collections at this point especially for longer queries. We can see that the term-frequency part of the Piv scheme is a lot poorer than the default term-influence setting for BM25 at this stage. We can see that normalisation is beneficial to all schemes for medium and long queries but slightly degrades some short queries. We can see that our full evolved scheme is the best performing scheme on the collections for all but the short queries on the LATIMES collection. We have shown that term-weighting schemes can be found by evolutionary techniques that fit certain known aspects of weighting schemes and also contain new features such as query length.

Adaptation Knowledge Discovery from a Case Base

M. d'Aquin¹ and F. Badra¹ and S. Lafrogne¹ and J. Lieber¹ and A. Napoli¹ and L. Szathmary¹

Abstract. In case-based reasoning, the adaptation step depends in general on domain-dependent knowledge, which motivates studies on adaptation knowledge acquisition (AKA). CABAMAKA is an AKA system based on principles of knowledge discovery from databases. This system explores the variations within the case base to elicit adaptation knowledge. It has been successfully tested in an application of case-based decision support to breast cancer treatment.

1 INTRODUCTION

Case-based reasoning (CBR [4]) aims at solving a target problem thanks to a case base. A case represents a previously solved problem. A CBR system selects a case from the case base and then adapts the associated solution, requiring domain-dependent knowledge for adaptation. The goal of adaptation knowledge acquisition (AKA) is to extract this knowledge. The system CABAMAKA applies principles of knowledge discovery from databases (KDD) to AKA. The originality of CABAMAKA lies essentially in the approach to AKA that uses a powerful learning technique that is guided by a domain expert, according to the spirit of KDD. This paper proposes an original and working approach to AKA, based on KDD techniques.

CBR and adaptation. A case in a given CBR application is usually represented by a pair $(pb, Sol(pb))$ where pb represents a problem statement and $Sol(pb)$, a solution of pb . CBR relies on the *source cases* $(srce, Sol(srce))$ that constitute the *case base* CB. In a particular CBR session, the problem to be solved is called *target problem*, denoted by tgt . A case-based inference associates to tgt a solution $Sol(tgt)$, with respect to the case base CB and to additional knowledge bases, in particular \mathcal{O} , the *domain ontology* that usually introduces the concepts and terms used to represent the cases.

A classical decomposition of CBR consists in the steps of retrieval and adaptation. *Retrieval* selects $(srce, Sol(srce)) \in CB$ such that $srce$ is judged to be similar to tgt . The goal of adaptation is to solve tgt by modifying $Sol(srce)$ accordingly.

The work presented hereafter is based on the following model of adaptation, similar to *transformational analogy* [1]:

- ① $(srce, tgt) \mapsto \Delta pb$, where Δpb encodes the similarities and dissimilarities of the problems $srce$ and tgt .
- ② $(\Delta pb, AK) \mapsto \Delta sol$, where AK is the adaptation knowledge and where Δsol encodes the similarities and dissimilarities of $Sol(srce)$ and the forthcoming $Sol(tgt)$.
- ③ $(Sol(srce), \Delta sol) \mapsto Sol(tgt)$, $Sol(srce)$ is modified into $Sol(tgt)$ according to Δsol .

Adaptation is generally supposed to be domain-dependent in the sense that it relies on domain-specific adaptation knowledge. There-

fore, this knowledge has to be acquired. This is the purpose of *adaptation knowledge acquisition* (AKA).

A related work in AKA. The idea of the research presented in [3] is to exploit the variations between source cases to learn adaptation rules. These rules compute variations on solutions from variations on problems. More precisely, ordered pairs $(srce-case_1, srce-case_2)$ of similar source cases are formed. Then, for each of these pairs, the variations between the problems $srce_1$ and $srce_2$ and the solutions $Sol(srce_1)$ and $Sol(srce_2)$ are represented (Δpb and Δsol). Finally, the adaptation rules are learned, using as training set the set of the input-output pairs $(\Delta pb, \Delta sol)$. The experiments have shown that the CBR system using the adaptation knowledge acquired from the automatic system of AKA shows a better performance compared to the CBR system working without adaptation. This research has strongly influenced our work that is globally based on similar ideas.

2 CABAMAKA

Principles. CABAMAKA deals with *case base mining* for AKA. Although the main ideas underlying CABAMAKA are shared with those presented in [3], the followings are original ones. The adaptation knowledge that is mined has to be validated by experts and has to be associated with explanations that make it understandable by the user. In this way, CABAMAKA may be considered as a semi-automated (or interactive) learning system. Another difference with [3] lies in the volume of the cases that are examined: given a case base CB where $|CB| = n$, the CABAMAKA system takes into account every ordered pair $(srce-case_1, srce-case_2)$ with $srce-case_1 \neq srce-case_2$ (whereas in [3], only the pairs of *similar* source cases are considered, according to a fixed criterion). Thus, the CABAMAKA system has to cope with $n(n - 1)$ pairs, a rather large number of elements, since in our application $n \simeq 750$. $(n(n - 1) \simeq 5 \cdot 10^5)$. This is why efficient techniques of knowledge discovery from databases (KDD [2]) have been chosen for this system.

Principles of KDD. The goal of KDD is to discover knowledge from databases, with the supervision of an analyst (expert of the domain). A KDD session usually relies on three main steps: data preparation, data-mining and interpretation.

Data preparation is based on formatting and filtering operations. The formatting operations transform the data into a form allowing the application of the chosen data-mining operations. The filtering operations are used for removing noisy data and for focusing the data-mining operation on special subsets of objects and/or attributes.

Data-mining methods are applied to extract pieces of information from the data. These pieces of information have some regular

¹ LORIA (UMR 7503 CNRS-INPL-INRIA-Nancy 2-UHP), BP 239, 54506 Vandœuvre-lès-Nancy, FRANCE

properties allowing their extraction. For example, CHARM [5] is a data-mining algorithm that performs efficiently the extraction of *frequent closed itemsets (FCIs)*. CHARM inputs a database in the form of a set of transactions, each *transaction T* being a set of boolean properties or *items*. An *itemset I* is a set of items. The support of *I*, $\text{support}(I)$, is the proportion of transactions *T* of the database possessing *I* ($I \subseteq T$). *I* is frequent, with respect to a threshold $\sigma \in [0; 1]$, whenever $\text{support}(I) \geq \sigma$. *I* is closed if it has no proper superset *J* ($I \subsetneq J$) with the same support.

Interpretation aims at interpreting the output of data-mining i.e. the FCIs in the present case, with the help of an analyst. In this way, the interpretation step produces new knowledge units (e.g. rules).

Formatting. The formatting step of CABAMAKA inputs the case base CB and outputs a set of transactions obtained from the pairs $(\text{srce-case}_1, \text{srce-case}_2)$. It is composed of two substeps. During the first substep, each $\text{srce-case} = (\text{srce}, \text{Sol}(\text{srce})) \in \text{CB}$ is formatted in two sets of boolean properties: $\Phi(\text{srce})$ and $\Phi(\text{Sol}(\text{srce}))$. The computation of $\Phi(\text{srce})$ consists in translating srce from the problem representation formalism to $2^{\mathcal{P}}$, \mathcal{P} being a set of boolean properties. Possibly, some information may be lost during this translation, but this loss has to be minimized. Now, this translation formats an expression srce expressed in the framework of the domain ontology \mathcal{O} to an expression $\Phi(\text{srce})$ that will be manipulated as data, i.e. without the use of a reasoning process. Therefore, in order to minimize the translation loss, it is assumed that if $p \in \Phi(\text{srce})$ and p entails q (given \mathcal{O}) then $q \in \Phi(\text{srce})$. In other words, $\Phi(\text{srce})$ is assumed to be deductively closed given \mathcal{O} in the set \mathcal{P} . The same assumption is made for $\Phi(\text{Sol}(\text{srce}))$. How this first substep of formatting is computed in practice depends heavily on the representation formalism of the cases.

The second substep of formatting produces a transaction $T = \Phi((\text{srce-case}_1, \text{srce-case}_2))$ for each ordered pair of distinct source cases, based on the sets of items $\Phi(\text{srce}_1)$, $\Phi(\text{srce}_2)$, $\Phi(\text{Sol}(\text{srce}_1))$ and $\Phi(\text{Sol}(\text{srce}_2))$. Following the model of adaptation presented in introduction (items ①, ② and ③), T has to encode the properties of Δ_{pb} and Δ_{sol} . Δ_{pb} encodes the similarities and dissimilarities of srce_1 and srce_2 , i.e.:

- The properties common to srce_1 and srce_2 (marked by “=”),
- The properties of srce_1 that srce_2 does not share (“-”) and
- The properties of srce_2 that srce_1 does not share (“+”).

All these properties are related to problems and thus are marked by pb . Δ_{sol} is computed in a similar way and $\Phi(T) = \Delta_{\text{pb}} \cup \Delta_{\text{sol}}$. For example,

$$\begin{aligned} \text{if } & \begin{cases} \Phi(\text{srce}_1) = \{a, b, c\} & \Phi(\text{Sol}(\text{srce}_1)) = \{A, B\} \\ \Phi(\text{srce}_2) = \{b, c, d\} & \Phi(\text{Sol}(\text{srce}_2)) = \{B, C\} \end{cases} \\ \text{then } & T = \{a_{\text{pb}}, b_{\text{pb}}, c_{\text{pb}}, d_{\text{pb}}, A_{\text{sol}}, B_{\text{sol}}, C_{\text{sol}}\} \end{aligned} \quad (1)$$

Mining. The extraction of FCIs is computed thanks to CHARM (in fact, thanks to a tool based on a CHARM-like algorithm) from the set of transactions. A transaction $T = \Phi((\text{srce-case}_1, \text{srce-case}_2))$ encodes a specific adaptation $((\text{srce}_1, \text{Sol}(\text{srce}_1)), \text{srce}_2) \mapsto \text{Sol}(\text{srce}_2)$. An FCI extracted may be considered as a generalization of a set of transactions. For example, if $I_{\text{ex}} = \{a_{\text{pb}}, c_{\text{pb}}, d_{\text{pb}}, A_{\text{sol}}, B_{\text{sol}}, C_{\text{sol}}\}$ is an FCI, I_{ex} is a generalization of a subset of the transactions including the transaction T of equation (1): $I_{\text{ex}} \subseteq T$. The interpretation of this FCI as an adaptation rule is explained below.

Interpretation. The interpretation step is supervised by the analyst. The CABAMAKA system provides the analyst with the extracted FCIs and facilities for navigating among them. The analyst may select an FCI, say I , and interpret I as an adaptation rule. For example, the FCI I_{ex} may be interpreted in the following terms:

if a is a property of srce but is not a property of tgt ,
 c is a property of both srce and tgt ,
 d is not a property of srce but is a property of tgt ,
 A and B are properties of $\text{Sol}(\text{srce})$ and
 C is not a property of $\text{Sol}(\text{srce})$
then the properties of $\text{Sol}(\text{tgt})$ are
 $\Phi(\text{Sol}(\text{tgt})) = (\Phi(\text{Sol}(\text{srce})) \setminus \{A\}) \cup \{C\}$.

This has to be translated as an adaptation rule r of the CBR system. Then the analyst corrects r and associates an explanation with it.

Implementation. The application domain of the CBR system we are developing is breast cancer treatment: in this application, a problem pb describes a class of patients with a set of attributes and associated constraints (holding on the age of the patient, the size and the localization of the tumor, etc.). A solution $\text{Sol}(\text{pb})$ of pb is a set of therapeutic decisions (in surgery, chemotherapy, etc.). The requested behavior of the CBR system is to provide a treatment and explanations on this treatment proposal. This is why the analyst is required to associate an explanation to a discovered adaptation rule.

The problems, solutions and the domain ontology of the application are represented in OWL DL (recommendation of the W3C).

3 CONCLUSION

The CABAMAKA system presented in this paper is inspired by the research presented in [3] and by the principles of KDD for the purpose of semi-automatic adaptation knowledge discovery. It has enabled to discover several useful adaptation rules for a medical CBR application. It has been designed to be reusable for other CBR applications: only a few modules of CABAMAKA are dependent on the formalism of the cases and of the domain ontology, and this formalism, OWL DL, is a well-known standard. One element of future work consists in searching for ways of simplifying the presentation of the numerous extracted FCIs to the analyst. This involves an organization of these FCIs for the purpose of navigation among them. Such an organization can be a hierarchy of FCIs according to their specificities or a clustering of the FCIs in themes.

Polynomial Conditional Random Fields for signal processing

Trinh-Minh-Tri Do and Thierry Artières¹

Abstract. We describe Polynomial Conditional Random Fields for signal processing tasks. It is a hybrid model that combines the ability of Polynomial Hidden Markov models for modeling complex dynamic signals and the discriminant power of Conditional Random Fields. We detail the learning of these models and report experimental results on handwriting recognition.¹

1 INTRODUCTION

Classification, segmentation and labelling of sequential data are major problems in many application fields such as bioinformatics, signal processing (e.g. handwriting), information extraction and so on. Generally speaking these tasks consist in transforming an observed input signal or sequence into a sequence of labels. For decades, Hidden Markov Models (HMMs) have been the most popular approach although they rely on strong independence assumptions and despite they are learned using a non discriminant criterion, namely Maximum Likelihood Estimation. This comes from the fact that HMMs are generative models and that they define a joint probability distribution on the sequence of observations X and the associated label sequence Y .

A number of models were proposed for relaxing classical independence assumptions; most rely on segmental HMMs where trajectory models (e.g. polynomial) are used in each state to implement probability density functions at the segment level [1]. Besides conditional models were recently proposed for sequence processing tasks, Conditional Random Field (CRF) is the most popular one [2]. CRFs aim at modelling directly the conditional distribution $P(Y|X)$, they are attractive since first they are learned with a discriminant criterion where each label sequence is viewed as a possible class for an input sequence and second, being conditional, these models do not explicitly model input signals distribution so that they do not require any simplifying assumptions over X . However, CRF rely on the definition by hand of set of (eventually many) features, computed from observations X and label sequence Y . In a way underlying assumptions over X are implicit and hidden in the manual design of features. Up to now CRFs have been used in specific text processing tasks such as information extraction, FAQ segmentation, POS-tagging for which efficient features may be easily designed. The use of conditional models for continuously varying signals is less straightforward. This paper aims at developing a model which combines the accurate modelling of polynomial HMMs (PHMMs) with the efficiency of CRF discriminant learning. We first present Polynomial CRF (PCRF) and then we report comparative experimental results on on-line digit recognition.

2 POLYNOMIAL CRF

Let $X = (x_1, x_2, \dots, x_T)$ with $x_t \in \mathbb{R}^d$ be an input signal. Assuming that successive observations are generated according to a polynomial function of time, this sequence of observations may be modelled with a polynomial regression function:

$$x_t = f(t) = \sum_{k=0}^P a_k f_k(t) + \varepsilon(t) \quad (1)$$

where P is the degree of f , a_k are coefficients of polynomial functions f_k and $\varepsilon(t)$ is an i.i.d. residual. $\{f_k\}_k$ consists of a fixed set of polynomials (e.g. x^k). Assuming $\varepsilon(t)$ is a white Gaussian noise, the likelihood of a sequence may be computed as:

$$P(X) \propto e^{-\frac{1}{2} \sum_{t=1}^T \left\| x_t - \sum_{k=0}^P a_k f_k(t) \right\|^2} \quad (2)$$

Such polynomial functions have been embedded in HMM to implement more accurate probability density functions (*pdf*) than traditional Gaussian distributions. These Polynomial HMMs (PHMMs) have been shown to be more accurate in speech modelling and recognition tasks, they are trained using a Maximum Likelihood training algorithm which is a generalization of the standard HMM training algorithm [1].

Besides in CRFs the conditional probability of the output Y (i.e. the label sequence) given the input X (i.e. the sequence of observations) is defined with:

$$P(Y|X) = \frac{e^{W^T F(X, Y)}}{Z(X)} \quad (3)$$

where $F(X, Y)$ is a feature vector, W is the weight vector, $W^T F(X, Y)$ is their dot product, and $Z(X)$ is a normalization factor. Training consists in maximizing the conditional log likelihood over the training set w.r.t. W :

$$L = \sum_i \log P(Y_i | X_i) \quad (4)$$

Our model is an extension of CRFs for signal classification using segmental (polynomial) features, i.e. features that are defined on segments of successive observations. In this model, we use an ideal polynomial curve describing the sequence of successive observations in each state. Let S be a segmentation of X in the model, i.e. a state sequence. It may be decomposed into a sequence

of segments where a segment stands for a sequence of successive observations that are assigned to the same state. Let note s_j the j^{th} segment and let β_j stands for the starting time of s_j . Then $s_j = (x_{\beta_j}, \dots, x_{\beta_{j+1}-1})$. The probability $P(Y/X)$ may then be defined as:

$$P(Y/X) = \frac{1}{Z(X)} \sum_S e^{\text{score}(S, Y, X)} \quad (5)$$

where $\text{score}(S, Y, X)$ stands for the score of the label sequence Y along a particular segmentation S for input X . It may be further decomposed into:

$$\text{score}(S, Y, X) = \sum_{j=1}^{|S|} \text{score}(s_j, q_{j,Y}, X) \quad (6)$$

Where $q_{j,Y}$ is the state corresponding to the j^{th} segment in segmentation Y and $\text{score}(s_j, q, X)$ stands for the score associated to j^{th} segment and state q . Following works on polynomial regression, this score is linked to how well the segment fits with the trajectory model associated to the state. Following works in [1] and using Eq. (1) and Eq. (2), it is computed as:

$$\text{score}(s_j, q, X) = \sum_{t=\beta_j}^{\beta_{j+1}-1} \left\| x_t - \sum_{k=0}^P a_k^q f_k(t - \beta_j) \right\|^2 \quad (7)$$

Where a_k^q stand for the coefficients of the polynomial function in state q . To perform sequence classification we build a CRF whose architecture is illustrated in Fig. 1. There is one left-right chain model for each class. At test time, the most probable sequence of states (i.e. left-right chain) indicates the recognized class [3].

Training aims at estimating model's parameters, i.e. a_k^q . As for standard CRFs, this is done through maximizing the criterion in Eq. (4). There are two main problems for training polynomial CRF. First, unlike what is usually done with standard CRFs, the training database is only partially labelled. This means that the segmentation S corresponding to a training sequence is not known, only its class is known. This problem may be solved by introducing, in the training algorithm, hidden variables that correspond to segmentations S of the training sequences [3,4]. One can then use an EM-like learning algorithm consists then in iterating two steps. In the E-step, we one estimates the distribution over hidden variables $P(S/X, Y)$. In the M-step one updates the model parameters to reach a better likelihood [3]. Second, unlike standard CRFs, training involves a non linear optimization problem since the usual dot product in Eq. (3) is replaced here by a non linear term (Eq. (7)). Hence, in the M-step algorithm, parameters a_k^q are updated using a standard gradient descent method till convergence.

3 EXPERIMENTS

We carried out experiments on on-line digit recognition. On-line handwriting signals are captured with an electronic pen or a digitalized tablet; there are temporal sequences of pen coordinates. As is usually done in handwriting processing, raw signals are first normalized and transformed into a sequence of direction feature (angle of the trajectory with the horizontal axis). There are about 50 samples for every digit '0' to '9'. We report in Table 1 comparative results of a generative system (PHMMs) and our discriminative system (PCRFs) that have been obtained using cross validation. Performances are reported for various settings concerning the number of states in the models (1 to 4) and the

Table 1. Accuracy of PHMM and PCRF for digit recognition as a function of the number of states per digit model and of the polynomial degree.

	#states	P=0	P=1	P=2	P=3

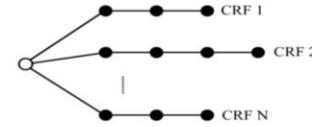

Figure 1. Mixture of chained CRF (i.e. with a chain structure) for sequence classification. Each chain corresponds to a class.

Figure 2. Mean samples of digits learned by a generative system (PHMM) on the left and a discriminant system (PCRF) on the right. Both systems are based on two-states models.

degree of polynomials (0 to 3). Almost whatever the number of states and the degree of polynomials PCRFs significantly outperform PHMMs. Although increasing the number of states in PHMMs improves accuracy it does not easily reach performance of PCRFs. In order to investigate deeper the behaviour of the models we generated from the learned models "mean samples" using polynomial trajectories learned in each state. Figure 2 compares these samples for the generative PHMM system as well as for the discriminant PCRF. One may see that although PHMM perform much lower, they allow modelling accurately the input signals. On the contrary PCRF, being discriminant, have focused on what distinguishes input signals of the ten digits so that mean samples do not represent well the original digits.

4 CONCLUSION

We presented Polynomial Conditional Random Fields for signal processing and discussed their learning. These models are hybrid and allow discriminant learning of trajectory models for signal classification and segmentation. PCRFs are shown to outperform non discriminant comparable polynomial generative models.

Stream Clustering Based on Kernel Density Estimation

Stefano Lodi and Gianluca Moro and Claudio Sartori¹

Abstract. We present a novel algorithm for clustering streams of multidimensional points based on kernel density estimates of the data. The algorithm requires only one pass over each data point and a constant amount of space, which depends only on the accuracy of clustering. The algorithm recognizes clusters of nonspherical shapes and handles both inserted and deleted objects in the input stream. Querying the membership of a point in a cluster can be answered in constant time.

1 Introduction

In many emerging scenarios, applications process the output of high speed, high volume data sources that originate continuous, unbounded flows of data, which have been termed *data streams*. Examples of data streams are call records of telephone companies, click streams, environmental data, and data from sensor networks. Stream processing is subject to tight constraints: Huge volume and high speed make random accesses and multiple scans of a memory image of the entire stream clearly infeasible, whereas unboundedness requires algorithms with constant time complexity per update, to avoid continuously increasing response times.

The design of stream data mining algorithms is especially demanding, as traditional solutions often entail combinatorial computations or exploring mutual relationships among the data. A fundamental data mining problem which has recently been studied in the stream domain is *data clustering*. Most formal definitions of the clustering problem capture the intuitive idea that similar objects must be grouped into the same cluster, whereas dissimilar objects must belong to different clusters. All approaches avoid storing the data records and maintain various kinds of statistics on the data, mostly in constant time. The statistics are sufficient to describe the clustering structure of the stream, and to answer cluster membership queries, at the price of some degree of inaccuracy.

We propose a novel stream clustering algorithm based on nonparametric kernel density estimation, capable of recognizing nonspherical clusters and allowing for both insertions and deletions of points from the stream.

Nonparametric density estimation is the construction of an estimate of the probability density function without assuming the data are drawn from a parametric family of distributions [5]. *Kernel estimators*, or *Parzen* estimators, are a popular family of nonparametric estimators [4]. Kernel estimators are expressed as summations of scaled copies of a single function; each copy is shifted and centered at a data point. Let us assume a set $D = \{\vec{x}_i \mid i = 1, \dots, N\} \subseteq \mathbb{R}^d$ of multidimensional data points. Kernel estimators formalize the idea that every data point contributes to the value of the estimate at a space

vector $\vec{x} \in \mathbb{R}^d$ an amount that monotonically decreases with distance from \vec{x} . Let $K: \mathbb{R} \rightarrow \mathbb{R}_+ \cup \{0\}$ be a non-negative, non-increasing function with unit integral on \mathbb{R} . K is called a *kernel function*. Examples of kernel functions are the square pulse function $\frac{1}{4}(\text{sign}(x+1) - \text{sign}(x-1))$, and the Gaussian function $\frac{1}{\sqrt{2\pi}} \exp(-\frac{1}{2}x^2)$. A *kernel density estimate* $\hat{\phi}_{K,h}[D](\vec{x}) : \mathbb{R}^d \rightarrow \mathbb{R}_+ \cup \{0\}$ is defined as the sum over all data records \vec{x}_i in D of the differences between \vec{x} and \vec{x}_i , scaled by a factor h , called *window width*, and weighted by the kernel function K :

$$\hat{\phi}_{K,h}[D](\vec{x}) = \frac{1}{Nh^d} \sum_{i=1}^N K\left(\frac{1}{h}(\vec{x} - \vec{x}_i)\right). \quad (1)$$

The estimate is therefore a sum of bumps centered at the data points, and the flatness of the bumps is controlled by h . Thus, the smoothness of the estimate depends on the window width h .

Nonparametric density estimates have been used in several data clustering algorithms both in the statistical literature [5] and in the data mining literature [2, 3]. Clustering based on nonparametric estimates offers numerous advantages: immunity to noise, recognition of nonspherical clusters, and data-driven, objective criteria to optimally choose K and h for a given dataset. The intuition underlying all approaches is that well separated, high density regions around local maxima of the estimate correspond to clusters. In a *center-defined* cluster [2], all points are connected to a single local maximum having a sufficiently large density by an uphill path. In [5], a forest of points is constructed such that every path from a leaf to a root is an uphill path. All these approaches cannot be adapted easily to the stream environment since they do not maintain information allowing for quick, repeated updates of the clusters as new points arrive.

2 Clustering Data Streams

The approaches reviewed in the previous section build polygonal paths; the direction of every segment starting at \vec{x} approximates the direction of the gradient of $\hat{\phi}[D](\vec{x})$. In our approach, we relax this condition and allow for curves along which $\hat{\phi}[D](\vec{x})$ increases at any rate.

Definition 1. $C \subseteq D$ is a subcluster for a local maximizer \vec{x}^* of $\hat{\phi}[D]$ if and only if $\vec{x}_i \in C$ implies that there exists a simple continuous curve $\vec{c}: [0, 1] \rightarrow \mathbb{R}^d$ satisfying $\vec{c}(0) = \vec{x}_i$, $\vec{c}(1) = \vec{x}^*$, and $\hat{\phi}[D](\vec{c}(t_1)) > \hat{\phi}[D](\vec{c}(t_2))$ when $t_1 > t_2$. C is a cluster if C is a maximal subcluster for some local maximizer of $\hat{\phi}[D]$.

We now define our problem. Let S be a stream of d -dimensional points $\dots, \vec{x}^{(-1)}, \vec{x}^{(0)}, \vec{x}^{(1)}, \vec{x}^{(2)}, \dots$, with $\vec{x}^{(i)} \in \mathbb{R}^d$, for $i \in \mathbb{Z}$, and let the index $i_0 \in \mathbb{Z}$ of the first data object read from input be given. Further let Q be a stream of cluster membership queries $\dots, q[-1], q[0], q[1], q[2], \dots$, where each $q[j]$ asks whether two objects $\vec{x}^{(i)}$,

¹ Department of Electronics, Computer Science and Systems, University of Bologna, Viale Risorgimento 2, IT-40136 Bologna BO, Italy, email: {stefano.lodi,gianluca.moro,claudio.sartori}@unibo.it

$\vec{x}^{(i')}, i, i' \leq j$ are in the same cluster. The problem is to output correct results (w.r.t. Definition 1) to the queries Q in such a way that: the number of data objects read from the input stream S between reading of $q[j]$ and writing its result is $O(1)$; the number of computation steps executed between reading $\vec{x}^{(i)}$ and $\vec{x}^{(i+1)}$, $i \geq i_0$, is $O(1)$; the number of computation steps between reading $\vec{x}^{(i)}$ and the earliest time the result to a query q equals the result of q applied to the clustering of $\{\vec{x}^{(i_0)}, \vec{x}^{(i_0+1)}, \dots, \vec{x}^{(i)}\}$ is $O(1)$. These requirements specify that a stream algorithm must not be left behind by an increasingly large lag as time passes.

A constant bound on the number of items which have to be updated to yield an updated clustering is attainable only if we can avoid building and maintaining a forest over the data objects. Alternatively, we maintain a forest of directed grid trees the vertex set of which is a set of regularly spaced points of \mathbb{R}^d covering the support of the density estimate. Note that smooth kernel functions with bounded support exist; for example, take $K(x) = \exp(1/(x^2 - 1))$ if $|x| < 1$; 0 otherwise.

Each vertex is associated to the value the density estimate takes at the vertex, that is, to a sample of $\hat{\phi}$. Let w be a sampling frequency, and let us denote any element of \mathbb{Z}^d by \vec{n} . Let $\vec{n}_1/w, \vec{n}_2/w$ be the corners of the minimal d -dimensional rectangle containing the support of $\hat{\phi}$. Note that \vec{n}_1, \vec{n}_2 can always be set initially so to contain the bounding box of the data, which is always known in practical cases, extended by h on all dimensions. The vertex set is therefore the d -dimensional rectangular grid of corners $\vec{n}_1/w, \vec{n}_2/w$ and spacing $1/w$ in all dimensions $\{\vec{n}/w : \vec{n}_1 \leq \vec{n} \leq \vec{n}_2\}$, where $\vec{n} \leq \vec{n}'$ if and only if \vec{n} holds componentwise. The main invariant we wish to maintain is the following.

Invariant 1. $(\vec{n}'/w, \vec{n}''/w)$ is an edge of the grid forest if and only if $\hat{\phi}[S](\vec{n}'/w) < \hat{\phi}[S](\vec{n}''/w)$ and \vec{n}'' maximizes $\hat{\phi}[S](\vec{n}/w)$ over all \vec{n}/w nearest to \vec{n}'/w , i.e., $\vec{n}'' = \text{argmax}_{\vec{n}} \{\hat{\phi}[S](\vec{n}/w) : \vec{n} = \vec{n}' + \vec{e}/w \text{ for some versor } \vec{e}\}$.

Therefore, in the data structures we store polygonal uphill paths constructed from segments that can only run parallel to some coordinate axis, and values of the density at every grid point. The structure can be updated as follows. When a new point $\vec{x}^{(i)}$ arrives from the stream S only the density at a bounded number of grid points can increase. (If deletions are allowed, their densities increase or decrease according to a sign attached to the new point.) The affected grid points are located inside the smallest hypercube containing the hypersphere of radius h , centered at $\vec{x}^{(i)}$. Edges going into or out of the hypercube must be checked for inversion. The number of density values and edge updates needed depends on h and w .

The forest induces a clustering of the space, for example by a nearest neighbour criterion. Therefore membership queries $q[i]$ in the stream Q can be answered by first finding the nearest vertex and then following the unique uphill path from the vertex. The cost is clearly independent of stream size, and depends only on the spacing w of the vertex set. Other types of queries can also be answered with similar costs. The total number of clusters can be maintained as the number of tree roots. Grid points which become roots, or are no longer roots can be detected easily during the updates. The size of a cluster can be computed by visiting the corresponding tree, and summing the values of a counter attached to every grid point. The counter is incremented whenever the grid point is the nearest grid point to a new stream point.

Preliminary experiments have shown that considerable accuracy can be achieved on clusters of arbitrary shape. The dataset shown in Figure 1 has been processed as a stream setting $w = 2$ and $w = 4$.

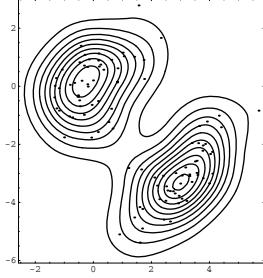

Figure 1. A test data set with a contour plot of its kernel estimate ($h = 0.7$).

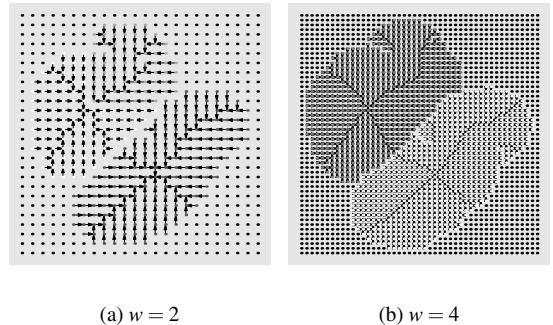

Figure 2. Grid forests constructed for $w = 2$ and $w = 4$.

The resulting grid forests are shown in Figures 2(a) and 2(b) respectively. Equal gray levels correspond to equal clusters. For $w = 2$, the top left cluster was erroneously split nearby its maximum since the directions of the grid edges do not yield an increase in $\hat{\phi}[S]$. Halving the spacing between grid points allows for correct recognition. This behaviour has been apparent in all experiments and, in fact, should reflect a formal convergence property showing that every path in the grid forest, although not guaranteed to be monotonic for $\hat{\phi}[S](\vec{x})$, as w increases, should converge to a monotonic path for $\hat{\phi}[S](\vec{x})$. The speed of convergence must also be investigated, as well as possible heuristics to merge clusters when w is large (e.g. due to limited resources). Moreover, the speed of processing stream data points must be experimentally evaluated and compared to the rate of a fast algorithm, e.g. CluStream [1]. Methods to choose h should also be investigated. In fact, the optimal value of h decreases with sample size (as $N^{-1/(d+4)}$) [5], therefore no value can be uniformly optimal.

Version space learning for possibilistic hypotheses

Henri Prade and Mathieu Serrurier¹

Abstract. In this paper, we are interested in learning stratified hypotheses from examples and counter-examples associated with weights that express their prototypical importance. It leads to an extension of the well-known version space learning framework. In order to do that, we emphasize that the treatment of positive and negative examples in version space learning is reminding of a bipolar revision process recently studied in the setting of possibilistic information representation. Bipolarity appears when the positive and negative sides of information are specified in a distinct way. Then, we use the possibilistic bipolar representation setting, which distinguishes between what is guaranteed to be possible, and what is simply not impossible, as a basis for extending version space learning to examples associated with possibility degrees. It allows us to define a formal framework for learning layered hypotheses.

1 Introduction

Version space learning [3] is a general framework for concept learning. It proposes to identify all the hypotheses coherent with a set of examples or counter examples. The way for treating positive and negative examples during the learning process reminds a bipolar revision process, that is at work when positive information is said apart from negative information [1]. Negative information states what is known to be impossible, what is rejected, while positive information states what is possible for sure, feasible or satisfactory. Examples and counter examples w. r. t. an if-then rule are instances of positive and negative information. When a bipolar view of information is maintained, consistency between positive and negative information, namely what is positively assessed is included in what is not negatively assessed, should be enforced when new information is received. We first point out the similarity between version space learning and bipolar revision, when learning from a set of examples and counter-examples. Then, examples are associated with possibility degrees that describe how much a positive example is guaranteed to be possible or how much a negative example is not impossible. By taking advantage of bipolar possibilistic revision, we propose an original algorithm for version space learning in order to identify the set of layered hypotheses that are sound w. r. to t. examples.

2 Version space and bipolar information

Let \mathcal{X} denote a *feature space*. In the bipolar [1] possibilistic setting, two $[0, 1]$ -valued possibility distributions over \mathcal{X} are considered : δ describes to what extent configurations are guaranteed to be possible and π describes what is not impossible. These two distributions are consistent in the bipolar framework iff $\forall x \in \mathcal{X}, \delta(x) \leq \pi(x)$. Given δ and π , which respectively describe what is guaranteed

to be possible and what is not impossible, when a new piece of information of the form π_{new} or δ_{new} is presented, a revision process takes place : $\forall x \in \mathcal{X} \pi_{revised}(x) = \max(\pi(x), \delta_{new}(x))$ and $\delta_{revised}(x) = \min(\pi_{new}(x), \delta(x))$. Let us describe the version space learning framework from the bipolar point of view. Let $\mathcal{U} = \{0, 1\}$ be a *concept space*, where 1 means that the example of the concept is positive (guaranteed possible i.e. $\delta(x) = 1$), and 0 means that the example is negative (totally impossible i.e. $\pi(x) = 0$). An hypothesis h is a mapping from \mathcal{X} to \mathcal{U} . \mathcal{H} denotes the hypotheses space. The version space framework takes as input a set $\mathcal{S} = \{(x_i, u_i)_{i=1, \dots, m} \text{ s.t } x_i \in \mathcal{X} \text{ and } u_i \in \mathcal{U}\}$ of m training examples, and a hypothesis space \mathcal{H} . The set \mathcal{H} is supposed to be equipped with a partial preorder \succeq expressing generality, formally: $h_1, h_2 \in \mathcal{H}, h_1 \succeq h_2$, iff $\{x \in \mathcal{X} | h_1(x) = 1\} \supseteq \{x \in \mathcal{X} | h_2(x) = 1\}$. An hypothesis h is *sound* w. r. t. a training example $(x, u) \in \mathcal{S}$ iff $h(x) = u$. If $\forall (x_i, u_i) \in \mathcal{S}, h$ is sound w.r.t (x_i, u_i) , then h is said to be sound w. r. t. \mathcal{S} . This framework defines the *version space* $\mathcal{V} = \{h \in \mathcal{H} | h \text{ is sound with } \mathcal{S}\}$. Version space learning aims at identifying the upper and the lower bounds of this version space \mathcal{V} . The upper bound \mathcal{V}_g will contain the most general hypotheses, i.e., the ones that classify more examples, whereas the lower bound \mathcal{V}_s will contain the most specific ones, i.e., the hypotheses that classify less examples, both being compatible with the training examples. The general algorithm for learning version space consists in updating \mathcal{V}_s and \mathcal{V}_g step by step by considering an increasing set of examples. If the example is positive, all the hypotheses of \mathcal{V}_g that are not coherent are removed, since they cannot be generalized, and all the hypotheses of \mathcal{V}_s that do not cover the examples are minimally generalized in order to cover it. On the contrary, if the example is negative the hypotheses that are incoherent with the example are removed if they are in \mathcal{V}_s or minimally specialized if they are in \mathcal{V}_g .

We can view a hypothesis as a possibility distribution, which states what feature configurations x are possible : $\forall h \in \mathcal{H}, \forall x \in \mathcal{X}, \mu_h(x) = h(x)$. Then, given a set of hypotheses, we define two possibility distributions : the most specific one $\forall H \in 2^{\mathcal{H}}, \forall x \in \mathcal{X}, \delta_H(x) = \min\{\mu_h(x); h \in H\}$ and the most general one $\forall H \in 2^{\mathcal{H}}, \forall x \in \mathcal{X}, \pi_H(x) = \max\{\mu_h(x); h \in H\}$. Let $\pi_{\mathcal{S}}$ and $\delta_{\mathcal{S}}$ be the possibility distributions that correspond respectively to the most general and the most specific distribution revised by the examples in \mathcal{S} . The set of hypotheses in \mathcal{V}_s contains the most specific hypotheses that cover all the positive examples and no negative examples. It means that these hypotheses must identify, if possible, only the situations that are *guaranteed to be possible* w. r. t. the set of examples and then $\delta_{\mathcal{S}} \leq \delta_{\mathcal{V}_s}$. In the same way, since \mathcal{V}_g contains the most general hypotheses that cover all the positive examples and no negative ones, these hypotheses describe the situations that are *not impossible* w. r. t. the set of examples and then $\pi_{\mathcal{S}} \leq \pi_{\mathcal{V}_g}$.

3 Weighted extension of version space learning

Alg. 1 SpecializeStratifiedHypothesis

Require: $h_w = \{(h_1, \alpha_1), \dots, (h_n, \alpha_n)\}$ with $\alpha_1 \geq \dots \geq \alpha_n$

Require: $\langle x, 0, \alpha \rangle$

- 1: Let i such that $(h_i, \alpha_i) \in h_w$ $\alpha_i \geq \alpha$ and $\exists j$ such that $\alpha_i > \alpha_j \geq \alpha$
- 2: **for all** (h_j, α_j) such as $j > i$ **do**
- 3: **if** $h_j(x) = 1$ **then**
- 4: turn h_j in (h_j, α_j) into one of its minimal specialization
- 5: **if** $h_i(x) = 1$ **then**
- 6: turn (h_i, α_i) into (h'_i, α_i) where h'_i one of the minimal specialization of h_i
- 7: **if** $\alpha_i \neq \alpha$ **then**
- 8: add (h_i, α) in h_w

Alg. 2 GeneralizeStratifiedHypothesis

Require: $h_w = \{(h_1, \alpha_1), \dots, (h_n, \alpha_n)\}$ with $\alpha_1 \geq \dots \geq \alpha_n$

Require: $\langle x, 0, \alpha \rangle$

- 1: **if** $\exists i$ such that $(h_i, \alpha_i) \in h_w$ and $\alpha_i = \alpha$ **then**
- 2: return all h_w in which h_i is turned into one of its minimal generalization
- 3: **else**
- 4: Let i such that $(h_i, \alpha_i) \in h_w$ $\alpha_i > \alpha$ and $\exists j$ such that $\alpha_i > \alpha_j > \alpha$
- 5: add (h_i, α_i) in h_w such that h'_i is a minimal generalization of h_i

We are now interested in version space learning with examples associated with weights corresponding to possibility degrees in a linearly ordered scale, here $[0, 1]$ for simplicity. These possibility values have a different meaning according as the examples are positive or negative. If the example is positive, the weight corresponds to a guaranteed possibility degree. If the example is negative, the weight refers to the possibility distribution π that describes what is not impossible. The examples are then described by $\mathcal{S}_w = \{(x, u, \alpha)\}$ with $\alpha = \delta(x)$ if $u = 1$ and $\alpha = \pi(x)$ otherwise. The hypothesis we want to learn describes a possibility distribution that associates a possibility degree to each example, which corresponds to the degree of compatibility of this example w. r. t. the target concept. The hypothesis is then a mapping from \mathcal{X} to $[0, 1]$. Given an hypothesis space \mathcal{H} , we now consider a stratified set of classical hypotheses $h_w = (h_1, \alpha_1), \dots, (h_n, \alpha_n)$ with $\forall i, h_i \in \mathcal{H}$ and $\alpha_1 \geq \dots \geq \alpha_n$. The result of h_w for x is $\forall x \in \mathcal{X}, h_w(x) = \max_i \{\min(h_i(x), \alpha_i)\}$ and the possibility distribution induced by h_w is $\forall x \in \mathcal{X}, \mu_{h_w} = h_w(x)$. The generality ordering on stratified hypotheses corresponds to the partial pre-order on possibility distributions, and thus $h_w^1 \leq h_w^2$ iff $\mu_{h_w^1} \leq \mu_{h_w^2}$.

A stratified hypothesis is sound w. r. t. an example if it does not underestimate the possibility of a positive example and does not overestimate the possibility degree of a negative example. So, h_w is sound w. r. t. \mathcal{S}_w iff $\forall (x, u, \alpha) \in \mathcal{S}_w = h_w(x) \geq \alpha$ if $u = 1$ and $h_w(x) \leq \alpha$ if $u = 0$. A totally positive (guaranteed possible) example corresponds to $(x, 1, 1)$, and a totally negative (impossible) example to $(x, 0, 0)$. On the contrary, the examples of the form $(x, 1, 0)$ and $(x, 0, 1)$ have no influence on the learning algorithm according to the definition of soundness. Indeed, an example of the

form $(x, 1, 0)$ means just that x is not guaranteed to be a positive example and $(x, 0, 1)$ means that we are certain that it is possible for x to be a positive example. The algorithm for learning the version space in the case of bipolar continuous examples follows the same structure as the classical version space learning algorithm by using specialization and generalization operators described respectively in Alg. 1 and Alg. 2.

Proposition 1 We note $\delta_{\mathcal{S}_w}$ and $\pi_{\mathcal{S}_w}$ the possibility distributions obtained by revising the bipolar distribution ($\forall x \in \mathcal{X}, \delta_{\mathcal{S}_w}(x) = 0, \forall x \in \mathcal{X}, \pi_{\mathcal{S}_w}(x) = 1$) with the new information of the form $\forall (x, u, \alpha) \in S \pi_{new}(x) = \alpha$ if $u = 0$ or $\delta_{new}(x) = \alpha$ if $x = 1$. Given $\mathcal{V}_w = \langle \mathcal{V}_{sw}, \mathcal{V}_{gw} \rangle$ the continuous version space from the set of example S , we have $\forall x \in \mathcal{X}, \delta_{\mathcal{S}_w}(x) \leq \delta_{\mathcal{V}_{sw}}(x)$ and $\pi_{\mathcal{S}_w}(x) \geq \pi_{\mathcal{V}_{gw}}(x)$.

This proposition shows that we can use version space learning for describing bounds of possibility distributions according to a set of descriptions of what is not impossible or guaranteed to be possible. Since it is described in intention in the version space case, the bounds may be too restrictive w. r. t. the maximal bounds described by bipolar revision due to the limited description capabilities of the hypothesis language.

4 Related works and concluding remarks

In this paper, we have emphasized the similarities that exist between the version space learning framework and the bipolar binary revision process. According to this remark, we have proposed an extension of version space learning that deals with examples associated with possibility degrees. These degrees correspond to non impossibility degrees for negative examples and to guaranteed possibility degrees for positive examples. What is learned is the bounding of the set of stratified hypotheses that are coherent with the data. As for the classical setting, it is obvious that bipolar version space learning cannot be used directly in applications, but can be used as a formal framework for possibilistic concept learning.

This approach could then be applied to possibilistic inductive logic learning [4], which learns stratified hypotheses from weighted examples. In this context, it suggests to modify the treatment of examples in order to consider weights as bipolar information and then to adapt the specialization and generalization operators as described in this paper. This approach is clearly different from the fuzzy version space in [2]. In particular, our approach makes a difference for the meaning, and then for the treatment, of the levels associated to the examples according to their positive or negative nature, which is not the case in fuzzy version space. Indeed, in the fuzzy case, a version space is learnt for each *alpha*-cut of the training set. What is learnt is then a stratified sets of version spaces and the soundness of hypotheses w. r. t. examples is classical, while what is learnt here is a version space of stratified hypotheses.

Ensembles of Grafted Trees¹

Juan J. Rodríguez and Jesús M. Maudes²

Abstract. Grafted trees are trees that are constructed using two methods. The first method creates an initial tree, while the second method is used to complete the tree.

In this work, the first classifier is an unpruned tree from a 10% sample of the training data. Grafting is a method for constructing ensembles of decision trees, where each tree is a grafted tree. Grafting by itself is better than Bagging.

Moreover, grafted trees can also be used with any other ensemble method. It is clearly beneficial for Bagging and Random Forests. When using grafted trees with Boosting, the results depends of the considered variant. The best overall method is Grafted Random Forest.

1 INTRODUCTION

One of the current research areas in Machine Learning is the construction of ensembles of classifiers [8]. It is one of the easiest ways of trying to improve the accuracies of existing methods. Some ensemble methods work combining several classifiers obtained with the same method. Combining identical classifiers is not useful. Hence, it is necessary to devise some approach that allows the construction of different classifiers from the same method. This paper presents a new approach.

In Bagging [2], each classifier is constructed using a different data set. It is obtained using sampling with replacement. In the Random Subspace method [7] each classifier in the ensemble is constructed using a random subset of the features. The main idea of Boosting [11] is, when constructing a classifier, to give more importance to the examples that were more misclassified by the previous members of the ensemble.

Random Forests [3] is a variant of Bagging, where the classifiers are constructed using Random Trees. Another way of constructing Random Trees is presented in [5]. These methods are designed specifically for ensembles of decision trees. Ensembles of cascaded trees is another method designed specifically for decision trees [9]. Each decision tree is constructed using a different feature in the root. The rest of nodes are constructed as usual.

The term “grafting” has already appeared in the Machine Learning community [12]. In this reference more nodes are added to a tree in order to improve its accuracy. The main difference with the present work is that we are considering grafted trees as ensemble members, and consequently we are looking for diverse classifiers. Hence, our objective is that the initial decision trees were different.

2 GRAFTED CLASSIFIERS

Given two induction methods, \mathcal{M}_1 and \mathcal{M}_2 , a grafted classifier is constructed in the following way:

- Construct a classifier C_1 using the method \mathcal{M}_1 with the training data.
- For each different output, i , of the classifier C_1 , construct a classifier $C_{2,i}$ using the method \mathcal{M}_2 . The training data for this classifier is the subset of instances of the training data that are assigned to i by C_1 .

In order to classify instances, a grafted classifier first classifies the instance using C_1 . Let be i its output. The predicted class is the classification given by the classifier $C_{2,i}$.

Grafted trees and ensembles. If \mathcal{M}_1 and \mathcal{M}_2 are decision tree methods, the grafted classifiers will be called grafted trees. A grafted tree is a decision tree.

In the present paper we are going to consider only a method \mathcal{M}_1 . It constructs an unpruned decision tree from a random sample. The size of this sample is 10% of the size of the original data. For the method \mathcal{M}_2 we are going to consider pruned trees, unpruned trees and random trees. Given that these grafted trees have a random component, it is possible to obtain different trees using the same data set. Hence, a way to generate an ensemble of decision trees is constructing several grafted trees with the same data set. These ensembles are called Grafting ensembles.

These configurations for the methods \mathcal{M}_1 and \mathcal{M}_2 were selected because we wanted diverse and accurate classifiers. These grafted trees can be diverse because a small subset of the training data is used to construct the initial levels of the trees. The grafted trees can be as accurate as standard decision trees because none of the information in the training data (instances, attributes) is discarded.

Moreover, grafted trees can be used with any other ensemble method that can be used with decision trees. Hence, for each ensemble method, there will be a grafted variant of that method. For instance, Grafted-Bagging, Grafted-Boosting...

3 EXPERIMENTAL VALIDATION

Settings. For the experiments, WEKA [13] was used. The used decision tree methods (J48 —a reimplementation of C4.5— and Random Trees) and ensemble methods (Bagging, AdaBoost.M1, Random Forests) are from this library. Bagging and AdaBoost.M1 are used with J48. The method Random Forests is a special case of Bagging, when Random Trees are used as base classifiers.

We consider two variants of AdaBoost.M1: the reweighting version and the resampling version [6]. In the tables, they are denoted,

respectively, with (W) and (S). The number of classifiers in each ensemble was 25. For the experiments, 10 10-fold stratified cross validation was used.

For the comparison of results the *corrected resampled t-test statistic* from [10] was used (significance level: 5%). The 100 (10×10) results for each method and data set are considered as the input for the test.

The 35 considered data sets, from the UCI Repository [1], were: anneal, audiology, autos, balance-scale, breast-cancer, cleveland-14-heart, credit-rating, german-credit, glass, heart-statlog, hepatitis, horse-colic, hungarian-14-heart, hypothyroid, ionosphere, iris, kr-vs-kp, labor, letter, lymphography, mushroom, pima-diabetes, primary-tumor, segment, sick, sonar, soybean, splice, vehicle, vote, vowel-context, vowel-nocontext, waveform, wisconsin-breast-cancer and zoo.

Grafting ensembles. First, Grafting ensembles are compared to other ensemble methods. Table 1 shows the number of wins, draws and losses when comparing Grafting with another methods. The table also shows the number of wins, draws and losses according to the used statistical test. From this table we can conclude that:

- Grafting is better than Bagging.
- Grafting is worse than Random Forests according to the direct comparison of the accuracies. On the other hand, according to the used statistical test, Grafting is better than Random Forest 4 times and worse only 2 times.
- The comparison of the accuracies of Grafting and AdaBoost.M1 is very even when pruned trees are used. If the trees are unpruned, there is a slight advantage for AdaBoost.M1.

Combining grafting with other ensemble methods. Table 2 shows the comparison of the results between ensemble methods. For each ensemble method, the number of wins, draws and losses of the version with grafted trees against the version with standard trees is shown. The table also shows the number of wins, draws and losses according to the used statistical test. From this table it can be concluded that:

- Grafting is clearly beneficial for Bagging.
- If we only consider the used statistical test, there is no difference between using the standard Random Forest method and Grafted Random Forest. Nevertheless, in the direct comparison of the results there are 28 wins and only 6 losses.
- For boosting methods, grafting does not improve the results. For the reweight version of AdaBoost.M1, Grafting is slightly harmful. On the other hand, for the resample version of AdaBoost.M1, grafting is slightly beneficial.

Ranking the methods. Although it is customary to use paired tests for comparing several methods, they were not designed for that purpose [4]. A better way of ranking the methods is doing a ranking for each data set. For the data set, the first method has a rank of 1, the second 2 ... If there are ties, average ranks are assigned. For each method, its average rank is calculated. Table 3 shows this average ranking. It provide a fair comparison of the methods [4]. From this ranking we can conclude that:

- Grafted Random Forest is the best method. Random Forest without Grafting is rather far from the top positions.
- Bagging without Grafting is the worst method. Grafted Bagging works much better, specially with unpruned trees.

- The results for AdaBoost.M1 are rather mixed, because it is not clear if Grafting is beneficial or harmful. The best variant of AdaBoost.M1 is the version with resampling, grafted unpruned trees.
- Grafting by itself is only clearly better than Bagging.

Table 1. Comparison of grafting with other ensemble methods. The prefix (P- or U-) indicates if the trees were (P)runed or (U)npruned.

Method	Wins/Draws/Losses	Significant	
		Wins	Draws/Losses
P-Bagging	25/1/9	4/31/0	3/29/3
P-AdaBoost.M1 (W)	17/1/17	3/29/3	3/29/3
P-AdaBoost.M1 (S)	18/1/16	3/29/3	
U-Bagging	24/1/10	4/31/0	4/29/2
U-Random Forest	14/1/20	4/29/2	1/32/2
U-AdaBoost.M1 (W)	14/1/20	1/32/2	1/31/3
U-AdaBoost.M1 (S)	14/1/20	1/31/3	

Table 2. Comparison of the grafted variant of some ensembles methods with the standard version. The prefix (P- or U-) indicates if the trees were (P)runed or (U)npruned.

Method	Wins/Draws/Losses	Significant	
		Wins	Draws/Losses
P-Bagging	23/1/11	5/30/0	0/34/1
P-AdaBoost.M1 (W)	15/0/20	0/34/1	0/35/0
P-AdaBoost.M1 (S)	18/0/17	0/35/0	
U-Bagging	27/1/7	7/28/0	
U-Random Forest	28/1/6	1/33/1	
U-AdaBoost.M1 (W)	16/1/18	0/34/1	
U-AdaBoost.M1 (S)	20/1/14	1/34/0	

Table 3. Average ranks of the methods. The first prefix (G- or N-) indicates if Grafting was used or not. The second prefix (P- or U-) indicates if pruning was used.

Method	Average Ranking	Method	Average Ranking
G-U-Random Forest	6.14	N-U-AdaBoost.M1 (W)	8.27
G-U-AdaBoost.M1 (S)	7.64	N-U-Random Forest	8.31
G-U-Bagging	7.77	N-U-AdaBoost.M1 (S)	8.60
N-P-AdaBoost.M1 (W)	7.77	G-U-AdaBoost.M1 (W)	9.00
G-P-Grafting	8.00	G-P-AdaBoost.M1 (W)	9.14
G-P-AdaBoost.M1 (S)	8.06	G-U-Grafting	9.19
N-P-AdaBoost.M1 (S)	8.09	N-P-Bagging	10.64
G-P-Bagging	8.13	N-U-Bagging	11.24

A Compression-Based Method for Stemmatic Analysis

Teemu Roos ¹ and Tuomas Heikkilä ² and Petri Myllymäki ¹

1 INTRODUCTION

Stemmatology studies relations among different variants of a text that has been gradually altered as a result of imperfectly copying the text over and over again. Underlying these variants there is what we could call a ‘family tree’, a graph representing the process of copying the text where each new version becomes a direct descendant of the exemplar(s) from which it is copied. The aim of stemmatic analysis is to reconstruct this family tree, known as the ‘stemma’, based on the surviving copies of the text. Applications are mainly in humanities, especially textual criticism, but the methods can be used to study the evolution of any symbolic objects, including chain letters [2] and computer viruses. We propose an algorithm for stemmatic analysis based on a minimum-information criterion and stochastic tree optimization. The intuitive idea behind compression-based approaches is that if a text can be significantly compressed, then the compression algorithm has found regularities which can be further exploited in an analysis such as ours. Our approach is related to phylogenetic reconstruction criteria such as maximum parsimony and maximum likelihood, and builds upon algorithmic techniques developed for bioinformatics. For a more detailed version see [14, 15].

2 A MINIMUM-INFORMATION CRITERION

In his seminal work on computer-assisted stemmatology, O’Hara used a parsimony method of the PAUP software [18] in Robinson’s Textual Criticism challenge [13]. For further applications of maximum parsimony and related method, see [8, 9, 17, 20] and the references therein.

Our compression-based *minimum information* criterion shares many properties of the maximum parsimony method. Both can also be seen as instances of the *minimum description length* (MDL) principle of Rissanen [12] which in turn is a formal version of Ockham’s razor. The minimum-information criterion measures the amount of information, or *code-length*, required to reproduce all the manuscripts by the process of copying and modifying the text under study. In order to describe a new version of an existing manuscript, one needs an amount of information that depends on both the amount and the type of modifications made. For instance, describing a deletion of a word or a change of word order requires less information than introducing a completely new expression.

In order to be concrete, we need a precise, numerical, and computable measure for the amount of information. The commonly accepted definition of the amount information in individual objects is Kolmogorov complexity, see [10], defined as the length of the shortest computer program to describe the given object. However, Kol-

mogorov complexity is defined only up to a constant, and fundamentally uncomputable. Therefore, in the spirit of a number of earlier authors [1, 2, 3, 4, 6, 11, 19], we approximate Kolmogorov complexity by using a compression program (`gzip`). In particular, given two strings, x and y , the amount of information in y conditional on x , denoted by $C(y | x)$ is given by the length of the compressed version of the concatenated string x, y minus the length of the compressed version of x alone. One of the advantages of using a string compression method that operates directly on the text is that only minimal preprocessing is required, contrary to most of the methods referred to above.

Let $G = (V, E)$ be an undirected graph where V is a set of nodes corresponding to the text variants, $E \subset V \times V$ is a set of edges. We require that the graph is a connected bifurcating tree, meaning that (i) each node has either one or three neighbors, and (ii) the tree is acyclic. Such a graph G can be made directed by picking any one of the nodes as the root and directing each edge away from the root. Given a directed graph \vec{G} , the total information cost of the tree is defined as

$$C(\vec{G}) = \sum_{v \in V} C(v | \text{Pa}(v)) \quad (1)$$

where the sum is over all the variants v , and $\text{Pa}(v)$ denotes the parent node of v unless v is the root in which case $\text{Pa}(v)$ is the empty string. For practical reasons (mainly for reduced computational cost) we make some modifications to this criterion, see the full version [15].

3 AN ALGORITHM FOR CONSTRUCTING STEMMATA

Since it is known that many of the text variants have been lost during the centuries between the time of the writing of the first versions and present time, it is not realistic to build a tree of only the available variants that we have as our data. The common way (in phylogeny) of handling this problem is to include in the tree a number of ‘hidden’ nodes, i.e., nodes representing individuals whose characteristics are unobserved. We construct bifurcating trees that have N observed nodes as leafs, and $N - 2$ hidden nodes as the interior nodes.

Evaluating the criterion (1) now involves the problem of dealing with the hidden nodes. Without knowing the values of v , it is not possible to compute $C(v | \text{Pa}_i(v))$. We solve this problem by searching simultaneously for the best tree structure \vec{G} and for the optimal contents of the hidden nodes with respect to criterion (1). Perhaps surprisingly, given a tree structure, finding the optimal contents is feasible. The method for efficiently optimizing the contents of the hidden nodes is an instance of dynamic programming (or ‘elimination’ in graphical models) and called ‘the Sankoff algorithm’ [5] or ‘Felsenstein’s algorithm’ [16].

There still remains the problem of finding the tree structure, which together with corresponding optimal contents of the hidden nodes

¹ Complex Systems Computation Group, Helsinki Institute for Information Technology, Finland, email: firstname.lastname@cs.helsinki.fi

² Dept. of History, University of Helsinki, Finland, email: tuomas.m.heikkila@helsinki.fi

minimizes criterion (1). The obvious solution, trying all possible tree structures and choosing the best one, fails because for N leaf nodes, the number of possible bifurcating trees is exponentially large (see [5]). Instead, we have to resort to heuristic search, trying to find as good a tree as possible in the time available. We use a simulated annealing algorithm that starts with an arbitrary tree and iteratively tries to improve it by small random modification, such as exchanging the places of two subtrees.

4 RESULTS AND CONCLUSIONS

We illustrate the behavior of the method by an artificial example in Fig. 1. Assume that we have observed five pieces of text, shown at the tips of the tree's branches. One of the trees — not the only one — minimizing the information cost with total cost of 44 units (bytes) is drawn in the figure. The sum of the (unconditional) complexities of the four words in the top-most string (“*sanctus henricus ex Anglia*”) is equal to $8 + 9 + 3 + 7 = 27$, which happens to coincide with the length of the string, including spaces and a finishing newline. The changes, labeled by numbers 1–5 in the figure, yield $5 + 3 + 3 + 3 = 17$ units of cost. Thus the total cost of the tree equals $27 + 17 = 44$ units.

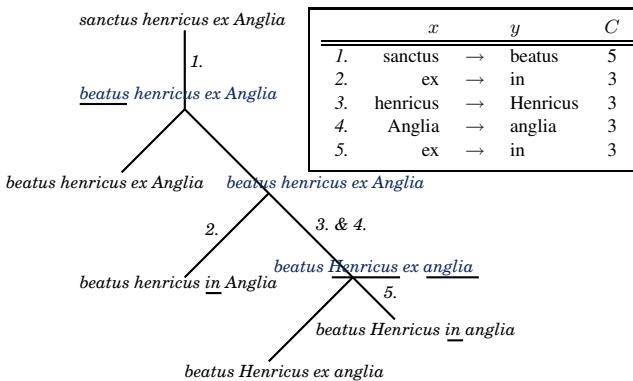

Figure 1. An example tree obtained with the compression-based method for the five strings at the tips of the branches. Changes are underlined and numbered. Costs of changes are listed in the box; no cost is incurred by a transition that leaves the string unchanged, i.e., $C(y | x) = 0$ if $y = x$. Best reconstructions at interior nodes are shown at the branching points.

In our main experiment, reported in the full version [15], we applied the presented method to the tradition of the legend of St. Henry of Finland³, of which some fifty manuscripts are known. Even for such a moderate number, manual stemma reconstruction is prohibitive due to the vast number of potential explanations, and the obtained stemma is the first attempt at a complete stemma of the legend of St. Henry. The relationships discovered by the method are largely supported by more traditional analysis in earlier work. Moreover, our results have pointed out groups of manuscripts not noticed in earlier manual analysis.

We are currently carrying out controlled experiments with artificial data with known ‘ground-truth’ solution to which the results can

³ St. Henry is a key figure of the Finnish Middle Ages. According to the medieval tradition, he was the Bishop of Uppsala (Sweden), and one of the leaders of a Swedish expedition to Finland around 1155, during which he was murdered. The oldest text concerning St. Henry is his legend written in Latin by the end of the 13th century at the very latest. For identification of the sources as well as a modern edition of the legend see [7].

be compared. Outside historical and biological applications, analysis of computer viruses is an interesting future research topic.

Patch Learning for Incremental Classifier Design

Rudy Sicard¹ and Thierry Artières² and Eric Petit¹

Abstract. We present a learning algorithm for nominal data. It builds a classifier by adding iteratively a simple patch function that modifies the current classifier. Its main advantage lies in the possibility to learn every patch function parameters optimally from the Bayesian point of view hence avoiding overtraining.

1 INTRODUCTION

We present a learning algorithm for nominal data for designing complex classifiers while avoiding overtraining limitation, which is useful for small training sets and high dimensional data. Bayesian Model Averaging (BMA) provides a theoretical solution for avoiding overtraining [1] through computing expected probabilities by summing over all model parameters values. Unfortunately BMA is usually intractable so that approximations were proposed like Point Estimate Approximation (PEA) [2]. PEA consists in replacing the expectation over parameter value by a single term computed for one particular parameter value, Maximum A Posteriori (MAP) estimation is a typical example. However, MAP requires an ad-hoc (since it depends on the data and the task) parameter prior distribution that favours simple classifiers. Other approximation schemes have been proposed in the past such as Kullback Leibler (KL) projection [3] which has been used up to now for simple classifiers only. Building on KL projection we propose to learn incrementally a complex classifier in a way that is close to Boosting [4], by adding iteratively simple patch functions, where each patch function slightly modifies the current classifier. The major idea of our approach is to use simple enough patch functions so that above approximation scheme (and then optimal learning) is tractable. We focus on patch functions defined with a single parameter. Depending of the nature of the patch functions the built classifier resembles standard classifiers like Naïve Bayes (NB), logistic classification or other standard techniques. We first present what a patch function is and its optimal learning. Then we discuss incremental learning of complex classifiers. Lastly, we report experimental results that show the generalization ability and the accuracy of our technique on various benchmark datasets.

2 PATCH DESIGN AND LEARNING

For the sake of clarity we focus here on a simple problem with two classes but the extension to a more general multi-class problem is straightforward. In our mind a patch is an elementary function that modifies the behaviour of a current probabilistic classifier, F , that takes as input a vector x (of d nominal features) and outputs class posterior probabilities $\{P_F(C_j/x), j = 1, 2\}$. In the following a patch

is defined with one parameter α and a Boolean test T . It is used to modify F into $F'_{T,\alpha}$ by changing the behaviour of F for inputs that verify T only. New classifier $F'_{T,\alpha}$ is defined as follows:

$$\begin{aligned} \text{if } T(x) \text{ is true} & \begin{cases} P_{F'_{T,\alpha}}(C_1/x) = 1/z(x) \times \alpha \times P_F(C_1/x) \\ P_{F'_{T,\alpha}}(C_2/x) = 1/z(x) \times (1-\alpha) \times P_F(C_2/x) \end{cases} \\ \text{else} & P_{F'_{T,\alpha}}(C_j/x) = P_F(C_j/x), j = 1, 2 \end{aligned} \quad (1)$$

where $z(x) = (\alpha \times P_F(C_1/x) + (1-\alpha) \times P_F(C_2/x))$ is a normalization factor. Examples of test functions would be: $T(x)$ is true if the i^{th} feature of x has a particular value v (single feature patch) or $T(x)$ is true if the i^{th} feature has a value u and the j^{th} feature has value v (double feature patch). Learning a patch is done through Bayesian learning. Using posterior class probability estimated with $F'_{T,\alpha}$, the posterior probability for parameter α (thus indexed by F'_T) is:

$$P_{F'_T}(\alpha / D) \propto Z(D) \times P(\alpha) \prod_{i/T(x_i)=\text{true}} P_{F'_{T,\alpha}}(y_i / x_i) \quad (2)$$

where $Z(D)$ is a normalization factor, $P(\alpha)$ is a prior distribution and the product ranges over training samples x_i (whose class is y_i) that verify the test T . The optimal Bayesian classifier may be defined through Bayesian Model Averaging [1]:

$$P_{F'_T}(C_i / D, x) = \int_{\alpha=0}^1 p_{F'_{T,\alpha}}(C_i / x) p_{F'_T}(\alpha / D) d\alpha \quad (3)$$

Given x , this BMA distribution minimizes the distance (measured as the KL divergence [3]) with the true distribution by averaging over α [1]. Computing this distribution may be done analytically for well chosen priors but this is expensive. Here, we seek to approximate this term with a PEA strategy which aims at replacing summation like in Eq. (4) with one term $p_{F'_{T,\alpha}}(C_i / x)$. Following

[3] we chose to seek a PEA approximation that is as close as possible to this optimal BMA classifier, w.r.t. KL divergence. Since the optimal PEA may depend on x , i.e. may be obtained with possibly different α , the solution is to minimize the expected KL divergence, over x , of PEA with respect to BMA [2]. We do not detail here methods to perform this minimization for space reasons but this is not a critical point, it is performed numerically (note that the criterion is convex and hence does no exhibit local minima).

3 COMPLEX CLASSIFIER CONSTRUCTION

Using the patch learning routine discussed above, one can build incrementally complex classifiers by adding sequentially a number of patches, starting from e.g. an initial neutral classifier ($\forall x, \forall j = 1..2, P(C_j/x) = 0.5$). Let $\{(T_i, \alpha_i)\}_{i=1..N}$ be the successive

¹ France Télécom – R&D/ TECH/IDEA/TIPS – France.

² LIP6 - Université Pierre et Marie Curie, France.

patches that are learned for building a classifier F , each patch is defined by a Boolean test T_i and a parameter value α_i . Then, the final classifier may be written in a standard form:

$$P(C_1 | x) = Z(x) \times \exp(W^t U(x)) \quad (4)$$

where $W = (\log(\alpha_i))_{i=1..N}$ is the parameter vector for classifier F and $U(x) = (T_i(x))_{i=1..N}$ is the feature vector corresponding to input x (with $T_i(x) = 0/1$). Depending on the nature of the patches, the final classifier may correspond to various classical models. For instance, when considering single feature patches, decision boundaries are linear and have similar form as for NB or logistic classification models. Training consists in applying iteratively a number of patches (eventually all possible patches). In the case of single feature patches, learning algorithm resumes to:

For each feature a and for each feature value v_a
Add the patch with test $T(x) = [x.a == v_a]$ and
optimal α parameter as discussed in section 2.

As usual, one may design more complex classifier through the use of complex features and the addition of many features but this may raise overtraining problem. At the opposite, using our optimal approach described in section 2 should overcome this problem. The counterpart of this generalization ability is that our approach cannot be shown to be the globally optimal. It is locally optimal only in that each patch is learned optimally. For instance, the final classifier will depend on the order the patches are added. However, we believe this global non optimality must be considered together with its generalization power.

4 EXPERIMENTS

We performed experiments on a number of UCI benchmark datasets² and compared our approach with standard techniques using the Weka package [5]. We report here two series of experiments. First we investigated overtraining robustness and compared our patch learning algorithm with single and double features patches to NB and Logistic classification (Lg). Figure 1 shows their performances averaged over 100 runs as a function of the training set size with a logarithmic scale to focus on small sizes on two datasets whose settings are detailed in Table 1. It may be seen first that NB is significantly less accurate than other approaches, second that our approach (with single or double patches) significantly outperforms others for a wide range of training set sizes, third that as more training data becomes PL2 and Lg tend to behave similarly while slightly outperforming PL1 on the kr-kp dataset. This was clearly expected. With small training set size our approach naturally outperforms standard methods such as Lg or NB. As more training data becomes available all models (except NB) perform similarly on vote dataset since it is almost linearly separable while PL1 perform slightly lower than richer (PL2) and globally optimally learned (Lg) models on the more difficult kr-kp dataset. Note that Lg may slightly outperform patch learning in some cases as we will see, which may come from the fact that Lg is globally optimal. The second series of experiments compare patch learning to standard methods, NB, Lg and AODE [6] on a number of UCI benchmark datasets (Table 1) with a standard training set size and a 10-fold cross validation procedure. It may be seen that, except for the zoo dataset, double feature

patches outperform single feature patches, that single patches is comparable or better than standard techniques and that double features patches outperforms all other methods in average. Hence patch learning is not only able to learn complex classifier while avoiding overtraining (as in Fig. 1), it also allows learning efficient classifiers that compare well to more standard techniques.

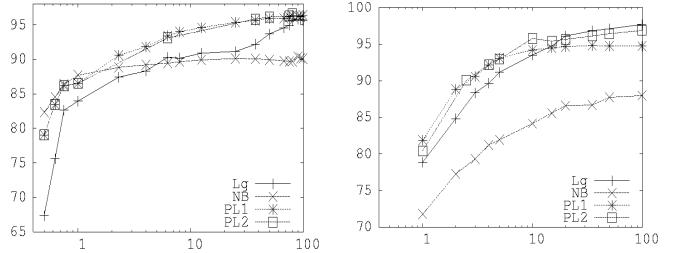

Figure 1. Comparison of generalization ability for Naive Bayes (NB), Logistic Classification (Lg), Patch learning with single (PL1) and double (PL2) feature patches. Performances are plotted as a function of the size of the training set (percentage of whole dataset size) on the UCI *vote* dataset (left) and *kr-kp* dataset (right) whose settings are detailed in Table 1.

Table 1. Comparison of error-rates for Naïve Bayes (NB), AODE, Logistic classification (Lg) and patch learning (PL1 and PL2) on various datasets from UCI⁴. The last row indicates mean error-rate relatively to NB performance. Note that the number of classes #C, the dimension of data d and the training set size TSS (#samples) are indicated for each dataset.

Data set	#C	d	TSS	NB	AODE	PL1	PL2	Lg
Audiology	23	70	226	26.6	26.6	19.1	16.4	17.3
Hepatitis	2	18	155	17.5	16.8	18.1	16.8	22.7
Kr-kp	2	37	3196	12.1	8.8	5.4	2.9	2.5
Mushroom	2	22	8124	4.2	0.05	0.05	0.0	0.0
P-tumor	23	18	329	49.9	50.4	53.4	54.3	55.1
Splice	3	60	3190	4.7	3.9	3.6	3.6	9.0
Vote	2	16	435	9.9	5.7	3.9	3.2	3.9
Zoo	7	17	101	6.8	4.9	2.8	3.8	5.8
Average performance				1.00	0.73	0.61	0.57	0.64

5 CONCLUSION

We presented an incremental learning algorithm for nominal data that allows designing iteratively complex classifiers. It relies on the optimal learning of simple patch functions. Although the resulting classifier is not globally optimal it exhibits good generalization behaviour with small training sets while comparing well to standard techniques with reasonable training set size. Note that up to now we used patches involving single and double features only since using more complex patches is computationally more expensive. This is still under investigation.

Version Space Support Vector Machines

E.N. Smirnov¹, I.G. Sprinkhuizen-Kuyper¹, G.I. Nalbantov² and S. Vanderlooy¹

1 Introduction

The task of reliable classification is to determine if a particular instance classification is reliable. There exist two approaches to the task: the Bayesian framework [3] and the typicalness framework [5]. Although both frameworks are useful, the Bayesian framework can be misleading and the typicalness framework is classifier dependent.

To overcome these problems we argue to use version spaces (VSs) [3] for reliable classification. The key idea is to construct VSs containing hypotheses of the target class or of its close approximations. In this way the unanimous-voting classification rule of VSs does not misclassify instances; i.e., instance classifications become reliable.

To construct VSs with the property above we propose an approach extending the volumes of VSs s.t. instance misclassifications are blocked. The approach and VSs are realized using support vector machines (SVMs) [4]. The combination is called version space support vector machines (VSSVMs). We show that VSSVMs are able to outperform the existing approaches to reliable classification.

2 Task of Reliable Classification

Consider training instances $\mathbf{x}_i \in \mathbb{R}^n$ with labels $y_i \in \{-1, +1\}$ of a target class s.t. \mathbf{x}_i is in set I^+ (I^-) if $y_i = +1$ ($y_i = -1$). Given a space H of hypotheses h ($h : \mathbb{R}^n \rightarrow \{-1, +1\}$), the task is to find $h \in H$ classifying correctly instances in \mathbb{R}^n . If correct classification of $\mathbf{x} \in \mathbb{R}^n$ is not possible, \mathbf{x} is unclassified (indicated by label 0).

3 Version Spaces

Given a hypothesis space H and training data $\langle I^+, I^- \rangle$, version space $VS(I^+, I^-)$ is the set of hypotheses consistent with $\langle I^+, I^- \rangle$:

$$VS(I^+, I^-) = \{h \in H | cons(h, \langle I^+, I^- \rangle)\},$$

where $cons(h, \langle I^+, I^- \rangle) \leftrightarrow (\forall \mathbf{x}_i \in I^+ \cup I^-) y_i = h(\mathbf{x}_i)$.

The unanimous-voting rule of VSs classifies instance \mathbf{x} as follows:

$$y = \begin{cases} +1 & VS(I^+, I^-) \neq \emptyset \wedge (\forall h \in VS(I^+, I^-)) h(\mathbf{x}) = +1, \\ -1 & VS(I^+, I^-) \neq \emptyset \wedge (\forall h \in VS(I^+, I^-)) h(\mathbf{x}) = -1, \\ 0 & \text{otherwise. (instance } \mathbf{x} \text{ is left unclassified)} \end{cases}$$

The volume $V(VS(I^+, I^-))$ of $VS(I^+, I^-)$ is the set of instances not classified by the unanimous-voting rule ($y = 0$). By theorem 1 the rule can be implemented by testing VSs for collapse [2].

Theorem 1 If $VS(I^+, I^-) \neq \emptyset$, then for each instance \mathbf{x} :

$$\begin{aligned} (\forall h \in VS(I^+, I^-)) h(\mathbf{x}) = +1 &\leftrightarrow VS(I^+, I^- \cup \{\mathbf{x}\}) = \emptyset, \\ (\forall h \in VS(I^+, I^-)) h(\mathbf{x}) = -1 &\leftrightarrow VS(I^+ \cup \{\mathbf{x}\}, I^-) = \emptyset. \end{aligned}$$

² ERIM, Erasmus University Rotterdam, Rotterdam 3000 DR, The Netherlands, email: nalbantov@few.eur.nl

Testing VSs for collapse is the consistency problem [2]. The problem is to check the existence of a hypothesis $h \in H$ consistent with data. Hence, the VSs unanimous-voting rule can be implemented by any algorithm for the consistency problem (consistency algorithm).

4 Volume-Extension Approach

VSs are sensitive to the class noise in the training data and the expressiveness of hypothesis space H [3]. The expressiveness of H indicates if the hypothesis h_t of the target class is in H . We analyze VS instance classification with these two factors.

Case 1: no class noise and expressive hypothesis space. In this case $h_t \in VS(I^+, I^-)$. Thus, if instance \mathbf{x} is classified by $VS(I^+, I^-)$, \mathbf{x} is classified by h_t ; i.e., \mathbf{x} is classified correctly (reliably).

Case 2: class noise. In this case the set I^+ (I^-) is a union of a noise-free set I_f^+ (I_f^-) and a noisy set I_n^+ (I_n^-). The noisy data $\langle I_n^+, I_n^- \rangle$ cause removal of version space $NVS = \{h \in VS(I_f^+, I_f^-) | \neg cons(h, \langle I_n^+, I_n^- \rangle)\}$ from $VS(I_f^+, I_f^-)$. Thus, $VS(I^+, I^-)$ classifies correctly (reliably) instances classified by $VS(I_f^+, I_f^-)$, but errs on some instances in the volume of NVS .

Case 3: inexpressive hypothesis space. Since $h_t \notin H$, some instances \mathbf{x} can be misclassified by all hypotheses in $VS(I^+, I^-)$.

The volume-extension approach is a new approach for cases 2-3. If $VS(I^+, I^-) \subseteq H$ misclassifies, then the approach is to find a new hypothesis space H' s.t. the volume of $VS'(I^+, I^-) \subseteq H'$ grows and blocks misclassifications. It is applied using theorem 2.

Theorem 2 Consider hypothesis spaces H and H' s.t. for all $\langle I^+, I^- \rangle$ if there is $h \in H$ consistent with $\langle I^+, I^- \rangle$, then there is $h' \in H'$ consistent with $\langle I^+, I^- \rangle$. Then, for all $\langle I^+, I^- \rangle$ the volume $V(VS(I^+, I^-))$ is a subset of the volume $V(VS'(I^+, I^-))$.

Below we apply the volume-extension approach for cases 2-3.

Case 2: since the volume V of NVS is the error region, we search for H' s.t. the volume of $VS'(I^+, I^-)$ comprises maximally V ;

Case 3: since the cause of misclassifications is that $h_t \notin H$, we search for H' s.t. $VS'(I^+, I^-)$ includes more hypotheses approximating h_t . This means that if \mathbf{x} is misclassified, we define H' s.t. $VS'(I^+, I^-)$ includes a hypothesis classifying \mathbf{x} as h_t does. Thus, \mathbf{x} is not classified, so the misclassification is blocked.

We conclude that our approach can block misclassifications for cases 2-3. This means that VSs can be used for reliable classification.

5 Support Vector Machines

Support Vector Machines (SVMs) construct hyperplanes $h(p, C, \langle I^+, I^- \rangle)$ in the hypothesis space $H(p)$ of oriented hyperplanes s.t. the margin between training sets I^+ and I^- is maximized given kernel parameter p and parameter C that controls the trade-off between the margin and the training errors [4].

6 Version Space Support Vector Machines

The key idea of VSSVMs is to use a SVM as a consistency algorithm. By theorem 1 we need a consistency test only for $\langle I^+ \cup \{x\}, I^- \rangle$ and $\langle I^+, I^- \cup \{x\} \rangle$. Since a SVM is not a consistency algorithm in $H(p)$ [4], we define a hypothesis space $H(p, C, \langle I^+, I^- \rangle)$ for which SVM is a consistency algorithm for $\langle I^+ \cup \{x\}, I^- \rangle$ and $\langle I^+, I^- \cup \{x\} \rangle$.

Definition 1 Given parameters p and C and data $\langle I^+, I^- \rangle$, if $\text{cons}(h(p, C, \langle I^+, I^- \rangle), \langle I^+, I^- \rangle)$, then $H(p, C, \langle I^+, I^- \rangle)$ equals:

$$\begin{aligned} & \{h \in H(p) | h = h(p, C, \langle I^+, I^- \rangle) \vee \\ & (\exists x)(h = h(p, C, \langle I^+ \cup \{x\}, I^- \rangle) \wedge \text{cons}(h, \langle I^+ \cup \{x\}, I^- \rangle)) \vee \\ & (\exists x)(h = h(p, C, \langle I^+, I^- \cup \{x\} \rangle) \wedge \text{cons}(h, \langle I^+, I^- \cup \{x\} \rangle)), \\ & \text{otherwise, } H(p, C, \langle I^+, I^- \rangle) = \emptyset. \end{aligned}$$

SVM is a consistency algorithm if the property below holds.

Definition 2 SVM has the instance-consistency property w.r.t. data $\langle I^+, I^- \rangle$ if and only if for any instance x :

- (i) if $h(p, C, \langle I^+ \cup \{x\}, I^- \rangle)$ is inconsistent with $\langle I^+ \cup \{x\}, I^- \rangle$, then for all x' $h(p, C, \langle I^+ \cup \{x'\}, I^- \rangle)$ and $h(p, C, \langle I^+, I^- \cup \{x'\} \rangle)$ are inconsistent with $\langle I^+ \cup \{x\}, I^- \rangle$;
- (ii) if $h(p, C, \langle I^+, I^- \cup \{x\} \rangle)$ is inconsistent with $\langle I^+, I^- \cup \{x\} \rangle$, then for all x' $h(p, C, \langle I^+ \cup \{x'\}, I^- \rangle)$ and $h(p, C, \langle I^+, I^- \cup \{x'\} \rangle)$ are inconsistent with $\langle I^+, I^- \cup \{x\} \rangle$.

Theorem 3 sets the SVM consistency test in $H(p, C, \langle I^+, I^- \rangle)$.

Theorem 3 If the instance-consistency property holds and $H(p, C, \langle I^+, I^- \rangle) \neq \emptyset$, then for each instance x we have:

$$\begin{aligned} & (\exists h \in H(p, C, \langle I^+, I^- \rangle)) \text{cons}(h, \langle I^+ \cup \{x\}, I^- \rangle) \leftrightarrow \\ & [\text{cons}(h(p, C, \langle I^+, I^- \rangle), \langle I^+ \cup \{x\}, I^- \rangle) \vee \\ & \text{cons}(h(p, C, \langle I^+ \cup \{x\}, I^- \rangle), \langle I^+ \cup \{x\}, I^- \rangle)], \\ & (\exists h \in H(p, C, \langle I^+, I^- \rangle)) \text{cons}(h, \langle I^+, I^- \cup \{x\} \rangle) \leftrightarrow \\ & [\text{cons}(h(p, C, \langle I^+, I^- \rangle), \langle I^+, I^- \cup \{x\} \rangle) \vee \\ & \text{cons}(h(p, C, \langle I^+, I^- \cup \{x\} \rangle), \langle I^+, I^- \cup \{x\} \rangle)]. \end{aligned}$$

By theorem 3 to test if there is a hyperplane in $H(p, C, \langle I^+, I^- \rangle)$ consistent with $\langle I^+ \cup \{x\}, I^- \rangle$ test if either of the SVM hyperplanes $h(p, C, \langle I^+, I^- \rangle)$ and $h(p, C, \langle I^+ \cup \{x\}, I^- \rangle)$ is consistent with $\langle I^+ \cup \{x\}, I^- \rangle$. Testing if there is a hyperplane in $H(p, C, \langle I^+, I^- \rangle)$ consistent with $\langle I^+, I^- \cup \{x\} \rangle$ is analogous.

Given $H(p, C, \langle I^+, I^- \rangle)$, VSSVMs are defined as follows:

Definition 3 Given data $\langle I^+, I^- \rangle$ s.t. $I^+ \supseteq I^+$ and $I^- \supseteq I^-$, the version space support vector machine $VS_C^p(I^+, I^-)$ is:

$$VS_C^p(I^+, I^-) = \{h \in H(p, C, \langle I^+, I^- \rangle) | \text{cons}(h, \langle I^+, I^- \rangle)\}.$$

The classification algorithm of VSSVMs realizes the unanimous-voting rule (figure 1). It starts classifying instance x by first building the SVM hyperplane $h(p, C, \langle I^+, I^- \rangle)$. If $h(p, C, \langle I^+, I^- \rangle) = \emptyset$. Thus, $VS_C^p(I^+, I^-) = \emptyset$ and by the unanimous-voting rule 0 is returned. If $h(p, C, \langle I^+, I^- \rangle)$ is consistent with $\langle I^+, I^- \rangle$, $VS_C^p(I^+, I^-) \neq \emptyset$. Hence, the algorithm tests if $h(p, C, \langle I^+, I^- \rangle)$ is consistent with $\langle I^+ \cup \{x\}, I^- \rangle$. If so, $VS_C^p(I^+ \cup \{x\}, I^-) \neq \emptyset$ and the algorithm builds $h(p, C, \langle I^+, I^- \cup \{x\} \rangle)$. If $h(p, C, \langle I^+, I^- \cup \{x\} \rangle)$ is inconsistent with $\langle I^+, I^- \cup \{x\} \rangle$, by theorem 3 $VS_C^p(I^+, I^- \cup \{x\}) = \emptyset$. Since $VS_C^p(I^+ \cup \{x\}, I^-) \neq \emptyset$ and $VS_C^p(I^+, I^- \cup \{x\}) = \emptyset$, by theorem 1 class +1 is assigned to x . If class +1 is not assigned, we check analogously if class -1 can be assigned. If no class is assigned, 0 is returned.

```

Build a hyperplane  $h(p, C, \langle I^+, I^- \rangle)$ ;
if  $\neg \text{cons}(h(p, C, \langle I^+, I^- \rangle), \langle I^+, I^- \rangle)$  then return 0;
if  $\text{cons}(h(p, C, \langle I^+, I^- \rangle), \langle I^+ \cup \{x\}, I^- \rangle)$  then
    Build hyperplane  $h(p, C, \langle I^+, I^- \cup \{x\} \rangle)$ ;
    if  $\neg \text{cons}(h(p, C, \langle I^+ \cup \{x\}, I^- \rangle), \langle I^+ \cup \{x\}, I^- \rangle)$  then return +1;
if  $\text{cons}(h(p, C, \langle I^+, I^- \rangle), \langle I^+ \cup \{x\}, I^- \rangle)$  then
    Build hyperplane  $h(p, C, \langle I^+ \cup \{x\}, I^- \rangle)$ ;
    if  $\neg \text{cons}(h(p, C, \langle I^+ \cup \{x\}, I^- \rangle), \langle I^+ \cup \{x\}, I^- \rangle)$  then return -1;
return 0.

```

Figure 1. The Classification Algorithm of VSSVMs.

The volume-extension approach for VSSVMs is applied for cases 2-3 using the parameter C of SVMs. Note that the probability that the SVM hyperplane $h(p, C, \langle I^+, I^- \rangle)$ is consistent with $\langle I^+, I^- \rangle$ increases with C . Thus, for values C_1 and C_2 of C s.t. $C_1 < C_2$ the probability that $h(p, C_2, \langle I^+, I^- \rangle)$ is consistent with $\langle I^+, I^- \rangle$ is higher than that of $h(p, C_1, \langle I^+, I^- \rangle)$. This implies by theorem 2 that the volume of VSSVMs increases with C .

Applying the approach means to find C s.t. $VS_C^p(I^+, I^-) \subseteq H(p, C, \langle I^+, I^- \rangle)$ classifies instances reliably. Since the volume of VSSVMs increases with C , we can find the minimal value for C in a validation process using binary search s.t. instances are classified reliably (correctly) and the volume of $VS_C^p(I^+, I^-)$ is minimized.

7 Experiments and Comparison

We tested VSSVMs using a polynomial kernel (VSSVM-P). We applied the volume-extension approach by incrementing the parameter C to find the maximal accuracy rate A_m and the maximal coverage rate C_m for A_m (coverage rate is the proportion of classified instances). Table 1 compares VSSVM-P with the naive Bayes classifier (NB) (Bayesian framework) and typicalness-based naive Bayes classifier (TNB) (typicalness framework). The comparison is made using A_m and C_m measured by the leave-one-out method. It shows that VSSVM-P outperform NB and TNB w.r.t. reliable classification.

Data Set	VSSVM-P		NB		TNB	
	C_m	A_m	C_m	A_m	C_m	A_m
labor	0.456	1.0	0.396	1.0	0.351	1.0
hepatitis	0.684	1.0	0.013	1.0	0.013	1.0
breast	0.158	1.0	0.072	1.0	0.079	0.921
sonar	0.221	1.0	0.053	1.0	0.005	1.0
colic	0.079	1.0	0.006	1.0	0.360	0.906
wisc.breast	0.687	1.0	0.017	1.0	0.005	1.0
ionosphere	0.706	1.0	0.168	1.0	0.120	1.0

Table 1. The maximal accuracy A_m and coverage C_m of VSSVM-P, NB, and TNB for 7 datasets from [1].

Meta-Typicalness Approach to Reliable Classification

E.N. Smirnov¹, S. Vanderlooy¹ and I.G. Sprinkhuizen-Kuyper¹

Abstract. We propose a meta-typicalness approach to apply the typicalness framework for any type of classifiers. The approach can be used to construct classifiers with specified classification performance. Experiments show that the approach results in classifiers that can outperform an existing typicalness-based classifier.

1 Introduction

Machine-learning classifiers were applied to many classification tasks [2, 4]. Nevertheless, only few classifiers were used in critical-domain applications [7]. This is due to the difficulty to determine if a classification assigned to a particular instance is reliable.

To decide if an instance classification is reliable we have two tasks:

- (T1) to obtain a confidence value for the classification; and
- (T2) to obtain a threshold on confidence values.

If the confidence value for a classification of an instance is greater than the threshold, the classification is considered as reliable. Otherwise, it is unreliable and the instance is left unclassified.

The typicalness framework was proposed for task T1 [5, 6, 8]. It provides confidence values for instance classifications under the assumption that the data are independent and identically distributed (iid). To apply the framework for a classifier an instance-strangeness function has to be constructed specific for that classifier. Since this is difficult, the framework applicability is restricted: it was applied so far only for SVMs [6] and the nearest-neighbor classifier [5].

To apply the typicalness framework for any type of classifiers we propose a meta-typicalness approach inspired by [1]. The approach is to learn a meta typicalness-based classifier predicting the correctness of each instance classification of a base classifier. Thus, the confidence values of the meta predictions are viewed as the confidence values of the instance classifications of the base classifier.

To obtain a threshold on the confidence values (task T2) for the meta-typicalness approach we propose a procedure that allows constructing classifiers with certain classification performance.

This paper is organized as follows. Section 2 introduces the classification task. The typicalness framework is given in section 3. Section 4 introduces the meta-typicalness approach. The procedure for classifier construction is presented in section 5. Section 6 describes experiments, and section 7 concludes the paper.

2 Classification Task

Let \mathbf{X} be an instance space and Y a class set. Training data D is a set $\{(\mathbf{x}_1, y_1), (\mathbf{x}_2, y_2), \dots, (\mathbf{x}_n, y_n)\}$ of n labelled instances (\mathbf{x}_i, y_i) where instance \mathbf{x}_i is in \mathbf{X} and class y_i is in Y . Given a space H of hypotheses h ($h : \mathbf{X} \rightarrow Y$), the classification task is to find $h \in H$ that correctly classifies future, unseen instances.

¹ MICC-IKAT, Universiteit Maastricht, Maastricht 6200 MD, The Netherlands, email: {smirnov, kuyper, s.vanderlooy}@cs.unimaas.nl

3 The Typicalness Framework

The typicalness framework [5, 6, 8] assumes that training data D and an instance \mathbf{x}_{n+1} to be classified are iid drawn from the same unknown distribution. Given a classifier C , we compute the p -value for each class $y_{n+1} \in Y$ that C can assign to \mathbf{x}_{n+1} as follows:

$$p(y_{n+1}) = \frac{\#\{i : \alpha_i \geq \alpha_{n+1}\}}{n+1}$$

where α_i is the strangeness of instance (\mathbf{x}_i, y_i) in the bag $\{(\mathbf{x}_1, y_1), \dots, (\mathbf{x}_{i-1}, y_{i-1}), (\mathbf{x}_{i+1}, y_{i+1}), \dots, (\mathbf{x}_{n+1}, y_{n+1})\}$. The class y_{n+1} with the largest p -value is the classification of \mathbf{x}_{n+1} . The typicalness (credibility) of this classification is the largest p -value and the confidence is one minus the second largest p -value.

To compute strangeness values α_i we need to construct an instance-strangeness function α for the classifier C used. Since this is difficult, the applicability of the typicalness framework is restricted.

4 Meta-Typicalness Approach

To apply the typicalness framework to any classifier we propose a meta-typicalness approach (see task T1). Consider a base classifier B trained on training data D . We learn a meta classifier M that predicts the reliability of each classification of B . Hence, the meta class set Y' of metadata D' for M consists of two meta classes: “0” (unreliable classification) and “1” (reliable classification). Metadata D' is formed using k -fold cross validation as follows: a labelled meta instance $(\mathbf{x}_i, y'_i) \in D'$ is formed from the labelled instance $(\mathbf{x}_i, y_i) \in D$ s.t. y'_i is equal to “1” if the classification of \mathbf{x}_i provided by classifier B is equal to y_i ; otherwise, y'_i equals “0”.

The classifiers B and M form one combined classifier denoted by $B:M$. The classification rule of $B:M$ is to assign a class y predicted by B to an instance \mathbf{x} if M decides that this classification is reliable (i.e., M assigns meta class “1” to \mathbf{x}); otherwise, \mathbf{x} is unclassified.

Assume that the classifier M is based on the typicalness framework and the classifier B is not (i.e., M outputs confidence values for classifications while B does not output such values). Then, we can use the p -values of M as the p -values for $B:M$ as follows. If B assigns a class y to an instance \mathbf{x} and M assigns meta class “1” to \mathbf{x} , then the meta-typicalness approach assigns the p -value p_1 of meta class “1” to the p -value of class y of B and the p -value p_0 of meta class “0” to p -values of all the remaining classes $Y \setminus \{y\}$. Thus, we can estimate the typicalness and confidence of each classification y of $B:M$. We note that p -values of the classes $Y \setminus \{y\}$ are overestimated if $|Y \setminus \{y\}| > 1$. Thus, the confidence estimate can be pessimistic.

5 Combined-Classifier Construction

To decide if a classification of a combined classifier $B:M$ is reliable, we threshold the classification-confidence values of $B:M$ (see task

T2). This is equivalent to thresholding the confidence values of M . By theorem 1 to build $B:M$ with accuracy \mathcal{A} we threshold the confidence values of M s.t. the precision of M becomes equal to \mathcal{A} ².

Theorem 1 [3] *The accuracy \mathcal{A} of the combined classifier $B:M$ equals the precision \mathcal{PR} of the meta classifier M .*

To build a meta classifier M with precision \mathcal{PR} we propose a procedure using ROC convex hull (ROCCH) [7] (figure 1). If meta class “1”(“0”) is the positive(negative) class, the procedure is as follows:

- (1) build the ROCCH of M using the confidence ratio $\frac{(1-p_0)}{(1-p_1)}$;
- (2) construct the iso-precision line of the desired precision \mathcal{PR} given by $tpr = \frac{\mathcal{PR}}{1-\mathcal{PR}} \frac{N}{P} fpr$, where $tpr(fpr)$ is the true(false) positive rate, and $P(N)$ is the number of positive(negative) meta instances;
- (3) determine the value R_I of the ratio $\frac{(1-p_0)}{(1-p_1)}$ in the intersection point I of the ROCCH and the iso-precision line.

If the confidence ratio $\frac{(1-p_0)}{(1-p_1)}$ of the meta classifications are thresholded by the value R_I , then the precision of M is \mathcal{PR} [7]. Thus, by theorem 1 the accuracy \mathcal{A} of $B:M$ will be equal to \mathcal{PR} .

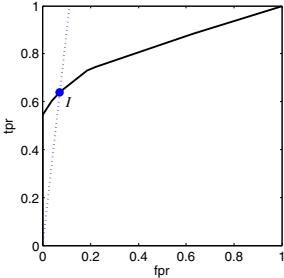

Figure 1. ROCCH of the typicalness-based nearest-neighbor classifier [5] trained on meta data obtained by a naive Bayes classifier on the Wisconsin breast-cancer data [2]. ROCCH is intersected by iso line of 90% precision.

By theorem 1 the accuracy \mathcal{A} of the combined classifier $B:M$ is maximized if the precision of M is maximized. This precision is maximized for the iso-precision line with slope equal to the slope of the line segment of the ROCCH starting from the origin. The highest point of this segment maximizes the number of covered meta instances (see point $(0, 0.56)$ of ROCCH in figure 1). Thus, in this point by theorem 1 the accuracy and the coverage of $B:M$ are maximized. They are denoted by \mathcal{A}_m and \mathcal{C}_m , respectively.

6 Experiments

We tested the meta-typicalness approach using the combined classifier $NB:TCMNN$ where NB is the naive-Bayes classifier [4] and $TCMNN$ is a typicalness-based nearest-neighbor classifier [5]. Note that NB does not compute classification-confidence values in contrast with $TCMNN$. The classification-confidence values of $NB:TCMNN$ were formed according to the meta-typicalness approach.

The metadata for $TCMNN$ in $NB:TCMNN$ were generated in an internal leave-one-out process. By thresholding classification-confidence values of $NB:TCMNN$ we constructed coverage/accuracy graphs of $NB:TCMNN$ using 10-fold cross validation. A comparison of the graphs with those of $TCMNN$ shows that $NB:TCMNN$ outperforms $TCMNN$ on the majority of the datasets. Since the space is not

² Classifiers M and $B:M$ may not classify all the instances. The accuracy and precision of these classifiers are defined only for the instances they are able to classify. Thus, coverage defined as the proportion of the classified instances is an important statistic for these classifiers.

7 Conclusion

In this paper we proposed a meta-typicalness approach that allows the typicalness framework to be applied to any classifier. We showed how the approach can be used for constructing classifiers with certain classification performance. The experiments showed that the approach allows constructing combined classifiers that are able to outperform the $TCMNN$ classifier.

Text Sampling and Re-sampling for Imbalanced Authorship Identification Cases

Efstathios Stamatatos¹

Abstract. Authorship identification can be seen as a single-label multi-class text categorization problem. Very often, there are extremely few training texts at least for some of the candidate authors. In this paper, we present methods to handle imbalanced multi-class textual datasets. The main idea is to segment the training texts into sub-samples according to the size of the class. Hence, minority classes can be segmented into many short samples and majority classes into less and longer samples. Moreover, we explore text re-sampling in order to construct a training set according to a desirable distribution over the classes. Essentially, text re-sampling can be viewed as providing new synthetic data that increase the training size of a class. Based on a corpus of newswire stories in English we present authorship identification experiments on various multi-class imbalanced cases.

1 INTRODUCTION

In recent years, researchers have paid increasing attention to authorship analysis in the framework of practical applications, such as verifying the authorship of emails and electronic messages, plagiarism detection in student essays, and forensic cases [1]. Authorship identification can be seen as a single-label multi-class text categorization problem where the candidate authors play the role of the classes. As concerns the text representation, various measures have been proposed in order to quantify the stylistic choices of the authors including function word frequencies, character n -gram frequencies, vocabulary richness measures, word-class frequencies, and syntactic analysis measures [2].

Very often, a common problem in authorship identification is the lack of sufficient text samples of undisputed authorship (at least for some of the candidate authors). On the other hand, a big amount of text samples may be available for other candidate authors. From a machine learning point of view, this constitutes the *class imbalance* problem (i.e., uneven distribution of the training set over the classes). This problem has been studied mainly within the framework of two-class datasets. The main approaches to deal with class imbalance attempt to re-balance the training set by performing either under-sampling of the majority class or over-sampling of the minority class. In general, the former approach has been proved to work better [3]. Alternatively, the sensitivity of the classification algorithm can be modified so that errors on minority class to be costlier than errors on majority class. Last but not least, the SMOTE approach creates new synthetic training data for the minority class [4]. This is achieved by adding a small value to some of the features of original training data and producing new data which lie close to

the original ones in the multi-dimensional space of the problem.

Given a text categorization task, each training text is considered as a unit for constructing the training set. Usually, the length of the training texts is fixed or defined by the source of the documents. Moreover, text representations usually produce sparse data not quite suitable for a SMOTE-like approach. In this paper, we present methods to efficiently segment the training texts into sub-samples according to the size of the class. Textual data can be handled flexibly so that to produce a variable amount of text samples of variable length. Moreover, by using text re-sampling methods it is possible to provide new synthetic data.

2 AUTHORSHIP IDENTIFICATION

In this paper, we are based on the frequencies of character n -grams for text representation. Let $\mathbf{G}_d = \{g_1, g_2, \dots, g_d\}$ be the ordered set (by decreasing frequency) of the most frequent character n -grams of the training set. Consider f_{ij} as the normalized frequency of the j -th n -gram of \mathbf{G}_d in the i -th text. Then, a text x_i is represented as the vector $\langle f_{i1}, f_{i2}, \dots, f_{id} \rangle$ (in this study, $d=5,000$ and $n=3$). A SVM, a model able to handle highly dimensional and sparse data, is then applied to these vectors. The Weka implementation was used with default parameters. Note that this approach is language-independent. However, for achieving best results given a particular corpus or natural language, one should explore the most appropriate amount and length of character n -grams.

An English corpus of newswire stories by 10 authors (100 texts per author) taken from the new Reuters Corpus Volume 1 has been used in this study. Apart from belonging to the same genre, all the texts fall under the CCAT topic (corporate/industrial) in order to minimize the factors that distinguish the classes despite authorship. Initially, this corpus was divided into non-overlapping training and test texts of equal size. In order to simulate the imbalance conditions of a real-world authorship identification case, a Gaussian distribution of training texts over the candidate authors is assumed. Given this setting, the *multi-class imbalance ratio* of the problem can be defined as *peak/base*, where *peak* and *base* are the size (in training texts) of the biggest and smallest classes, respectively. Figure 1 (left) shows an example distribution of the training set for *peak*=20 and *base*=5. Authors near the center of the distribution are the majority classes while the authors at both sides of the distribution are the minority classes. Different values of *base* and *peak* produce multi-class imbalanced datasets (see Table 1).

3 TESTED METHODS

When using all the training texts, the accuracy is 79.4% which is considered as the upper bound. On the other hand, when each training text is considered as unit and all training texts are used, a

Base	Peak	Ratio	Accuracy (%)				
			UB	LB	M1	M2	M3
2	10	5	79.4	51.2	52.4	56.8	56.6 57.34
2	20	10	79.4	47.4	52.4	56.8	51.8 55.38
2	50	25	79.4	53.6	52.4	56.8	54.6 59.02
5	10	2	79.4	60	49.8	59.8	65.2 58.52
5	20	4	79.4	56.4	49.8	59.8	59 61.44
5	50	10	79.4	59.6	49.8	59.8	62.4 65.76
10	20	2	79.4	62.8	61.4	68.8	65.6 66.18
10	50	5	79.4	65	61.4	68.8	68 69.18

lower bound of accuracy is provided for any imbalanced case. The following methods were tested (results in Table 1):

- Method-1: Under-sampling of the majority classes. For all authors, exactly *base* training texts were used.
- Method-2: Under-sampling of the majority classes using fixed length samples. All the available training texts were concatenated in one text per author. Let x_{min} be the size (in text lines) of the shortest author file. Then, the first x_{min} text lines of each author file were segmented into text sub-samples of length a (in text lines). It was observed that small values of a (2 or 3) tend to provide better results (in Table 1, $a=3$). Note that, in RCV1 each text line comprises one full sentence.
- Method-3: Re-balancing the dataset by variable length text samples. As previously, author files are produced. Let x_i and x_{max} be the text length (in text lines) of the i -th author and the longest author file, respectively. Then, each author file is segmented into text sub-samples of length x_{max}/x_i . Thus, a balanced dataset is produced having k text samples per class (in Table 1, $k=50$).
- Method-4: Re-balancing the dataset by text re-sampling. Again, author files are produced. A variable number of text samples per author is produced according to the length of their file. Many short text samples are produced for the minority classes and less but longer text samples are produced for the majority classes. The text lines included in a text sample are selected randomly and a text line may be included in more than one text sample (in Table 1, average accuracy after 50 runs is shown). Note that this method produces an imbalanced training set (in contrast to methods 1-3). However, the originally minority classes are now represented by more samples than the originally majority classes (see Figure 1).

Table 2 shows the identification accuracy per author (when *base*=5 and *peak*=20) as deviation from the baseline. The baseline method roughly resembles the distribution of training texts over the authors (the more training texts of one author, the better the results). Method-1 improves minority authors but fails to keep the majority authors on high level. Method-2 improves the minority authors

Table 2. The identification accuracy per author of the presented methods on imbalanced corpus (*base*=5, *peak*=20) expressed as deviation from the lower bound (LB).

without a dramatic loss in majority authors. Method-3 achieves to keep majority authors on high level (it even improves them) but it fails to significantly improve the minority authors. Finally, method-4 considerably improves minority authors with the cost of a slight reduction on the majority authors.

4 CONCLUSION

Since textual data can be easily segmented in small pieces, they can be handled more flexibly in comparison to other kinds of data. Various text sampling and re-sampling methods were examined to handle multi-class imbalanced textual data. The main idea of the most successful method was to produce many short text samples for the minority classes and less but longer text samples for the majority classes. The basic methods presented here can be combined in order to further improve the results. For instance, method-3 and method-4 can be applied together. Alternatively, they could be used to train different classifiers which, then, can be combined in an ensemble scheme. Recall from Table 2 that the classification errors made by these methods are to a great extent uncorrelated, a crucial condition to build effective ensembles.

Is Web Genre Identification Feasible?

Benno Stein¹ and Sven Meyer zu Eissen¹

Abstract. This paper contributes to a facet from the area of Web Information Retrieval that has recently received much attention: The satisfaction of a user's personal information need with respect to text type, presentation type, or information quality. We imply that such properties can be quantified for all kinds of Web documents, and we subsume them under the term "Web genre" or "genre".

Recent surveys show that there is—to a certain degree—a common understanding of Web genre. However, the strictness by which genre and non-genre aspects of a document are experienced is an individual matter. To get a better understanding of the challenges of Web genre identification and its possible limits we investigate in this paper a very interesting question, which has not been posed by now:

Given a categorization \mathcal{C} of documents (or bookmarks, links, document identifiers), can we provide a reliable assessment whether \mathcal{C} is governed by topic or by genre considerations?

Keywords unsupervised learning, knowledge discovery, text mining, personal information retrieval

1 INTRODUCTION

Nearly all retrieval processes are topic-centered: We type in a keyword, provide a sample document, or browse a directory tree to get the desired piece of information. However, with the number of indexed documents develops the urgent need for information quality: Users are interested in certain *kinds* of information, or, as it is called here, in particular genres. In connection with text documents genre describes, among others, the set of conventions in the way in which information is presented, such as the style of writing, the presentation style, or the functional trait. An in-depth discussion of the term genre is beyond the scope of this paper,² but, for the time being it is sufficient to remember the following characterization: Topic and genre are orthogonal—or, with Dewdney [3]: "The form is the substance." This is illustrated in Figure 1, where the same articles of a newspaper page are classified under both topic and genre considerations.

Genre *identification* shall discover groups of texts that share a common form of transmission, purpose, or discourse properties [10, 12]. This means in the WWW context that genre identification can be understood as differentiation between research Web pages, personal experience reports, or commercial product information, for example. The application scenario of our paper connects at this point: Given a user's categorized document collection, \mathcal{C} (in the form of bookmark folders for instance), we ask whether one is able to reliably determine the organization principle, say, the underlying categorization type behind \mathcal{C} : Is it topic or genre?

The remainder of this paper outlines Web genre research, provides technical background, and answers the question posed.

Figure 1. The difference between topic and genre, illustrated at a newspaper page.

1.1 Related Work on Web Genre

There is little work on automatic Web genre identification, and, the question of feasibility is—if at all—answered indirectly only, following a simplistic three step approach: (i) definition of particular genre classes, (ii) compilation of a respective genre corpus, (iii) quantification of the learnability by constructing a classifier. In the following we organize the research in an ascending chronological order.

Bretan et al. propose a richer representation of retrieval results in Web search interfaces. Their approach combines content-based clustering and genre-based classification that employs simple part-of-speech information along with substantial text statistics. The features are processed with the C4.5 algorithm; the authors give no information about the achieved classification performance [2]. Based on an exploratory user study Roussinov et al. develop a genre scheme that comprises five genre classes: Topic, Publication, Product, Education, FAQ. Their work describes an ongoing study, and no discovery approach has been implemented [9]. Dimitrova et al. argue that shallow text classification techniques can be used to sort documents according to genre. The paper describes an ongoing study but experience related to classification performance is not reported [4]. Lee and Myaeng define seven genre types. Aside from Web-specific genres like Q&A or Homepage, the authors use also the newspaper-specific genres Reportage and Editorial. The feature set is a list of about hundred document terms tailored to the different genre classes [7]. Meyer zu Eissen and Stein report on a user study on Web genre usefulness from which they derive eight genre classes, which in turn form the building blocks of three genre profiles: Education, Geek, and Private. Within their comprehensive experiments classification performances between 60% and 80% were achieved [8]. Boese investigates the effects of Web document evolution on genre classification and poses the question: "How much do Web pages change over time within each genre?" The author answers this and related questions for two publicly available genre corpora [1].

Note that existing classification approaches treat not the problem that is addressed here; they start with the assumption that the type of the analyzed collection is *a-priori* known, namely, genre.

¹ Faculty of Media / Media Systems. Bauhaus University Weimar, Germany.
benno.stein@medien.uni-weimar.de

² Santini has compiled an up-to-date discussion of this term [10].

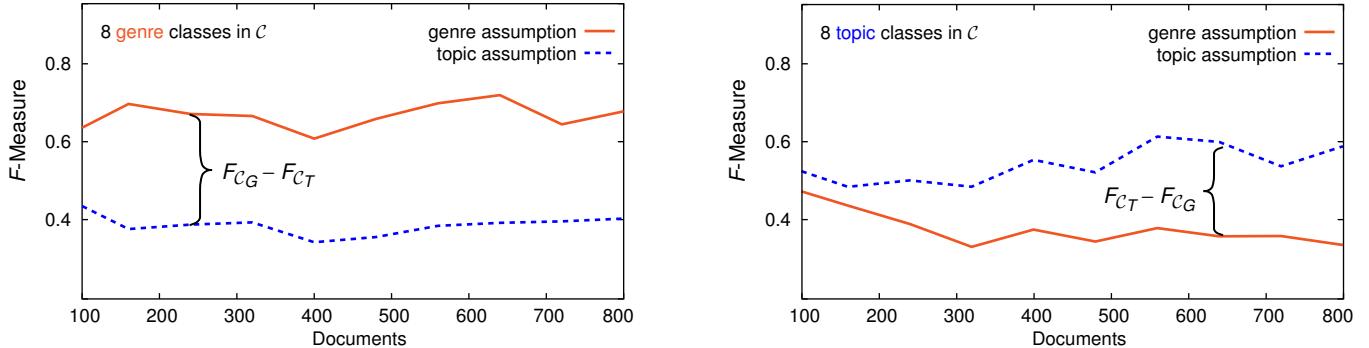

Figure 2. Plots that quantify the adequacy of the document models R_G and R_T . They unveil whether a categorization \mathcal{C} is organized by genre or by topic.

2 DETERMINANTS OF A GENRE CLASSIFIER

With respect to the investigated features the existing approaches to genre identification fall into three groups: Classifiers that rely on a subset of a document's terms [11, 7], classifiers that employ linguistic features along with additional features related to text statistics and computational linguistics [6, 8], or both [5]. The following list gives an overview over the different feature types:

- customariness and style features
- part-of-speech and syntactic group analysis
- closed-class word sets and presentation-related features

Based on these features a powerful document retrieval model, R_G , for genre identification can be built. To keep the computational footprint of our genre model small we applied a discriminant analysis to select 18 features along with an appropriate weighting scheme.

By contrast, to capture the gist of a document with respect to its *topic*, the vector space model, R_T , is the most successful document retrieval model. It encodes a document d as a simple vector, which comprises weighted frequency values of the terms occurring in d .

3 HYPOTHESIZING CATEGORIZATION TYPES

Let D be a set of documents. An exclusive categorization $\mathcal{C} \subseteq \{C_1, \dots, C_k\} | C \subseteq D$ of D is a division of D into sets for which $\bigcup_{C_i \in \mathcal{C}} C_i = D$, and $\forall C_i, C_j \in \mathcal{C} : C_i \cap C_{j \neq i} = \emptyset$. The categorization \mathcal{C} may be governed by topic or by genre considerations, and we introduce the following procedure to verify the underlying categorization type:

1. Construct for each $d \in D$ two document models, one under the genre document retrieval model, R_G , and one under the topic document retrieval model, R_T .
2. Based on a similarity measure (Euclidean or cos-similarity) construct two similarity graphs G_G and G_T . The edge weights in these graphs result from the similarity computations under R_G and R_T respectively.
3. Apply a clustering algorithm to the graphs G_G and G_T . The resulting clusterings are designated as \mathcal{C}_G and \mathcal{C}_T .
4. Compute the F -measure (or another external reference measure) to quantify the congruence between \mathcal{C} and \mathcal{C}_G as well as between \mathcal{C} and \mathcal{C}_T . The resulting values are designated as F_{C_G} and F_{C_T} .
5. If $|F_{C_G} - F_{C_T}|$ is significant, \mathcal{C} is organized under genre considerations if $F_{C_G} > F_{C_T}$, and under topic considerations otherwise.

The F -measure quantifies the degree of congruence between a (human) reference categorization $\mathcal{C} = \{C_1, \dots, C_k\}$ and a clustering $\mathcal{C}' = \{C'_1, \dots, C'_l\}$. The recall of cluster j with respect to category i , $rec(i, j)$, is defined as $|C'_j \cap C_i| / |C_i|$. The precision of cluster j with respect to category i , $prec(i, j)$, is defined as $|C'_j \cap C_i| / |C'_j|$. The F -measure of a clustering \mathcal{C}' , $F_{\mathcal{C}'}$, is:

$$F_{\mathcal{C}'} = \sum_{i=1}^k \frac{|C_i|}{|D|} \cdot \max_{j=1, \dots, l} \{F_{i,j}\}, \text{ with } F_{i,j} = \frac{2 \cdot prec(i, j) \cdot rec(i, j)}{prec(i, j) + rec(i, j)}$$

A perfect clustering matches the given categories exactly and yields an F -measure value of 1.

Experiments Our experiments rely on the corpus of [8], where eight Web genre classes are distinguished: Help, Article, Discussion, Shop, Portrayal (priv and non-priv), Link Collection, and Download. The orthogonal topic categorization distinguishes the following eight topics: Sports, Annual results, International relations, Religion, Crime, Management moves, Money supply, Legal/judicial.

Based on this corpus we compiled 40 categorizations of different sizes and under both topic and genre considerations. It turned out that for each of these categorizations its type could be unambiguously determined by computing $|F_{C_G} - F_{C_T}|$, whereas a genre model comparable to [2] and as topic model the vector space model was employed. Figure 2 shows the developing of the respective F -measure values F_{C_G} and F_{C_T} . The runtime complexity is dominated by the cluster analysis, and, using k -means, linear in \mathcal{C} .

Our current research focuses on document models for special retrieval situations and related learning strategies.

Adaptive Context-based term (re)weighting

An experiment on Single-Word Question Answering

Marco Ernandes and Giovanni Angelini and Marco Gori and Leonardo Rigutini and Franco Scarselli¹

Abstract. Term weighting is a crucial task in many Information Retrieval applications. Common approaches are based either on statistical or on natural language analysis. In this paper, we present a new algorithm that capitalizes from the advantages of both the strategies. In the proposed method, the weights are computed by a parametric function, called *Context Function*, that models the semantic influence exercised amongst the terms. The Context Function is learned by examples, so that its implementation is mostly automatic. The algorithm was successfully tested on a data set of crossword clues, which represent a case of Single-Word Question Answering.

1 Introduction

Term weighting is an important task in many areas of Text Processing, including, Document Retrieval, Text Categorization and Question Answering (QA). The goal of term weighting is to assign to each term w found in a collection of text documents a specific score $s(w)$ that measures the importance, with respect to a certain goal, of the information represented by the word. Common approaches to term weighting can be divided into two groups: statistical and linguistic techniques. Statistical techniques [1] (e.g. TFIDF) are efficient and easy to develop, but they tend to consider the words of a document as unordered and independent. The techniques inspired by natural language theories [6], as morphological analysis, naturally exploit the information provided by word contexts. This makes the processing more expressive, but also slower and more complex to design.

In this paper, we present a term weighting algorithm that aims to combine the advantages of both statistical and linguistic strategies. The method exploits the relationships among the words of a document. The intuition is that the relevance of a term can be computed recursively as the combination of its intrinsic relevance and the relevance of the terms that appear within the same context. The influence exercised by a word on another one is computed using a parametric function, called *Context Function*. This function can use both statistical and linguistic information, and it can be trained by examples.

The Context-based algorithm has been evaluated on a specific problem, that of Single-Word Question Answering (QA), where the goal is to find the single correct word that answers a given question. The experimental results prove that the approach is viable.

2 Adaptive Context-based term (re)weighting

The proposed method exploits the word contexts. A word context primarily consists of the text surrounding a given word, but could also include other features, e.g. document titles, hyper-linked documents. The basic idea is that, in order to measure the relevance of a word with respect to a certain goal (e.g. a query, a document category), the features of the context in which the term appears are important as

well as the features of the word itself. In this work we assume that a text document can be represented by a social network [5], where the importance of the words can be computed on the basis of their neighbours. More precisely, the weight $s(w)$ of the word w is computed as

$$s(w) = (1 - \lambda)d_w + \lambda \sum_{u \in r(w)} s(u)c_{w,u}, \quad (1)$$

where d_w is the *default score* of w , $r(w)$ is the set of words that belong to the context of w , $c_{w,u}$ is a real number measuring the influence exercised by u over w , and $\lambda \in [0, 1]$ is a damping factor.

Eq. (1) defines the term weights by a sparse linear system of equations. In our experiments, the solution of such a system was computed by Jacobi algorithm, an efficient algorithm which can be applied even on huge problems with billions of variables [3].

Context Functions In order to define the influence factors, it has to be taken into account that words are multiply instantiated in different positions of a document, and each instance (a word-occurrence) is affected by a different context. Therefore, we distinguish between words, w , and word occurrences, \hat{w} . We assume that $c_{w,u}$ can be computed as the sum of the contributions of all the occurrences \hat{w} , \hat{u} of w and u , respectively, such that \hat{u} belongs to the context of \hat{w}

$$c_{w,u} = \sum_{\hat{w} \in occ(w)} \sum_{\hat{u} \in ict(\hat{w}, u)} C_p(\hat{w}, \hat{u}). \quad (2)$$

Here, $occ(w)$ is the set of instances of word w , and $ict(\hat{w}, u)$ is the set of the occurrences of u that belong to the context of \hat{w} , i.e. $ict(\hat{w}, u) = occ(u) \cap ctxt(\hat{w})$, where $ctxt(\hat{w})$ is the context of \hat{w} ; p is a set of parameters, and $C_p(\hat{w}, \hat{u})$ is a parametric function that establishes the strength of the influence between the instances \hat{w} (the word under evaluation) and \hat{u} (the context word). In this work we define the context of a word $ctxt(\hat{w})$ as the set of words that are contained in the same document and within the surround of \hat{w} .

The function $C_p(\hat{w}, \hat{u})$ establishes how word couples can influence one another on the basis of features extracted from the words and from the relationships between words. This function can exploit any sort of feature from \hat{w} and \hat{u} : info-theoretical, morphological or lexical. The features that have been used in our preliminary experiments are exclusively statistical (Tab. 1).

The most general approach to the implementation of $C_p(\hat{w}, \hat{u})$ is by a modeling tool that has the universal approximation property, e.g. neural networks, polynomials, and rationales. For the introductory scope of this paper we preferred to adopt a simpler implementation of $C_p(\hat{w}, \hat{u})$. We defined the influence function as $C_p(\hat{w}, \hat{u}) = \prod_{i=0}^n \sigma(\alpha_i x_i + \beta_i)$, where x_i is the value associated with the i -th feature, α_i, β_i are the model parameters, and σ is the logistic sigmoid function $\sigma(x) = 1/(1 + e^{-x})$. Each term $\sigma(\alpha_i x_i + \beta_i)$ is a sort of soft switch related to the i -th feature and controlled by α_i (steepness and direction) and β_i (medium value) so that the whole function is a sort of boolean expression composed by AND operators.

Name	Feature Set
FS-A	$idf(w)$, $idf(u)$, $dist(\hat{w}, \hat{u})$
FS-B	$idf(w)$, $idf(u)$, $dist(\hat{w}, \hat{u})$, $dist(\hat{u}, Q)$
FS-B*	$idf(w)$, $idf(u)$, $dist(\hat{w}, \hat{u})$, $dist(\hat{u}, Q)$, <i>sw-list</i>

Table 1. The set of features used by the Context Functions. $dist(\hat{w}, \hat{u})$ is the number of words between \hat{w} and \hat{u} , $dist(\hat{u}, Q)$ is the number words between \hat{u} and the word occurrences of query Q . Symbol *sw-list* denotes the cases that a stop word list is used to remove non informative terms.

Learning Context Functions The goal of the learning procedure is the optimization of a cost function e_p that measures the performance of the weighting system. We adopted the resilient parameter adaptation [4], which is an efficient technique that updates the parameters using the signs of the partial derivatives of the cost function.

The cost function e_p depends on the specific task that is addressed by the application. The mean reciprocal rank of the correct answer (MRR) is a standard positional and cumulative evaluation measure can be used for QA evaluation. Formally, given a set of queries $Q = \{q_1, \dots, q_n\}$ and denoted by $pos(a^q)$ the position of the correct answer a^q for question q , we have $MRR(Q) = \frac{1}{n} \sum_{q=1}^n \frac{1}{pos(a^q)}$.

On the other hand, MRR is a discrete function and cannot be used for gradient-based learning procedures. In order to design a differentiable cost function, we defined a “soft position” function *soft_pos* to replaces *pos*: $soft_pos(a) = \sum_{w \in W, w \neq a} \sigma(\gamma(s(w) - s(a)))$, where W is the set of words considered by the weighting algorithm, a is the correct answer, γ is a predefined parameter and σ is a sigmoid function. In fact, it can be easily observed that for large γ , *soft_pos(a)* approximates *pos(a)*. Finally, we defined a differentiable evaluation function which approximates MRR simply by replacing *pos(a)* with *soft_pos(a)*. Once the system is trained using this soft function, the results can be measured by the standard MRR.

3 Experimental Results

The Single-Word QA problem The proposed method was experimentally assessed on Single-Word QA, a special case of QA where each question has to be answered with a single correct word, given a number of documents related to the question. A popular and challenging example of Single-Word QA is provided by crossword clues.

Our experiments aim to show that the Context-based algorithm improves the ranking quality of the candidate answers provided by WebCrow, a Web-based system designed to answer crossword clues [2].

The dataset consisted of 525 Italian crossword clues randomly extracted from the archive in [2]. The examples were divided into two subsets: *NE*-questions (165 examples), whose answers are factoid Named Entities, and, *nonNE*-questions (360 examples), whose answers are non-Named Entities (common nouns, adjectives, verbs, and so on. e.g. *<Reduce the area by two: foldinhalf>*).

Compared approaches The Context-based algorithm was compared with three different weighting techniques. The first is TFIDF, a standard measure that gives a statistical evaluation of the importance of a word to a document. The other two techniques, *WebCrow-S* and *WebCrow-SM*, are two ranking methods used in WebCrow. WebCrow-S exploits only statistical information of the words, the documents and the queries. WebCrow-SM additionally uses a morphological analysis of the documents joined with a morphological Answer Type classification of the clues (see [2]).

The experiments The subsets (*NE* and *nonNE*-questions) were randomly divided into a train set (40%) and test set (60%). Each example consisted of a question/answer couple, a set of H documents related by Google to the question; the vector of the ranked terms \mathbf{W} (the candidate answers), extracted from the H documents. Several

	Def TW	FS	NE	nonNE
TFIDF			0,216	0,071
TFIDF + context reweighting	FS-A	0,233	-	
WebCrow-S			0,290	-
WebCrow-S + context reweighting	FS-B	0,346	-	
WebCrow-S + context reweighting	FS-B*	0,355	-	
WebCrow-SM			0,293	0,104
WebCrow-SM + context reweighting	FS-B*	0,345	0,121	

Table 2. MRR performance. The results of the three baseline algorithms are given in bold. Def TW denotes the algorithm used for the default term weights d_w , FS specifies the Feature Set of the Context Function.

Context Functions with different set of features (Tab. 1) were trained. We chose 20 as a fixed dimension for the context window.

The achieved results, displayed in Table 2, confirm that the Context-based algorithm outperformed the other weighting techniques. For the *NE* subset (Table 2, *NE* column), the performance was impressive. In particular, the reweighting of the default scores provided by WebCrow-S, produced a 22,3% increment of the MRR (from 0,29 to 0,355, row 5). An insightful resume of the performance improvements is provided by the Success Rate curve (Fig. 1), that shows the probability of finding the correct answer within the first N words of \mathbf{W} . Each weighting scheme under comparison appears consistently below the curve of its Context-based reweighting.

4 Conclusions and Further work

In this paper we proposed a novel term weighting that exploits the information provided by word contexts. The approach has been proved to be very effective on the problem of Single-Word Web-based Question Answering. Future matter of research includes the application of the method to Document Classification and Information Extraction.

How to Analyze Free Text Descriptions for Recommending TV Programmes?

Bernd Ludwig¹ and Stefan Mandl²

Abstract. This paper presents an approach to exploit free text descriptions of TV programmes as available from EPG data sets for a recommendation system that takes the content of programmes into account³. The paper focusses on classifying free text descriptions in relation to natural language user queries.

1 Introduction

Via satellite the Electronic Programme Guide (EPG) provides an enormous amount of information about TV programmes including natural language descriptions of programmes. Viewers are overwhelmed by the huge number of channels when they select a programme. Therefore, they would prefer to know more about the content of a programme when deciding whether to watch it or not. This requires that a recommendation system has information about the content available and can analyze programme descriptions semantically comparing it with the viewer's interests.

At the beginning of this paper, we compare our work with previous research efforts. In Section 1.2 we report on a user study that shows how viewers select programmes. In Section 2 we explain our approach to analyse free text descriptions. We conclude the paper with a report on a first evaluation of the system in Section 3.

1.1 The State-of-the-Art Recommendation Systems

The design and implementation of TV recommendation systems has attracted great interest in different research groups already. They use sophisticated user models such as in [1]. In order to allow for default reasoning, stereotypes for users are applied which are based on the analysis of the average user's lifestyle (see [4]). In order to increase the user's confidence in the system proposals, the generation of trust-worthy suggestions that take programmes watched earlier into account has been studied in detail (see [2]). In contrast to the reported research, we focus on the question of how a system could take the contents of TV programmes into account.

1.2 How Do Viewers Select TV Programmes?

A user study [7] conducted as part of the research project EMBASSI (see [5, 6]) revealed a number of interesting facts about how users like to select TV programmes. Candidates were situated in front

of a computer display that suggested an automatic recommendation system to be at work. Actually, in a room nearby, a human person monitored the candidate and responded according to the information available from a TV magazine. The users were allowed to ask arbitrary questions about the currently available TV programmes. On the display a list of proposals was presented and users could ask more specific questions on certain proposals – mostly about their *content*:

Liebe, Romantik (Love, romance)

Spannung, Magie, Fantasie (Tension, magic, fantasy)

Eine politische Sendung (A programme on politics)

Users often expressed emotional attitudes they desired the programme to have:

Entspannen (To relax)

Show, Witz (Show, fun)

2 Recommendations Based on Free Texts

Recommendations for TV programmes could be improved if they relied not on genre types only, but if it was possible to know more about the content of programmes and connect this information with its knowledge about the user and his/her inquiry in natural language. The current section explains our solution to this issue.

The method we propose for shallow semantic analysis of EPG programme descriptions is based on the DORNSEIFF lexicon for German. Like a thesaurus, it groups words according to certain topics, i.e. in each group there are words (even of different word categories) that describe a particular aspect of a certain topic. The DORNSEIFF lexicon⁵ is not a synonym lexicon, but a “topic” lexicon. Structured in a two-level hierarchy, the lexicon organizes topics in chapters (e.g. chapter 15 contains subtopics *social life*) and subchapters (e.g. subchapter 15.39 is the topic *reward*). If the meaning of a word is ambiguous, it is listed in more than one subchapter.

The central idea is to quantify on the one hand how well a free text for a TV programme (its content) matches the user query and on the other hand whether the emotions entailed in the query can be found in the free text as well. Both aspects cover almost all user queries we have collected (see Sect. 1.2). Proposals are computed by finding pareto-optimal sets for both criteria.

2.1 Measuring the Semantic Distance

The first step is the identification of those components of the feature vector that cover the “main theme” of a programme description. A

² Chair for Artificial Intelligence, University of Erlangen-Nuremberg, Germany, email: Stefan.Mandl@informatik.uni-erlangen.de

³ Our research is sponsored by *Software-Offensive Bayern*⁴. Ferdinand Herrmann, Heike Ott, Kristina Makedonska, and Sebastian von Mammen provided valuable help implementing major parts of the presented system.

⁵ Interested readers can test the online version of the DORNSEIFF lexicon on <http://wortschatz.uni-leipzig.de>. It contains about 9 million different words and word groups.

triangular semantic-distance matrix is computed for the DORNSEIFF groups occurring at least once. Each group name (a German noun, adjective, or verb) is looked up in GERMANET. We get a set of trees of the group name's synsets. The distance $\text{dist}(s, t)$ between group names s and t is measured by the number of steps from the leaf to the first node in the tree for s that is also found in the tree for t . If there are multiple readings in GERMANET, the maximum number of steps is taken. If two group names don't have a common hyperonym, the pair is omitted further on.

Next, a mean value for the distance of group names is calculated from the entries in the matrix. Pairs whose distance exceeds the variance are set to have ∞ distance. Finally, group names with no distance smaller than ∞ to any other group name are deleted. The group names remaining after this process are those topics in a free text description which are semantically as close as possible.

The relevance $\text{semrel}(s, t)$ of each pair (s, t) of the remaining DORNSEIFF groups is computed by:

$$\text{semrel}(s, t) = -\log \left(\frac{\text{freq}(s) \cdot \text{freq}(t)}{\text{maxfreq}^2} \cdot \frac{\text{dist}(s, t)}{\text{maxdist}} \right)$$

maxfreq is the highest frequency in the description and maxdist is the greatest distance in the distance matrix.

2.2 Valence and Arousal

For quantifying emotions, we were looking for an exhaustive list of emotions and a mapping from words to basic emotions. COWIE and his colleagues (see [3]) provide such a list of 107 emotional attitudes. We apply this list as follows: In a preprocessing step, we build a mapping for DORNSEIFF groups to \mathbb{R}^2 . For example, the attitude *adventurous* is mapped as follows: In German, *adventurous* means *abenteuerlich*. Looking up the word in the DORNSEIFF lexicon, one finds it in the groups 9.72 *Gefahr* (*danger*), 10.23 *Lächerlich* (*ridiculous*), 10.38 *Tollkühn* (*daredevil*), and 11.26 *Einbildung*, *Wahn* (*illusion*). These groups cover all connotations of the attitude *adventurous* that are expressed in German by *abenteuerlich*.

[3] assigns a position in a two-dimensional diagram to each attitude (for *adventurous* the coordinates are (4.2, 5.9)). The first coordinate expresses the attitude's *valence*, which addresses its quality (ranging from very negative over neutral to very positive). The second coordinate stands for *arousal*, which refers to the (quantitative) activation level of the feeling (ranging from very low to very high). To map words to basic emotions, each DORNSEIFF group is mapped to the position of the related attitude ((4.2, 5.9) in our example). This procedure has been applied to all 107 emotional terms in [3].

For feature extraction, the DORNSEIFF group names are mapped onto a corresponding set of emotions. For each emotion (x, y) out of this set its relevance is computed taking the frequency of its underlying DORNSEIFF group names, the semantic distance to the other groups, and their user rating into account:

$$\text{emrel}(x, y) = -\sum_{s \text{ mapped to } (x, y)} \log \left(\frac{\text{freq}(s)}{\text{maxfreq}} \cdot (1 - \text{ur}(s)) \prod_t \frac{\text{dist}(s, t)}{\text{maxdist}} \right)$$

$\text{ur}(s)$ measures the user's long-time preference of s from 0% up to 100%. Finally, for each programme description d we have two characteristic matrices: one for the content and one for the emotional attitudes of the programme description. The same procedure is applied to the user query. The distance between d and q is defined by the mean square error of the characteristic matrices. Then the pareto-optimal set that optimizes both criteria is determined and presented to the user as the set of proposals for his/her query.

3 A First Evaluation

As we want to develop a system that is considered to offer more comfort and flexibility to the users, the most important figure to evaluate is how good do proposals match the user query in the user's view.

For a first evaluation, in a public presentation of the demonstrator system people of different sex, age, education and interest could test the system as long as they wanted to. They used the NL interface by typing in queries such as those in Sect. 1.2. People tested the system for about 15 minutes and entered around five queries in the average. The system responded by presenting a list of the programmes on air at the time of the query sorted according to how well each programme matched the query. Then the users filled in a questionnaire. 60 questionnaires have been evaluated. One of the questions was: *How useful do you consider the text input-and-search function of the system?* It was answered as follows:

answer	share	answer	share
very useful	36%	useless	7%
useful	26%	very useless	1%
fair	20%	no idea	10%

These results are promising and provide motivation for further work.

4 Conclusions

Applying the DORNSEIFF lexicon appears to be a successful approach to abstract from a given text. It offers a way to generalization that does not exclusively rely on statistical methods which are the key work horse for shallow processing of unrestricted text. Instead of that, corpus linguistic experience can be incorporated into the analyses which leads to new interesting hybrid algorithms. The evaluation of the user feed back indicates that such an approach is also accepted in typical situations of using text retrieval systems.

Soft Uncoupling of Markov chains for Permeable Language Distinction: A New Algorithm

Richard Nock¹, Pascal Vaillant¹, Frank Nielsen², Claudia Henry¹

Abstract.

Without prior knowledge, distinguishing different languages may be a hard task, especially when their borders are permeable.

We develop an extension of spectral clustering — a powerful unsupervised classification toolbox — that is shown to resolve accurately the task of soft language distinction. At the heart of our approach, we replace the usual hard membership assignment of spectral clustering by a soft, probabilistic assignment, which also presents the advantage to bypass a well-known complexity bottleneck of the method.

Experiments with a readily available system display the potential of the method, which brings a visually appealing soft distinction of languages that may define altogether a whole corpus.

1 Introduction

Many corpora collected in spontaneous situations (e.g. newsgroup or chatroom archives) are not “clean”: different languages are intermingled in the texts. The different languages can be all the more tricky to distinguish as they share a common vocabulary, which tends to be the case when they are genetically close (this is so with the text corpora we are working on, which mix French and Caribbean French Creole). In this paper we tackle the problem of automatically distinguishing languages whose borders tend to be “permeable”, in their use (they are intermingled in texts) as well as in their systems (they are parent dialects with an important share of common vocabulary). No prior information is available, either about the texts in the corpus or about the languages. We use a new spectral clustering algorithm which amounts to finding a best split of the text-generating Markov chain states set. However, the method we propose does not assign every state into a unique cluster (which interprets as: it does not assign a single unique language to each word); instead, it proposes a probability distribution of each state into the different clusters. The algorithm we present is an algorithm of *soft* spectral clustering. Finally, the information is used to build overlapping language lexica; and, back to the text, to help visualize the linguistically homogeneous segments.

2 Maximum-likelihood Markov chains

In a first step, the data found in the corpus is interpreted as the result of a random walk in a Markov chain. The corpus is analysed as a sequence of n tokens of v distinct word-types in a finite vocabulary \mathcal{V} ($n \geq v$). Let $n_{i,j}$ represent the number of times a token of word i is followed by a token of word j in the corpus ($i, j \in [1, v]$), and n_i the total number of tokens of word i in the corpus. We can build a simple bigram-model Markov chain representing the maximum-likelihood model of the generation process fitting in a chain of v

¹ Université des Antilles et de la Guyane, Schoelcher, Martinique (France)

² Sony CS Labs, Tokyo, Japan

states: every transition from state i to state j is then weighted with the probability of transition from word i to word j , which is estimated to be: $n_{i,j}/n_i$. The $v \times v$ matrix with these coefficients is the bigram transition matrix of the texts of the corpus.

This first matrix generally is not symmetric, since $n_{i,j}$ does not necessarily equal $n_{j,i}$. In order to remove any assumption, even the mildest, about the language used in the corpus, we decide to consider the texts as static objects, taking no account of the writing direction: with this purpose, we define a new matrix W whose coefficients are: $w_{i,j} = (n_{i,j} + n_{j,i})/2$. The $w_{i,j}$ somehow represent a direction-independent weight function between word i and word j . A new transition matrix P is defined with coefficients $p_{i,j} = w_{i,j}/n_i$. Writing D the diagonal matrix whose $\langle i, i \rangle$ coefficients represent the number of occurrences of word i ($d_i = n_i$), we can also simply write: $P = D^{-1}W$. The matrix P so defined will be used from now on. It is the transition matrix of a Markov chain \mathfrak{M} . \mathfrak{M} is the maximum-likelihood bigram model Markov chain, not of the texts in the corpus themselves, but of their weak, direction-independent, counterparts (it is like if every text could be read equally from left to right or right to left, with a random direction at every reading step). P is a real $v \times v$ matrix, valued in $[0, 1]$. It is stochastic, since on every line $\sum_{j=1}^v d_{i,j} = d_i$. It is not necessarily symmetric, but as it is defined as the product of two symmetric matrices, it has v real eigenvalues.

\mathfrak{M} as defined above is irreducible. We can also make the assumption that it is aperiodic. This derives from a clearly mild assumption, namely that it satisfies for a vocabulary large enough, as in this case loops of arbitrary long size tend to appear between words. Irreducibility and aperiodicity imply that \mathfrak{M} is ergodic, i.e. regardless of the initial distribution, it will settle down over time to a single stationary distribution π solution of $P^\top \pi = \pi$, with $\pi_i = n_i/n$ [4].

3 From hard to soft spectral clustering

Let us now state the general problem: let $q > 1$ be some user-fixed integer that represents the number of clusters to find within the state space of chain \mathfrak{M} —i.e. the vocabulary of the corpus.

The ideal objective would be to find a mapping $Z : \mathcal{V} \rightarrow \mathbb{S}^q$, with $\mathbb{S} = \{0, 1\}$, mapping that we represent by a matrix $Z = [z_1, z_2, \dots, z_q] \in \mathbb{S}^{v \times q}$. Under appropriate constraints, the mapping should minimize a *multiway normalized cuts* (MNC) criterion [1, 2, 3, 4, 5, 6, 7]:

$$\begin{aligned} \arg \min_{Z \in \mathbb{S}^{v \times q}} \mu(Z) &= \sum_{k=1}^q \kappa_k(Z)/\alpha_k(Z) , \\ \text{s.t. } Z^\top Z &\text{ positive diagonal} \\ \text{s.t. } \text{tr}(Z^\top Z) &= v , \end{aligned} \quad (1)$$

with $\kappa_k(Z) = \sum_{i,j=1}^v w_{i,j}(z_{i,k} - z_{j,k})^2$ (“surface” of cluster k) and $\alpha_k(Z) = \sum_{i=1}^v z_{i,k}^2 d_i$ (“volume”). Since that does not change the value of $\mu(Z)$, we suppose without loss of generality that $w_{i,i} = 0, \forall 1 \leq i \leq v$. Because of the constraints on Z in (1), it induces a natural hard membership assignment on \mathcal{V} (*i.e.* a partition), as follows:

$$\mathcal{V}_k = \{v_i : z_{i,k} = 1\}, \forall 1 \leq k \leq q. \quad (2)$$

There is one appealing reason why clustering gets better as MNC in (1) is minimized. Suppose we start (at $t = 0$) a random walk with the Markov chain \mathfrak{M} , having transition matrix P , and from its stationary distribution π . Let $[\mathcal{V}_k]_t$ be the event that the Markov chain is in cluster k at time $t \geq 1$. We obtain the following result [4]:

$$\mu(Z) = 2 \sum_{k=1}^q \mathbf{Pr}([\overline{\mathcal{V}}_k]_{t+1} | [\mathcal{V}_k]_t) \quad (3)$$

for the partition defined in eq. (2). Thus, $\mu(Z)$ sums the probabilities of escaping a cluster given that the random walk is located inside the cluster: minimizing $\mu(Z)$ amounts to partitioning \mathcal{V} into “stable” components with respect to \mathfrak{M} .

Unfortunately, the minimization of MNC is NP-Hard, already when $q = 2$ [7]. To approximate this problem, the output is relaxed and the goal rewritten as seek:

$$\begin{aligned} \arg \min_{Y \in \mathbb{R}^{v \times q}} \nu(Y) &= \sum_{k=1}^q \kappa_k(Y), \\ \text{s.t. } Y^\top D Y &= I. \end{aligned} \quad (4)$$

This problem is tractable by a spectral decomposition of \mathfrak{M} (see e.g. [7]), which yields that Y is the set of the q column eigenvectors associated to the smallest eigenvalues of the generalized eigenproblem ($\forall 1 \leq k \leq q$):

$$(D - W)\mathbf{y}_k = \lambda_k D\mathbf{y}_k, \quad (5)$$

and it comes $\nu(Y) = 2 \sum_{k=1}^q \lambda_k$. If we suppose, without loss of generality, that eigenvalues are ordered, $\lambda_1 \leq \lambda_2 \leq \dots \leq \lambda_q$, then it easily comes $\lambda_1 = 0$, associated to a constant eigenvector \mathbf{y}_1 [7]. People usually discard this first eigenvector, and keep the following ones to compute Z after a heuristic thresholding of Y . The proof that this thresholding is heuristic follows from the fact that if we restrict (4) to thresholded matrices (whose rows come from a set of at most q distinct row vectors), then it becomes equivalent to (1), *i.e.* intractable [1].

Notice however that the spectral relaxation finds the *optimal* solution to (4) in time $O(qv^3)$ (without algorithmic sophistication), from which the heuristic thresholding only aims at recovering a hard membership assignment. Whenever a soft membership assignment is preferable, we show that one can be obtained directly from Y , which is optimal with respect to a criterion similar to (3), while its computation bypasses the complexity bottleneck of hard membership, thus killing two birds in one shot.

For this purpose, define matrix \tilde{Y} from Y as $\tilde{y}_{i,k} = d_i y_{i,k}^2$. Then, we have $\tilde{Y}^\top \mathbf{1} = \mathbf{1}$, *i.e.* each column vector $\tilde{\mathbf{y}}_k$ of \tilde{Y} defines a probability distribution over \mathcal{V} . Since $\tilde{\mathbf{y}}_k$ is associated to principal axis k , it seems natural to define it as the probability to draw v_i given that we are in \mathcal{V}_k , the cluster associated to the axis. Following the notations of eq. (3), we thus let:

$$\tilde{y}_{i,k} = \mathbf{Pr}([v_i]_t | [\mathcal{V}_k]_t) \quad (6)$$

be the probability to pick type v_i , given that we are in cluster k , at time t . This is our soft membership assignment: axes define clusters, and the column vectors of \tilde{Y} define the distributions associated to each cluster. Notice that this provides us with a sound extension of the hard MNC solution (2) for which $\tilde{y}_{i,k}$ equals 1 for a single cluster, and zero for the other clusters ($\forall 1 \leq i \leq v$). We also have more, as this brings a direct and non trivial generalization of (3).

Define matrix $P^{(k)}$ such that $p_{i,j}^{(k)} = (w_{i,j} y_{j,k}) / (d_i y_{i,k})$. $p_{i,j}^{(k)}$ is akin to the difference between the probabilities of reaching respectively \mathcal{V}_k and $\overline{\mathcal{V}}_k$ in j , given that the random walk is located on i ($\forall t \geq 0$): $p_{i,j}^{(k)} = \mathbf{Pr}([v_j \wedge \mathcal{V}_k]_{t+1} | [v_i]_t) - \mathbf{Pr}([v_j \wedge \overline{\mathcal{V}}_k]_{t+1} | [v_i]_t)$.

Provided we make the assumption that reaching a type outside cluster k at time $t + 1$ does not depend on the starting point at time t , an assumption similar to the memoryless property of Markov chains, we obtain our main result, whose proof relies on applications of Bayes rules.

$$\mathbf{Theorem 1} \quad \nu(Y) = 4 \sum_{k=1}^q \mathbf{Pr}([\overline{\mathcal{V}}_k]_{t+1} | [\mathcal{V}_k]_t).$$

By means of words, solving (4) brings the soft clustering whose components have *optimal* stability, and whose associated distributions are given by \tilde{Y} . As a consequence, we easily obtain that $\tilde{\mathbf{y}}_1 = \pi$, the stationary distribution. This is natural, as this is the observed distribution of types, *i.e.* the one that best explains the data.

4 Conclusion

In this paper, we have provided a novel way to interpret the results of spectral decomposition, in terms of soft clustering. This probabilistic interpretation allows to avoid the complexity gap that follows from traditional hard spectral clustering. This brings a natural approach to process a Markov chain, and make a soft clustering out of its state space. We bring an extensive comparison of hard and soft spectral clustering, along with some extended results on conventional spectral clustering.

In future works, we plan to drill down our soft spectral clustering results, to converge towards a complete probabilistic interpretation of spectral decomposition. Another target of our future research is using this method on other matrices computed from a text, like the matrix of distributional similarity (measuring “paradigmatic” syntactic distance instead of “syntagmatic” syntactic distance, cf. Introduction), with the aim of clustering syntactic and semantic categories in loosely-described languages.

Tools for Text Mining over Biomedical Literature

Fabio Rinaldi and Gerold Schneider and Kaarel Kaljurand and Michael Hess¹

Abstract.

This poster describes OntoGene: an environment, based on a deep-linguistic parser, aimed at supporting the process of Text Mining from Biomedical Scientific Literature. We will illustrate in particular the Relation Extraction component and the development support facilities.

1 Introduction

The Biomedical domain is witnessing a rapid growth of the amount of published scientific results, which makes it increasingly difficult, even for the domain experts, to rapidly identify the information that they need. PubMed is the best-known resource: it offers a keyword search over the entire collection of published articles (currently more than 14 million). Alternatively the experts can make use of ‘curated’ resources, which attempt to store in a knowledge-rich format the most significant results presented in the literature. Well-known examples are the Gene Ontology and the Kyoto Encyclopedia of Genes and Genomes. The creation of such resources is a very labour intensive process, therefore a (partial) automation of this activity is highly desirable. The first step is the identification of all biological relevant entities (genes, proteins, diseases, etc.). This task has been addressed quite extensively by the research community, as witnessed by events such as BioCreAtIVe. The task is made particularly difficult by the high ambiguity of the entity names in this domain: not only is there a high degree of polysemy and synonymy, also very common words can be used as names of entities.

As our aim is to show how a deep-linguistic approach can be used in a Text Mining application, offering high-precision relation extraction (while at the same time retaining a high recall), we have sidestepped the problem of entity extraction, either by using manually annotated resources, or by adopting external tools for entity detection. Our attention has been instead focused on the next step, which is the detection of the possible interactions among the entities mentioned in a document. Our results have been validated on the manually annotated GENIA corpus [4]. Separate experiments have been performed using automatic annotation tools [3].

Section 2 describes in detail our approach to relation mining, while section 3 briefly describes the two corpora on which we have performed our experiments and presents evaluation results. For a survey of related work, the reader is invited to consult [4].

2 Corpus Analysis and Relation Mining

The analysis of the documents is based on a broad-coverage probabilistic Dependency Parser [5]. The parser is wrapped into a pipeline which uses a number of other NLP tools, as described below. The output of the pipeline provides the basis for our relation mining and knowledge discovery approach.

¹ Institute of Computational Linguistics, IfI, University of Zurich,
{rinaldi, gschnied, kalju, hess}@ifi.unizh.ch

The pipeline performs a sequence of processing tasks, described below.²

1. Replace given terms with their heads
2. Sentence splitting by MXTERMINATOR
3. Tokenization by the Penn treebank tokenizer
4. Part-of-speech tagging by MXPOST
5. Lemmatization by morpha
6. Terminology detection by matching the token stream against existing term lists from biomedical ontologies
7. Noun and verb group chunking by LTCHUNK
8. Detection of chunk heads by a simple pattern matching over the part-of-speech tags of the tokens
9. Dependency parsing

When the pipeline finishes, each input sentence has been annotated with additional information: sentences are tokenized and their borders are detected; each sentence and each token has been assigned an ID; each token is lemmatized; tokens which belong to terms are grouped; each term has a normal-form and a semantic type; tokens and terms are then grouped into chunks; each chunk has a type (NP or VP) and a head token; each sentence is described as a syntactic dependency structure; each dependency occurs between two tokens and has a type.

The parser expresses distinctions that are especially important for a predicate-argument based deep syntactic representation, which includes PP-attachment, most long distance dependencies, relative clause anaphora, participles, gerunds, and the argument/adjunct distinction. The parser is very robust and has been applied to parsing large amounts of text data, including the 100 Million word British National Corpus.

Our approach to relation mining is based on 3 levels of rules. On the first level, we exploit simple *syntactic patterns* detected in the data. On the second level we combine various patterns into a single *semantic rule*, which does away with many possible syntactic variants (e.g. active, passive, nominalizations). On the third level, we combine semantic rules with lexical and ontological constraints to obtain very specialized queries that can detect a given domain-specific relation, as specified by the user.

Syntactic rules capture general linguistic phenomena and as such are highly reusable across different domains. Simpler rules can easily be combined into more complex rules - thus making the system more modular. An example of a syntactic rule for the passive case is shown below:³

```
synRel(simple_passive, [H,B,A],  
       [ dep(subj,H,B), dep(pobj,H,A), dep(prep,A,By),  
         pos(H,'VBN'), lemma(By,['by','through','via']) ] ).
```

The next step is then to combine different syntactic patterns to yield a *semantic rule*. For example, once we have defined a syntactic

² Some of these steps (e.g. tagging, terminology detection) are not necessary - and are automatically skipped - if the relevant information is already provided in the Corpus.

³ A prolog-based syntax is adopted.

pattern for the active case (e.g. *A regulates B*), another pattern for the passive case (*B is regulated by A*), and a pattern for the nominalized case (*The regulation of B by A*), we can define a semantic relation which combines these possible syntactic patterns into a single relation SemRel(H, A, B). Once such a relation is defined, it can be used in query, like the following:

```
applyRel(SemRel([regulate,A,B]))
```

which returns all the sentences containing a *regulate* relation, where A and B are instantiated respectively by the agent and the target of the relation, irrespective of their syntactic realization.⁴

The query mechanism has been further extended to allow the user to match semantic types of the arguments, if available in the data. For example in the GENIA corpus, there is a semantic type called G#Protein, and we can use the following query to retrieve all ‘activate’ relations where the agent is an entity belonging to this type:

```
applyRel(SemRel([activate,type:'G#Protein',B]))
```

If a domain Ontology is available, our system can make use of it in the query process, extending the interpretation of the type restriction to refer not only to the objects that directly match the given type, but also to those that are subsumed by it.

As the set of patterns and rules is gradually enriched, so are the possible lexico-syntactic variants that can be captured. An example of a more advanced rule is the one which captures “*A triggers the H of B*”, where H represent a nominalized verb (*activation, regulation, etc.*). Similar complex rules have designed, e.g. for “*under the control of*”, “*involved in*”, “*be able to*” etc. Because such rules are built on top of the lower-level rules, they automatically capture the known syntactic variants, such as “*The H of B is triggered by A*”. We refer to relations defined at this level as *domain relations* as they rely on lexical constraints which are typical of a given domain. The user query can happen at each one of the 3 levels. So it is possible to test individual syntactic rules, semantic rules, and domain rules.

3 Experiments and Evaluation

The tools described in this paper have been applied to extract semantic relations from 2 distinct corpora. GENIA [2] is a corpus of 2000 Medline abstracts which have been *manually* annotated (by domain experts) for various biological entities according to the GENIA Ontology. The ATCR Corpus (Arabidopsis Thaliana Circadian Rhythms) is a corpus of 147 Medline abstracts (up to year 2004), extracted using the keywords: “Arabidopsis Thaliana” and “Circadian Rhythms”. It has been *automatically* annotated using the “Biolab Experiment Assistant (BEA)”TM.⁵

Based on the interaction with a domain expert, we have identified a set of relations that are of particular interest in this domain. Some examples of relevant relations are: *activate, bind, block, regulate, control, express*. We have designed the extraction algorithm to maximally expand the arguments of the predicate, following all their dependencies. Each argument is then assigned a type based on its head. We then removed all records where a type had not been assigned to either agent or target. This remaining set was inspected by a domain expert. We asked the domain experts to evaluate each relation and each argument of the relation, and mark them according to its correctness and its biological significance.

⁴ We refer to the argument A as the agent, to B as the target of the relation, adopting the terminology used in [1]. The first argument (H) defines the type of the relation (e.g. “*regulate*”).

⁵ Due to lack of space only results on the former are reported here, results on the latter can be found in [3]. For further information on BEA please see <http://www.biovista.com/>.

	agent				target			
	Y	A	P	N	Y	A	P	N
activate	72	64	5	8	77	54	8	10
bind	36	18	1	8	39	18	1	5
block	3	0	0	0	1	1	0	1
TOTAL	111	82	6	16	117	73	9	16
	52%	38%	3%	7%	55%	34%	4%	7%
	correct	90%	incorrect	10%	correct	89%	incorrect	11%

Table 1. Analysis of precision

Corpus	Relation	Observed or Estimated Recall
ATCR (observed)	control regulate	60% 60%
GENIA (estimated)	control regulate	38 - 41% 50 - 65%

Table 2. Estimate of recall. Extrapolated percentages are in **boldface**

The evaluation on the GENIA corpus results in the values shown in table 1. The results show that we obtain precision of at least 50% exactly correct [Y] for both agent and target. Including the cases where only a part of the relevant information or too much information is highlighted [A] leads to a precision of about 90%. The expert browsing these results, easily and quickly corrects these over- or underexpansions, scanning the context few words to the left or right is sufficient. Unresolved pronouns [P] need a reader to deal with a substantially larger context. Our system does not yet have pronoun resolution. We have therefore decided to report these cases as incorrect.

In the absence of a gold standard, only approximative recall values can be reported. In [3] we report a value of 40% for a measure that we call “worst-case recall”, which basically implies that our actual recall is at least as good as this value. On a smaller subset of the corpus we actually measured a recall value of 60%. Using the recall obtained on the development set and the (measurable) coverage on the test set, we can estimate the value of recall on the latter. The results can be seen in table 2.

Additionally, the OntoGene Text Mining environment provides facilities for debugging and visualization. For example, each result bears the name of the rules that generated it. This allows immediate detection of problems and their quick correction. We also provide a “visual diff” facility that shows in the same graphical format the matches that have been acquired or lost as a consequence of the addition of a new pattern or rule. For further information and examples please visit <http://www.ontogene.org/>.

SUMMaR: Combining Linguistics and Statistics for Text Summarization

Manfred Stede and Heike Bieler and Stefanie Dipper and Arthit Suriyawongkul¹

Abstract. We describe a text summarization system that moves beyond standard approaches by using a hybrid approach of linguistic and statistical analysis and by employing text-sort-specific knowledge of document structure and phrases indicating importance. The system is highly modular and entirely XML-based so that different components can be combined easily.

1 INTRODUCTION

Most text summarization systems nowadays take the approach of *sentence extraction*: Following the determination of most relevant terms in the document, sentences are selected that contain such relevant terms, and the sequence of these sentences is deemed the summary. Term relevance is traditionally measured by relative frequencies in different corpora; various extensions of this basic method are being used, such as the position of sentences in documents (e.g., prefer sentences at the beginning of the document or at the end).

In contrast to generic summarization systems that emphasize robustness (produce *some* summary for *any* text), our project trades breadth against quality and argues that good summarization should be *text-sort-specific*. The idea is that the notion of ‘importance’ is relative to the sort of text; for example, in a news story, the most important information is the event stated right at the beginning, whereas for an op-ed piece, the most important information is the topic plus the opinion the author conveys. Our approach is to use a declarative representation of text-sort knowledge that supplements the standard extraction technique in creating the summary. With SUMMaR², we created a highly modular, XML-based architecture that allows for plugging in various analysis tools and combining their results flexibly. A GUI displays interim analysis results as well as the final summary, thus facilitating further fine-tuning. SUMMaR is an implemented prototype with some components still under improvement. Among the text sorts we are working with (news, commentary, scientific papers, reviews), reviews are currently most prominent; in particular, here we use *movie reviews* to illustrate our approach.

2 OVERVIEW OF SYSTEM ARCHITECTURE

For text analysis in any application, flexible module combination is an important desire. We achieve this by consistently using *standoff annotation*: For each information layer, a single XML representation is created, which points either to the tokenized source document, or to another layer (e.g., PoS layer points to source text, whereas syntax-chunk layer points to PoS layer). Details of the XML format can

be found in [Dipper 2005]. The analysis modules can then inspect layers individually or create combinations of them by merging them to a standard inline XML representation; for this purpose, we use the approach of [Witt et al. 2005].

SUMMaR processes documents in plain text, XML, and (to some extent) HTML. The first step is to map these input formats to a common XML format representing the basic layout of the text, i.e., the structure of headlines and paragraphs (see Section 3). Then, tokenization identifies sentence and token boundaries. This is input to a syntactic parser followed by co-reference analysis; these steps are taken to identify cohesion problems in the resulting text extracts, which will later be resolved by partial re-generation.

For developing the system, it has proven useful to employ a GUI that displays the source text and, on demand, the various annotations as produced by analysis modules. This could to some extent be achieved by configuring a workbench such as GATE (<http://gate.ac.uk>), but we found it more comfortable to write our own web-based GUI geared specifically to the needs of summarization, so that, e.g., the most relevant sentences of the text can be highlighted dynamically when changing relevance thresholds, etc.

We claim that for quality summarization, the system needs to know the *text sort* of the document under consideration: It makes a difference for the summarization process whether, for example, a news report or a company white paper or a review article is being handled. The key is to encode these differences in a declarative knowledge source so that the processing modules can in fact stay the same. One piece of text-sort-specific information is the *target template* for the summary: For movie reviews, it should contain the source of the review, movie title, the assigned overall rating (if any), indication of the story, and indication of more specific judgements of the reviewer. Such a task-oriented summarization is in effect a mixture of traditional information extraction (“find the title; find the overall rating”) and traditional summarization (“condense the description of the story, and the evaluative portions, if any”).

Our module for *content structure* identification employs text-sort knowledge in order to assign labels to paragraphs similar to the *zones* in [Teufel and Moens 1997]. When zones have been identified, their contents are either directly transferred to the target template (for movie reviews: title and overall rating), or they are subject to *sentence relevance* calculation, as described in Section 4.

3 DOCUMENT STRUCTURE KNOWLEDGE

The basis for our text analysis modules is an XML format that marks paragraphs, headings, and emphasized text portions (e.g. italics, bold face). It represents the logical document structure in a sense similar to a Latex source, albeit much simpler. Considerably less simple is the procedure to derive this logical structure from different types of

¹ University of Potsdam, Germany, email: stede|bieler|dipper|art@ling.uni-potsdam.de

² Project funded by Bundesministerium für Bildung und Forschung, grant 03WKH22. The authors are responsible for the content of this paper.

Figure 1. Excerpt from movie review webpage

source documents. We process different kinds of XML formats (from our partner projects), plain text, and to some extent HTML. The current implementation of our logical structure extractor is written in Python, with optional help from an XSL Transformation engine. For the case of plain text documents, the only layout information is the use of spacing, vertically and horizontally, and some creative typography like using asterisks around characters for **emphasis**. We built a set of heuristic rules that identify paragraph breaks on the basis of average line length and presence of single and double line breaks in the document; similarly, headings are identified on the basis of length, cue words (like numbering), and surrounding line breaks.

Having derived the logical structure, we enrich it with information on content zones. The inventory of zones has been determined by a corpus study. For movie reviews, it includes labels such as Title, Rating, DescStory, CommentOnStory, CommentOnActors, Credits, LegalNotice. Our corpus includes 50 reviews from 10 different sources, and so the documents differ widely, both in length and in structure. There are regularities, however: Title is at the beginning; legal notice, if any, at the end; overall rating either towards beginning or towards end; story is usually told continuously (no intervening non-story paragraphs), and so on. We have formalised the regularities not as a document grammar, but as a set of local rules, and the process of assigning each paragraph of the logical structure a content-label is one of constraint satisfaction with optimization. These steps of inferring logical and content structure are described in detail in [Stede and Suriyawongkul, to appear].

4 SUMMARY PRODUCTION

As mentioned earlier, the first items of the summary template (title and rating) are determined by simple information extraction rules from the content structure representation. For the indicative summary of the story, only those paragraphs that have received a 'Story' label are submitted to our sentence relevance calculation, which is based on computing term weights with the $tf * idf$ method, where the relation of the frequency of the term in the specific document and the number of documents in which this terms occur, plays a role. As to the notion of 'term', we are experimenting with wordforms (easy to

detect, but with inflection problem), stems as determined by a Porter-stemmer (resolves inflection problems, but overgenerates), n grams (all combinations of n adjacent characters in the text; a very robust method that can cope with spelling errors), and lemmas (for applications where a lemmatizer for the language is available). The $tf * idf$ measure counts how often a term occurs in the document (term frequency tf), and in how many documents of our corpus for the specific text sort (document frequency df). Terms with high term frequency and a low document frequency are the most indicative terms, because they reflect the specific topic (in this case, of the movie).

For a text like that of Figure 1, the method would find terms such as *East German's*, *Lenin*, *amnesia* – but it would not find terms such as *popular*, *seamlessly*, *satisfying*. The latter are typical for any opinion-conveying text and thus will be frequent in a corpus of reviews of any kind, including movies. In order to determine the reviewer's opinion (which should be reflected in a good summary), we look for sentences including such evaluative expressions (currently from a hand-collected list, but this is being replaced by a trained statistical classifier), and use these sentences as the basis for the final entry of the summary template, 'Evaluation'. This is an important difference to other approaches to sentence extraction: text-sort-specific terms (here: evaluative ones) are used to determine *important* sentences, whereas the $tf * idf$ measure is used to determine sentences that are *indicative* of the content. The list of evaluative phrases is thus part of the text-sort knowledge (albeit in this case shared between movie reviews and all kinds of other product reviews), which collectively is represented as a distinct XML document. It contains the information on necessary and possible zones for the text sort, and terms acting as indicators for zones, such as the above-mentioned evaluative terms, or a number of asterisks for the 'Rating' Zone (e.g., in Figure 1: "****1/2 (our of four)". In the end, the filled output template for the text in Figure 1 would look like this:

Source: Film Freak Central, Feb 22, 2006
Title: Good Bye, Lenin (2003)
Rating: ***1/2 (out of four)
Story: <extract from story description>
Evaluation: <extract from evaluative portions>

5 CONCLUSION

Document analysis is to a large extent a matter of statistical relevance calculations, but it should also be driven by information on document structure. We have illustrated this for the case of text summarization: Given loosely-structured documents consisting of a fairly predictable set of content zones (but not in a fixed order; otherwise it is a highly-structured document), we propose to first identify this content structure as a useful step of preprocessing. For summarization, this helps to make sure that portions of all relevant zones are actually part of the result.

Phonetic Spelling and Heuristic Search

Benno Stein¹ and Daniel Curatolo²

Abstract. We introduce a new approach to spellchecking for languages with extreme phonetic irregularities. The spelling for such languages can be significantly improved if knowledge about pronunciation and sound becomes the central part of the spelling algorithm. However, given a weak phoneme-grapheme-correspondence the standard spelling algorithms, which are rule-based or edit-distance-based, are severely limited in their phonetic capabilities.

A production approach to spelling can overcome the limitations—but suffers from its search space size. We describe in this paper the main building blocks to tackle this problem with heuristic search. Our ideas have been operationalized in the SMARTSPELL algorithm, with impressive results related to spelling correction and runtime.

1 INTRODUCTION AND PROBLEM SETTING

Orthography is the study or practice of correct spelling or writing; spelling is the choice of which letters or symbols to combine to represent a word. A (single word) spelling algorithm takes a dictionary D and a possibly misspelled word w as input and returns the most similar words w_1, \dots, w_k from D with respect to w . The “quality” or “power” of a spelling algorithm depends on the operationalized similarity measure, implicating an inevitable tradeoff between runtime performance and spelling quality.

The difficulty of a spelling problem depends on both the type of the spelling error to be detected and the underlying language. Table 1 illustrates common types of spelling errors with respect to the single word spelling problem.

Spelling error type	Example
Permutations or dropped letters	hpantom → phantom
Misremembering spelling details	recieve → receive, remembering believe
Trying to spell out pronunciation	tuleboks → toolbox

Table 1. A hierarchy of spelling errors with increasing problem complexity.

A language’s key impact to spelling is governed by its *phonemicity*, which describes the extent to which spelling is a guide to pronunciation: A word is called phonemic if its spelling corresponds to its pronunciation. However, Trost pointed out that written language is rarely a true phonemic description [10]. Table 2, taken from an IEA survey [3], arranges languages with respect to their degree of phonemicity.

One of the many examples for the high irregularity of the English language is the word “school” where among others the following writings produce the same sound: skool, scool, scule, skule. The sources of irregularity are positional spelling, i. e., the sound of letters varies according to the position in a word, and polyvalence, i. e., letters can produce different sounds.

Highly regular <		Spelling system	-> Irregular	
Finnish	Spanish, Portuguese, Italian, Hungarian, Slovenian	German, Dutch, Greek Swedish, Norwegian, Icelandic	Danish, French	English

Table 2. Languages ordered with respect to their degree of phonemicity [3].

Considering the sound of a written word within a spelling process is by far more complex than simply computing edit distances, since extra combinatorics is introduced at two places: (i) Which letters form a group that produces a single sound? (ii) Which sound is produced? This paper shows how heuristic search can be used to significantly speed up the similarity analysis in the huge search space. The operationalization of the presented ideas led to an efficient algorithm, SMARTSPELL, which is used in real-world applications.

The paper is organized as follows. The remainder of this section classifies possible solutions to the spelling problem, and Section 2 outlines the main ideas of the heuristic search behind SMARTSPELL.

1.1 Handling Misspelling

To classify existing work on spelling correction for single words we developed the taxonomy shown in Figure 1.

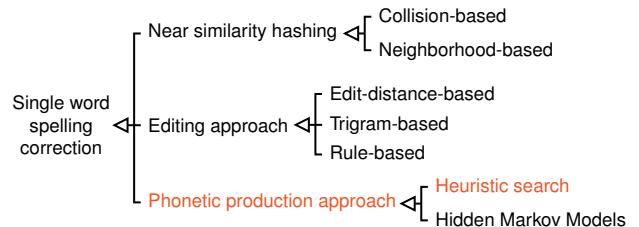

Figure 1. Classification of spelling correction methods.

At its top-level the taxonomy distinguishes three main approaches: (i) approaches that rely on the computation of hash keys for the words in D , (ii) editing approaches, which transform a word $w \notin D$ into a word from D , and (iii) phonetic production approaches, which construct a letter sequence that produces the observed sound.

The hashing approaches further subdivide into methods that exploit hash collisions (e. g. Soundex [6]) or evaluate neighborhoods in the list of the sorted hash keys (cf. SpeedCop [9] or [7]). Today, many approaches to handle misspelling are based on edit distances: The candidates for the correct spelling of some word w minimize the number of editing operations that transform w into some word of a dictionary D . The Levenshtein distance is a well-known measure to operationalize this idea; it associates each substitution, deletion, or insertion of a letter with certain cost [4]. This idea can be applied to trigrams [1] or become refined by phonetic transformation rules (cf. Aspell [2] or Correct [5]).

2 PHONETIC SPELLING VIA SEARCH

We understand phonetic spelling as the generation of the most probable letter sequence with respect to phonological interpretation. Such a production approach may be realized with Hidden Markov Models or with heuristic search [8]; it is much more ambitious than an editing approach with respect to the explored search space. Note in this connection that editing approaches are too limited to be used as a guide to phonetic similarity. Examples:

- The Levenshtein distance between the words “eaecutioib / execution” and “aksekjushen / execution” is 2 and 8 respectively. Observe that the phonetic similarity in the second case is significantly higher than in the first case.
- The phonetically motivated edit rule “k → c” works fine to correct the misspelling “kat / cat”, but it fails in the case “cule / cool”.

The following three concepts—here applied to phonetic spelling—together form the elements of heuristic search:

1. *Search Space*. Defines all segmentations of all words in the dictionary D , along with operators to move between them.
2. *Evaluation Function ϕ* . Quantifies the quality of a segmentation of an unknown word with respect to the entire search space.
3. *Control Strategy*. Guides the exploration of the search space.

Search Space Since a hyphenation-based segmentation may not be optimum with respect to phonetics, the search space of SMARTSPEL contains for each word $w \in D$ the set Π_w of all possible segmentations, where each segment $s \in \pi_w$ in a segmentation $\pi_w \in \Pi_w$ is either a letter, 2-, 3-, or 4-gram. Hence, possible segmentations π_w for $w = “execution”$ are:

e - x - e - c - u - t - i - o - n, ex - e - cut - i - on, e - x - ecu - tio - n

Altogether, “execution” has $|\Pi_w| = 773$ segmentations; a word of length n has $\sum_{i=1}^n \text{seg}(n-i)$ segmentations, with $\text{seg}(0) = 1$.

Evaluation Function ϕ $\phi(v, w, \pi_v, \pi_w)$ computes the similarity between two words, v, w , provided two segmentations, π_v, π_w ; it is based on the phonetic a-priori similarity, $\varphi(s_i, s_j)$, for two segments s_i, s_j . φ is language-dependent and defines about 2500 segment similarities for the English language, among others:

$$\begin{array}{llllll} s_i & s_j & \varphi(s_i, s_j) & ac & ec & .95 \\ & & & ac & ec & .80 \\ & & & ac & eck & .85 \end{array} \quad \begin{array}{llllll} ad & ed & .95 & af & ef & .95 \\ ad & edd & .90 & af & eff & .90 \\ ad & eg & .57 & af & es & .38 \end{array}$$

For the 24 essential sounds of RP English (received pronunciation) we developed a new concept to construct the function φ automatically: Based on so-called sound contexts, which are activated by the different consonant types like plosives, nasals, etc., raw estimates for the similarities are computed and statistically smoothed.

Let $\pi_v = s_{v,1} \dots s_{v,|\pi_v|}$ and $\pi_w = s_{w,1} \dots s_{w,|\pi_w|}$, then ϕ is defined as follows:

$$\phi(v, w, \pi_v, \pi_w) = \frac{\sum_{i=1}^{\min\{|\pi_v|, |\pi_w|\}} (|s_{v,i}| + |s_{w,i}|) \cdot \varphi(s_{v,i}, s_{w,i})}{|v| + |w|}$$

For example, the computation of ϕ for the two pairs of segmentations e-x-e-c-u-ti-o-n / a-ks-e-k-ju-sh-o-n and e-x-_e-c-u-ti-o-n / a-k-s-e-k-ju-sh-o-n yields the following values:

$$\begin{array}{llll} \varphi(s_i, s_j) & & & \\ e & a & .70 \cdot 2 & = 1.40 \\ x & ks & .80 \cdot 3 & = 2.40 \\ e & e & 1.00 \cdot 2 & = 2.00 \\ c & k & .95 \cdot 2 & = 1.90 \\ u & ju & .75 \cdot 3 & = 2.24 \\ ti & sh & .90 \cdot 4 & = 3.60 \\ o & o & 1.00 \cdot 2 & = 2.00 \\ n & n & 1.00 \cdot 2 & = 2.00 \end{array} \quad \begin{array}{llll} e & a & .70 \cdot 2 & = 1.40 \\ x & k & .30 \cdot 2 & = .60 \\ s & & 0 \cdot 2 & = 0 \\ e & e & 1.00 \cdot 2 & = 2.00 \\ c & k & .95 \cdot 2 & = 1.90 \\ u & ju & .75 \cdot 3 & = 2.24 \\ ti & sh & .90 \cdot 4 & = 3.60 \\ o & o & 1.00 \cdot 2 & = 2.00 \\ n & n & 1.00 \cdot 2 & = 3.00 \end{array}$$

$$\phi = 8.77/(9+11) \Rightarrow 88\% \quad \phi = 7.87/(9+11) \Rightarrow 79\%$$

From all segmentations, Π_v, Π_w , for two words, v, w , one is interested in those that maximize ϕ ; they are implicitly defined by ϕ^* :

$$\phi^*(v, w) = \max_{\pi_v \in \Pi_v, \pi_w \in \Pi_w} \phi(v, w, \pi_v, \pi_w)$$

ϕ fulfills the standard properties of a similarity measure; i.e., it is normalized, reflexive, and symmetric. In addition, it has a monotonic characteristic in word lengths: $|v| < |u| \Rightarrow \phi(w, uv) > \phi(w, uw)$

Control Strategy Checking the spelling of a word w regarding its phonetics means to identify a word $v \in D$ such that two segmentations $\pi_v \in \Pi_v$ and $\pi_w \in \Pi_w$ can be found that maximize ϕ . A typical value for $|D|$ is 10^6 , a typical value for $|\Pi_w|, w \in D$, is $> 10^2$. Hence, the size of the search space for an ordinary spelling query is in $O(10^{10})$. To achieve an acceptable response time SMARTSPEL operationalizes a sophisticated control strategy that combines the following elements:

- Segmentation Heuristic. Segmentations are constructed stepwise, striving for a minimum length difference of the residual strings.
- Early Pruning. Exploitation of the monotonicity of ϕ for pruning.
- Iterative Deepening. Candidates for a Depth-First Search are chosen from a pool whose pruning threshold is successively lowered.
- Nogood Construction. Segments that are unlikely to match are stored in a special nogood table for φ .
- Memorization. Strings with high ϕ -values are remembered.

Results Following examples illustrate the power of the phonetic production approach and the SMARTSPEL algorithm:

angenehing	→	engineering 92%
buysikel	→	physical 85%, bicycle 82%
dshungal	→	jungle 90%
hachock	→	hedgehog 95%
jentelman	→	gentleman 85%
kompilayshon	→	compilation 89%
refridjeraitar	→	refrigerator 79%
siantifik	→	scientific 87%
tradisionell	→	traditional 93%
tshylt	→	child 97%
tulebogs	→	toolbox 93%

The function φ was constructed for English, German, and Spanish; moreover, SMARTSPEL has proven its usability in several real-word applications. On request we will provide Web-based access.

CBR-TM: A new Case-Based Reasoning System for Help-Desk Environments

Juan Ángel García-Pardo¹ and Stella Heras Barberá¹ and Rafael Ramos-Garijo¹
 and Alberto Palomares² and Vicente Julián¹ and Miguel Rebollo¹ and Vicent Botti¹

Abstract. In this paper, a new CBR system for help-desk environments is presented. This CBR system provides intelligent customer support for multiple domains. It is also portable and flexible. The system is implemented as a module of a complete help-desk application to make it as independent as possible of any change in the help-desk system. Each phase of the reasoning cycle is also separated as an independent module, making the CBR system easy to update. The system has been tested in a real call center managed by the Spanish company TISSAT S.A.

1 Introduction

Customer support has become a profitable business. A quick and accurate response to customer problems ensures their satisfaction and a good reputation for the company. Companies usually attend to customers via a call center, where a number of operators manage the queries using a help-desk application. To provide high-quality customer support the operators must be trained. Moreover, the knowledge of experienced operators should be saved in order to maintain it over the course of time or if the operators leave the company. Reusing successful past solutions may be a suitable method to improve the performance of a customer support system.

A Case-Based Reasoning system (CBR) tries to solve a new problem (case) by means of reusing the solution of a past similar case. This solution is previously stored in a case memory (case-base) and can either be retrieved and directly applied to the current problem, or revised and adapted to fit the problem. The successful application of CBR systems in help-desks for managing call centers has proved the suitability of these systems since the 90s [2][5]. There are also many companies that sell software for applying CBR to help-desks. We were asked to implement a new CBR system as generic as possible to provide intelligent customer support to a help-desk environment without using any copyrighted software or any CBR tool that is only available for research purposes. Even though it has been tested in a specific help-desk that provides technical support for computer systems, one of our main objectives was to develop a modular CBR system which can be easily adapted and applied to any domain related to customer support.

² TISSAT S.A. <http://www.tissat.es>

2 The CBR-TM module

The Spanish company TISSAT S.A [3] provides customer support for public administration organisms and private companies. In order to improve the service, TISSAT has developed a help-desk toolkit called I2TM (Intelligent and Integrated Ticketing Manager, version 6). Each request received by TISSAT is called *ticket* and is tracked by means of the I2TM application. This application works with either queries related to computer errors (network systems failures and personal computer problems) or with requests of citizens about public services (such as the international emergency phone number 112 of the Valencia region, which covers the emergencies of over four and a half million people). Therefore, I2TM must be able to rapidly solve requests from very diverse domains.

The CBR system that we have developed, called CBR-TM (Case Based Reasoning for Ticketing Management) acts as an intelligent module for the I2TM system, helping it with the problem-solving process. Implementing CBR-TM as a module allows both systems to be changed and updated independently. We have integrated CBR-TM into I2TM using web-services. This approach was chosen because of its flexibility and distributed access possibilities. The webservices work as a bridge between I2TM and CBR-TM. The overview of the entire system architecture is shown in Figure 1.

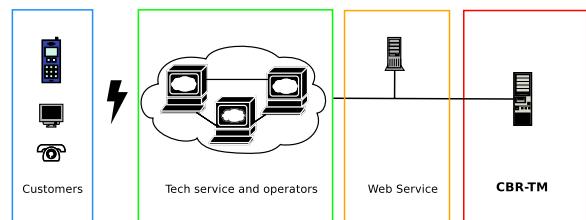

Figure 1. I2TMv6 architecture overview

The CBR methodology for problem solving is typically divided into the phases of the CBR cycle [1]: *Retrieve*, *Reuse*, *Revise* and *Retain*. The design decisions adopted for each phase in CBR-TM were principally influenced by the customer support domain and our goal to provide flexibility. In CBR-TM, a case is the prototyped representation of a set of tickets with the same features and the same successfully applied solutions. Each case has a set of attribute-value pairs (variables of any value type) that describe the characteristics

of the problem. The indexing schema hierarchically organises the cases in the computer memory to facilitate the retrieval. The indexing process in our system consists of establishing a set of categories for each ticket that classifies it as belonging to a certain type of problem, which is currently being done manually. These categories are also stored in each case as attributes.

The main goal of the retrieval phase is to obtain the set of stored cases that are similar to the new one. Due to the multiple domains of the requests that the I2TM system receives, the CBR-TM module must be able to work with heterogeneous tickets and must also be able to compute the similarity among them. Moreover, the ticket attributes may have missing values. It would be desirable to have a modular system into which we could insert different types of retrieval algorithms, without the inconvenience of having to redesign the entire system if a new representation space is considered. Thus, we have adapted and tested several known distance measures to work with heterogeneous data. The most similar case or cases are selected by means of a *k-nearest neighbour* algorithm using these distance measures to compute the similarity among cases. Currently, we have implemented two Euclidean-based similarity measures (*Normalized* and *Classic*) and a similarity measure based on the ratio model proposed by *Tversky* [4].

Once the most similar case is selected, its solution is proposed to solve the new problem that has been reported to the system, in a simple reuse phase. At this time, the solution is copied and applied to the new problem without any changes, but it is also configurable and, if necessary, any adaption process can be introduced. When a solution has been provided, the customer must indicate to the system whether that solution has really solved the problem. By means of this revision phase, the system can learn the degree of suitability of the responses that CBR-TM provides. Finally, if there is not a case that is similar enough to the new ticket, the system stores this ticket and its solution in the case-base during the retention phase.

3 Discussion

In order to evaluate the CBR-TM module, we used a synthetic database of tickets that came from computer errors. Note that a ticket of this database is not equivalent to a case, since a case is the prototyped representation of a set of tickets with the same features and the same solution that has been applied satisfactorily in the past.

We used the ticket database to test the CBR-TM performance. This performance may be influenced by the number of tickets processed by the system or the number of customers sending requests simultaneously. The tests were performed using a *cross-partition* technique separating the ticket database into two databases for training (loading the case-base) and testing the system. We repeated the tests for each similarity measure implemented in order to analyse its behaviour in the computer error domain.

The top graph of Figure 2 shows that as the number of tickets in the case-base of the CBR-TM system increases, the mean error in the answers provided by the system decreases. This fact demonstrates that the system knowledge goes up as the amount of processed data increases and, thus, CBR-TM is learning effectively. The bottom graph of Figure 2 shows the

response time when the number of customers making simultaneous requests increases. As expected, this time increases in proportion to the number of simultaneous customers. In addition, this test shows that CBR-TM is able to answer the requests quickly even when there are a considerable number of simultaneous requests. The results of the tests also show that all the similarity measures behave in a very similar way and any of them might be suitable for this domain.

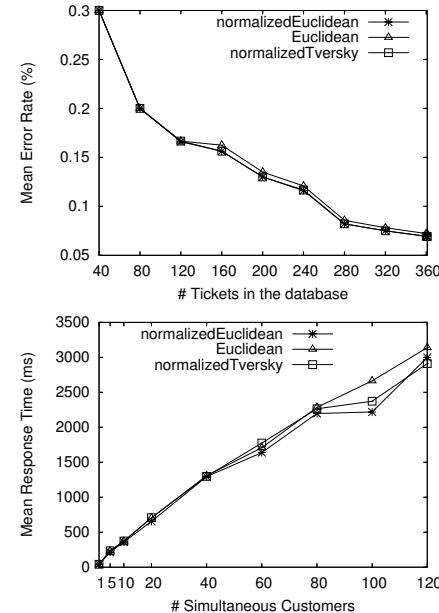

Figure 2. Top: Influence of the database size on the CBR-TM system performance; Bottom: Influence of the number of simultaneous customers on the CBR-TM system performance

Although the CBR-TM system has been tested in a help-desk whose purpose is to solve computer errors, TISSAT plans to use it in different domains in the near future. Moreover, since this system has been recently implemented, more intensive research to improve the algorithms and the techniques applied will be performed. One of our main interests is to change the manual categorisation for an automatic one. This would prevent CBR-TM from making mistakes due to human error.

ACKNOWLEDGEMENTS This project was supported by the Spanish Government under grant PROFIT FIT-34001-2004.

Verification of Medical Guidelines using Task Execution with Background Knowledge

Arjen Hommersom and Perry Groot and Peter Lucas¹
Michael Balser and Jonathan Schmitt²

Abstract. The use of a medical guideline can be seen as the execution of computational tasks, sequentially or in parallel, in the face of patient data. It has been shown that many of such guidelines can be represented as a ‘network of tasks’, i.e., as a number of steps that have a specific function or goal. To investigate the quality of such guidelines we propose a formalization of criteria for good practice medicine a guideline should comply to. We use this theory in conjunction with medical background knowledge to verify the quality of a guideline dealing with diabetes mellitus type 2 using the interactive theorem prover KIV. Verification using task execution and background knowledge is a novel approach to quality checking of medical guidelines.

1 INTRODUCTION

The trend of the last decades has been to base clinical decision making more and more on sound scientific evidence, i.e., *evidence-based medicine*, which has led medical specialists to develop medical guidelines, i.e., structured documents providing detailed steps to be taken by health-care professionals in managing the disease in a patient, for promoting standards of medical care. For their employment, computer-oriented languages are being developed. Examples are PROforma [2] and Asbru [6], which model complex clinical processes as a ‘network of tasks’, i.e., a number of steps that have a specific function or goal [2]. However, guidelines should not be considered *static* objects as new scientific knowledge becomes known on a continuous basis. Rapidly changing evidence makes it difficult to adjust guidelines in such a way as to keep them up to date.

In this article, we approach this problem by applying formal methods to quality checking of medical guidelines. Here, we are mainly concerned with the meta-level approach [4] which we use to formalize general quality criteria of good practice medicine a guideline should comply to. A solid foundation can already be found in literature. In [2, 5] logical methods have been used to analyze properties of guidelines. In [4], it was shown that the theory of abductive diagnosis can be taken as a foundation for the formalization of quality requirements of a medical guideline in temporal logic. This result has been used in verifying quality requirements of good practice medicine of alternative treatments [3].

The contribution of this paper is twofold. First, we formalize quality requirements of medical guidelines which include, besides treatments, also the temporal relations between treatments. Second, us-

ing our quality requirements and medical background knowledge, we interactively verify a guideline dealing with the management of diabetes mellitus type 2. More specifically, we model the guideline as a ‘network of tasks’ using the language Asbru and, additionally, verify meta-level properties for this model in KIV, an interactive theorem prover. To the best of our knowledge, verification of a fully formalized guideline, as a network of tasks, using medical background knowledge has not been done before.

2 FORMALIZATION OF GUIDELINES

An example of a fragment of a guideline is shown in Figure 1, which is part of the guideline for general practitioners about the treatment of diabetes mellitus type 2, and is used as a running example in this paper. The guideline gives recommended interventions to be used for the control of the glucose level.

-
- Step 1: diet.
 - Step 2: if queetelet index (QI) ≤ 27 , prescribe a sulfonylurea drug; otherwise, prescribe a biguanide drug.
 - Step 3: combine a sulfonylurea drug and biguanide (replace one of these by a α -glucosidase inhibitor if side-effects occur).
 - Step 4: one of the following:
 - oral antidiabetic and insulin
 - only insulin
-

Figure 1. Guideline fragment on diabetes mellitus type 2 management. If one of the steps k is ineffective, the management moves to step $k + 1$.

It has been shown previously that the step-wise, possibly iterative, execution of a guideline can be described precisely by means of temporal logic [5]. In this paper we will use the variant of this logic supported by KIV [1], which is based on linear temporal logic, where time points are linearly ordered. For the verification of medical guidelines we assume at least three types of knowledge involved: medical background knowledge, order information from the guideline, and quality requirements.

Background knowledge: In diabetes mellitus type 2 various metabolic control mechanisms are deranged and many different organ systems may be affected. Glucose level control, however, is the most important mechanism. At some stage in the natural history of diabetes mellitus type 2, the level of glucose in the blood is too high (hyperglycaemia) due to decreased production of insulin by the B

¹ Institute for Computing and Information Sciences, University of Nijmegen, Netherlands, email: {arjehn, perry, peterl}@cs.ru.nl

² Institut für Informatik, Universität Augsburg, Germany, email: {balser, jonathan.schmitt}@informatik.uni-augsburg.de

cells. Oral anti-diabetics either stimulate the B cells in producing more insulin (sulfonylurea) or inhibit the release of glucose from the liver (biguanide). Effectiveness of these oral diabetics is dependent on the condition of the B cells. Furthermore, as a causal treatment, insulin can be prescribed. The mechanisms have been formalized in terms of a first-order predicate knowledge:

$$\text{knowledge} : \text{patient} \times \text{patient}$$

This predicate has been axiomatized with knowledge concerning the mechanism described above. For example

$$\begin{aligned} \text{knowledge}(\text{pre}, \text{post}) \rightarrow \\ (\text{insulin} \in \text{pre}[\text{'treatment'}] \rightarrow \\ \text{post}[\text{'uptake(liver,glucose)'}] = \text{up} \wedge \\ \text{post}[\text{'uptake(peripheral-tissue,glucose)'}] = \text{up}) \end{aligned}$$

denotes the physiological effects of insulin treatment. In this way, the predicate **knowledge** can be used to reason about the state transitions that occur during verification with temporal logic.

Medical guidelines in Asbru: The guideline fragment (Figure 1) was modelled in Asbru, as shown in Figure 2. This model consists of seven plans, which are ordered in a hierarchy. The top level plan **Treatments_and_Control** sequentially executes the four subplans **Diet**, **SU.or.BG**, **SU_and.BG**, and **Insulin.Treatments**. The latter is further refined by the two subplans **Insulin_and_Antidiabetics** and **Insulin**, which can be executed in any order.

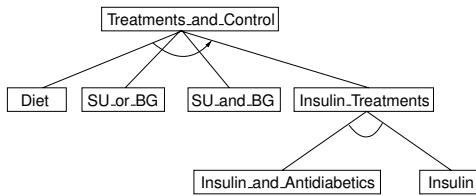

Figure 2. Asbru plan hierarchy of the diabetes mellitus type 2 guideline

Quality requirements: Here, we extend the formalization of good practice medicine of treatment choice [4, 3] to medical guidelines. Let \mathcal{B} be medical background knowledge, T be a treatment, P be a patient group, N be a collection of intentions, which the physician has to achieve, and M be a medical guideline. Then M is called a *proper* guideline according to the theory of abductive reasoning, i.e., $M \in \text{Pr}_P$, if:

- (M1) $\mathcal{B} \cup M \cup P \not\models \perp$ (the guideline does not have contradictory effects), and
- (M2) $\mathcal{B} \cup M \cup P \models \diamond N$ (the guideline eventually handles all the patient problems intended to be managed)

Furthermore, let \prec_φ be a partial order denoting a preference relation with $T \prec_\varphi T'$ meaning that T' is *more preferred* to T given criterion φ . If, in addition to (M1) and (M2), (M3) holds, with

- (M3) $O_\varphi(M)$ holds, where O_φ is a meta-predicate standing for an optimality criterion or combination of optimality criteria φ defined as: $O_\varphi(M) \equiv \forall M' \in \text{Pr}_P : \neg(M \prec_\varphi M')$,

then the guideline is said to be *in accordance with good-practice medicine*, denoted as $\text{Good}_\varphi(M, P)$.

3 VERIFICATION USING KIV

Using the interactive verification tool KIV, we have verified the quality requirements discussed above, written as a sequent with the initial state of a patient group, the initial state of the guideline, the medical guideline, effects of treatment plans, the background knowledge, and environment assumptions as assumptions. For example, we verified that the order of any two treatments in the guideline was consistent with the preference order \leq , which minimizes drugs and number of insulin injections:

$$\begin{aligned} \square \forall T (\text{Tick} \wedge T = \text{Patient}[\text{'treatment'}] \rightarrow \\ \rightarrow \square (\text{last} \vee (T \rightarrow \neg(T \leq \text{Patient}[\text{'treatment'}])))) \end{aligned}$$

Verification of such quality requirements could be done with a high degree of automation of upto 90%.

4 CONCLUSIONS

In our study we have setup a general framework for the verification of medical guidelines, consisting of a medical guideline, medical background knowledge, and quality requirements. We developed a model for the background knowledge of glucose level control in diabetes mellitus type 2 patients and a theory for quality requirements of good practice medicine based on the theory of abductive diagnosis. This model of background knowledge and theory of quality requirements were then used in a case study in which we verified several quality criteria of the diabetes mellitus type 2 guideline used by the Dutch general practitioners. In the case study we use Asbru to model the guideline as a network of tasks and KIV for the formal verification.

In the course of our study we have shown that the general framework that we have setup for the formal verification of medical guidelines with medical background knowledge is feasible and that the verification of quality criteria can be done with a high degree of automation. We believe both the inclusion of medical background knowledge and semi-automatic verification of the quality of decisions advised by the medical guideline are necessary elements for adequately supporting the development and management of medical guidelines.

The Incompleteness of Planning with Volatile External Information

Tsz-Chiu Au and Dana Nau¹

Abstract. In many real-world planning environments, some of the information about the world is both external (the planner must request it from external information sources) and volatile (it changes before the planning process completes). In such environments, a planner faces two challenges: how to generate plans despite changes in the external information during planning, and how to guarantee that a plan returned by the planner will remain valid for some period of time after the planning ends. Previous works on planning with volatile information have addressed the first challenge, but not the second one.

This paper provides a general model for planning with volatile external information in which the planner offers a guarantee of how long the solution will remain valid after it is returned, and an *incompleteness theorem* showing that there is no planner that can succeed in solving *all* solvable planning problems in which there is volatile external information.

1 INTRODUCTION

In many real-world planning environments, the planner must request information from external information sources (databases, CAD systems, web services, and the like), incurring a lag time for receiving the answers. In practical planning situations, the planning activity may take more time than is needed to execute the resulting plan [6, 8, 9]. In such cases, some of the information on which the plan depends will change while the planning process is going on. For instance:

- [8] describes a domain-specific system that uses AI planning to do web service composition. Information from web services can change before planning finishes, and the system modifies its plans in response to such changes.
- At our university, the web site for booking concert-hall tickets displays a countdown timer showing how much longer the system will hold the seats that the user has booked. If the countdown ever reaches 0 (e.g., if user spends too much time examining the rest of the concert schedule), the booking will expire and the user will have to select seats all over again.
- When a traveler tries to construct a travel plan, the information about an airline flight may expire while the traveler was trying to plan some other details of the trip.

In such environments, how to cope with changes of external information and at the same time generate a plan that can be executed correctly is a big challenge. Most existing planners will not do this correctly unless they are modified.

In some cases, the interleaving of planning and execution [3, 7] is a good strategy to deal with volatile information.

But if the wrong choice of action can cause a failure that is irrecoverable (or recoverable only at a large cost), then it is necessary to reason, while the plan is being generated, about whether the assumptions that are being used to choose an action will still be true when the action is executed.

In [1] we described *query management strategies* that can adapt existing planners to deal with volatile external information by backtracking the planner to the first point in the planning process that makes use of outdated information, obtaining the up-to-date information, and resuming the execution from that point. A primary limitation of that work was that it provided no guarantee of completeness, i.e., no guarantee that a planner using such a query management strategy could succeed in every solvable planning environment.

In this paper, we provide an *impossibility theorem* showing that it is *impossible* to have a planner that can successfully find a valid solution in every solvable environment. This resembles the famous impossibility theorems in distributed systems (<http://www.podc.org/influential/2001.html>), which says that some problems in distributed systems are fundamentally unsolvable [2]. Remedy this problem is far from trivial, because it requires a modification to the fundamental assumptions of the distributed system model people have been used. Many of those solutions are not ideal, but they are needed in order to able to solve certain problems.

2 INCOMPLETENESS IN VEI-PLANNING

Let L be a planning language such as PDDL [5]. We construct a new language \hat{L} that contains all the symbols of L plus some additional symbols called *unknowns* as follows: given a set \hat{U} of unknowns, and a set $dom(u_i)$ of terms (called the *values* of u_i) in L for each unknown u_i , \hat{L} is a set of expressions produced by taking any expression e in L and replacing zero or more terms in e with corresponding unknowns.

For each unknown u , there is a piecewise-constant function $\mathbb{V}_u : \mathbb{R} \rightarrow dom(u)$, such that u 's value at time t is $\mathbb{V}_u(t)$. To learn about the value of u , a planner $\tilde{\mathcal{A}}$ must issue *queries* to an *information source* I_u : if $\tilde{\mathcal{A}}$ sends a query q for an unknown u to I_u , I_u will return a value $v(q) = \mathbb{V}_u(t')$ for q at time $t' = t_{return}(q)$. If $\tilde{\mathcal{A}}$ knows nothing about how long $v(q)$ will remain true, it cannot provide any sort of guarantee about the correctness of the plan it generates: the information may change during plan execution, invalidating the plan. Thus, we assume that I_u 's answer $ans(q)$ will include both $v(q)$ and an *expiration time* $t_{expire}(q)$. $v(q)$ is guaranteed to be valid until $t_{expire}(q)$, after which time it may change (see Fig. 1).

A *VEI-problem* \hat{P} (“*VEI*” stands for “volatile external information”) is a triple $\langle \hat{P}, T, \mathbb{E} \rangle$, where \hat{P} is a planning problem written in \hat{L} , T is a non-negative real number called a

¹ University of Maryland, College Park, U.S.A., email: {chiu,nau}@cs.umd.edu

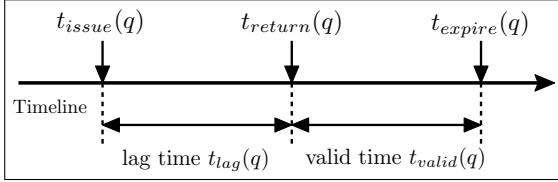

Figure 1. The lag time and the valid time of a query q . $v(q)$ is guaranteed valid only between $t_{return}(q)$ and $t_{expire}(q)$. After $t_{expire}(q)$, the value may possibly change.

validity guarantee, and \mathbb{E} is a (finite or infinite) set of VEI-environments, each of which is a pair $\langle \mathcal{E}_{lag}, \mathcal{E}_{ans} \rangle$, where $\mathcal{E}_{lag} : \hat{U} \times \mathbb{R} \rightarrow \mathbb{R}$ and $\mathcal{E}_{ans} : \hat{U} \times \mathbb{R} \rightarrow \hat{V} \times \mathbb{R}$ are functions giving the lag time and the answer to a query q for u issued at time t , respectively. We assume that a planner $\tilde{\mathcal{A}}$ resides in one of the VEI-environments in \mathbb{E} during its execution, but $\tilde{\mathcal{A}}$ has no prior knowledge about which one it is.

A value v of u is *confirmed* at time t if and only if $\tilde{\mathcal{A}}$ has issued a query q for u and has received an answer $ans(q) = (v, t_{expire}(q))$ such that $t_{return}(q) \leq t < t_{expire}(q)$. v is *T-confirmed* at time t if and only if v is confirmed at time t' for all $t \leq t' < t + T$. A solution π is *T-confirmed* at time t if all the values used by $\tilde{\mathcal{A}}$ for constructing π are *T-confirmed* at time t . A planner $\tilde{\mathcal{A}}$ *succeeds* in a VEI-problem $\langle \hat{P}, T, \mathbb{E} \rangle$ if and only if no matter which VEI-environment (among \mathbb{E}) $\tilde{\mathcal{A}}$ resides in, $\tilde{\mathcal{A}}$ returns a *T-confirmed* solution when $\tilde{\mathcal{A}}$ terminates. A VEI-problem \hat{P} is *solvable* if and only if there exists a planner that succeeds in \hat{P} . A planner $\tilde{\mathcal{A}}$ is *complete* if and only if $\tilde{\mathcal{A}}$ succeeds in *all* solvable VEI-problems.²

Theorem 1 states the necessary condition under which there exists a successful planner for a VEI-problem.

Theorem 1 A VEI-problem $\langle \hat{P}, T, \mathbb{E} \rangle$ is solvable only if for all $\mathcal{E} = \langle \mathcal{E}_{lag}, \mathcal{E}_{ans} \rangle \in \mathbb{E}$, (1) There exists a solution π for some instantiation of \hat{P} with values v_1, v_2, \dots, v_m for unknowns u_1, u_2, \dots, u_m , respectively; and (2) there exist times t_1, t_2, \dots, t_m such that the length of the time interval $\bigcap_{1 \leq j \leq m} [t_j + \mathcal{E}_{lag}(u_j, t_j), t_j + \mathcal{E}_{lag}(u_j, t_j) + t_{expire}^j] \geq T$, where where $\mathcal{E}_{ans}(u_j, t_j) = (v_j, t_{expire}^j)$.

For the above condition to be sufficient for solvability, the planner would need to be able to know instantaneously whenever a value expires. But that would require a communication channel with an infinite bandwidth and information sources with infinite amount of computational power—an impossible requirement. In practice, there is usually an unavoidable delay between two consecutive queries. For example, a database can only process one query at a time, and there is a delay between the processing of two consecutive queries. Therefore, it is realistic to make the following assumption:

Assumption 1 (Limited Accessibility) For each query q for an unknown u issued at time t , there is a period of time after t such that the planner cannot issue a query for u in the time period $[t, t + t']$, where t' is the length of the period.

Using this assumption, we can find two VEI-environments such that no planner can succeed in them at the same time.

² Our definition of completeness is the usual one for search algorithms [10, p. 71] and planning algorithms [4, p. 544]: an algorithm is complete if it finds a solution whenever a solution exists.

Lemma 1 Under the limited accessibility assumption, there exist two VEI-problems $\hat{P}_1 = \langle \hat{P}, T, \{\mathcal{E}_1\} \rangle$ and $\hat{P}_2 = \langle \hat{P}, T, \{\mathcal{E}_2\} \rangle$ that are solvable, but the combined VEI-problem $\langle \hat{P}, T, \{\mathcal{E}_1, \mathcal{E}_2\} \rangle$ is unsolvable.

This follows that there is no complete planner; otherwise, this lemma contradicts the fact that if both $\langle \hat{P}, T, \{\mathcal{E}_1\} \rangle$ and $\langle \hat{P}, T, \{\mathcal{E}_2\} \rangle$ can be solved by the same planner $\tilde{\mathcal{A}}$, the combined VEI-problem $\langle \hat{P}, T, \{\mathcal{E}_1, \mathcal{E}_2\} \rangle$ can also be solved by $\tilde{\mathcal{A}}$.

Theorem 2 (Incompleteness) Under the limited accessibility assumption, there is no complete planner.

3 CONCLUSIONS

Our incompleteness theorem shows that even if we restrict our attention to solvable VEI-environments, there is no planner that can solve every one of these environments. A consequence of this is that no planner dominates all other planners in terms of its coverage, i.e., there is no planner that can solve all of the environments that are solvable by other planners.

In future, we would like to study how to get around the incompleteness, so that one can create planners that are complete if certain restrictions are satisfied. One possible solution is to provide information about the timings of queries to planners, so that planners can schedule its queries in advance. Another solution is to look for randomized query strategies that have a high probability of success.

Cost-Optimal Symbolic Planning with State Trajectory and Preference Constraints

Stefan Edelkamp¹

Abstract. State trajectory and plan preference constraints are the two language features recently introduced to PDDL in the context of the 5th international planning competition. For planning with soft constraints, an objective function monitors their violation. This paper introduces a symbolic approach for finding cost-optimal plans. The set-based branch-and-bound algorithm exploits an efficient symbolic representation of the objective function. State trajectory constraints are compiled into automata, while ordinary preferences are evaluated on-line for the intersection of the search frontier with the goal.

1 Introduction

Planning via Model Checking [2] exploits Boolean functions to lessen the costs associated with the exponential memory blow-up for the state sets involved as problem sizes get bigger. Given a fixed-length binary encoding for the state vector of a search problem, *characteristic functions* represent state sets. As the mapping is bijective, they are identified with the corresponding state sets. Transitions are formalized as relations, i.e., as sets of tuples of predecessor and successor states, or, equivalently, as the characteristic function of such sets. The *transition relation* T has twice as many variables as the encoding of the state. In action planning, we observe that T is the disjunction of all T_O with $O \in \mathcal{O}$ being an (instantiated) operator.

There are many different possibilities to come up with an efficient binary state encoding. The more obvious ones leads to bad performance of symbolic algorithms. Similar to [8], we infer a minimized finite domain encoding of a propositional planning domain.

2 Cost-Optimal Symbolic Search

For symbolic BFS, let Open_i be the set of states reachable from the initial state \mathcal{I} in i steps (initialized with $\text{Open}_0 = \mathcal{I}$) such that $\text{Open}_{i+1}(x') = \bigvee_{O \in \mathcal{O}} \exists x (T_O(x, x') \wedge \text{Open}_i(x))$. Note that S on the right hand side of the equation depends on x compared to x' on the left hand side. Thus, it is necessary to substitute x' with x in Open_i , written as $\text{Open}_i[x \leftrightarrow x']$. To terminate the exploration, we check if $\text{Open}_i \models \mathcal{G}$, with \mathcal{G} being the goal condition.

In order to retrieve the step-optimal plan we assume that all sets $\text{Open}_0, \dots, \text{Open}_i$ are available. We start with a state that is in the intersection of Open_i and \mathcal{G} . We take its characteristic function S into the relational product with T to compute its potential predecessors. Next we select the second last state on the solution path in the intersection of Pred and Open_{i-1} and iterate, until the entire plan has been constructed.

     $U \leftarrow ConstructAndStorePlan(Metric(x))$ 

```

Figure 1. Cost-Optimal BFS Planning Algorithm.

For the symbolic computation of a linear objective function $f(x) = \sum_{i=1}^n a_i x_i$, we first compute the minimal and maximal values (\min_f and \max_f) that f can take. This defines the range that has to be encoded in binary. For the ease of presentation we assume a cost-minimization problem, $x_i \in \{0, 1\}$, and $\min_f = 0$. The work of [1] implies that the BDD for representing f has at most $O(n \sum_{i=1}^n |a_i|)$ nodes and can be constructed with matching time performance. For preference constraints of type (*preference* $p \phi_p$) we associate a Boolean variable v_p (denoting the violation of p) and construct indicator relation $X_p(v) = (v_p \Leftrightarrow \phi_p)$.

Figure 1 displays the pseudo-code for a symbolic BFS-exploration incrementally improving an upper bound U on the plan cost. The search frontier denoting the current BFS layer is tested for an intersection with the goal condition, and this intersection is further reduced according to the already established bound. As there can be many different goal states contained in the remaining set, the plan construction process in *ConstructAndStorePlan* determines a state in the intersection that has the minimal cost. This is achieved by iterative intersection of $[v = i]$, for $i \in \{0, \dots, U\}$. The obtained value minus 1 is the return value for the next threshold.

Theorem The latest plan stored by the algorithm *Cost-Optimal-Symbolic-BFS* has minimal cost.

Proof The algorithm applies full duplicate detection and traverses the entire planning state space. It generates each possible planning state exactly once. Only clearly inferior states in *Intersection* are pruned when evaluated in *Eval* and taken into a conjunct with *Bound*. Therefore, *Metric* is trivial, only if there is no state in the intersection of the search frontier *Open* with the goal \mathcal{G} that has an improved bound.

3 Cost-Optimal Search with State Trajectories

State trajectory constraints can be interpreted Linear Temporal Logic (LTL) [7] and translated into automata that run concurrent to the search and accept when the constraint is satisfied [6]. LTL includes temporal modalities like A for *always*, F for *eventually*, and U for *until*. It is possible to compile the automata back to ordinary PDDL with each transition introducing a new operator [3]. Every automaton state for each automaton is represented by a proposition. For detecting accepting states we additionally include according predicate to the domain description. The initial state of the planning problem includes the start state of the automaton and a flag in case it is accepting. For all automata, the goal condition includes their acceptance.

As an example, for (*sometimes* ϕ) we apply automata-based model checking to build a (Büchi) automata for the LTL formula $F\phi$. Let \mathcal{S} be the original planning space and $A_{F\phi}$ be the constructed (Büchi) automaton for formula $F\phi$ and \otimes the synchronous cross product between two automata, then $\mathcal{P} \leftarrow \mathcal{P} \otimes A_{F\phi}$ and $\mathcal{G} \leftarrow \mathcal{G} \cup \{\text{accepting}(A_\phi)\}$. The initial state is extended by the initial state of the automaton, which in this case is not accepting.

For preferences for state trajectories that are constructed via automata theory, we apply the following changes. Instead of adding the automaton acceptance to the planning goal, we combine the acceptance with the violation predicate. If the automaton accepts then the preference is not violated; if it is located in a non-accepting state, then it is violated. For example, given (*preference p (at-most-once* ϕ) we explore the cross product $\mathcal{P} \leftarrow \mathcal{P} \otimes A_{\mathbf{A}\phi \rightarrow (\phi U(G \neg \phi))}$. Let $a = \{\text{accepting}(A_{\mathbf{A}\phi \rightarrow (\phi U(G \neg \phi))})\}$. A specialized operator *skip* allows to fail the automata constraint. Using a *dead* state, we assure that if an automaton is ignored once during the exploration, it remains invalid for the rest of the computation.

BDDs already save space for large state sets. However, even for symbolic search, additional memory can be saved. For example, Symbolic Branch-And-Bound Search seems to produce smaller search frontiers than Symbolic A* [9]. Our implementation features *Frontier-Search* [10], which has been proposed for undirected or directed acyclic graph structures. In the more general benchmark planning problems, a *duplicate detection scope* of 5 was sufficient to guarantee termination of *Cost-Optimal-Symbolic-BFBnB*. Moreover, it is not necessary to memorize an intermediate BDD layer corresponding to trajectory automaton transitions. Only the layers that correspond to the original unconstrained state space have to be stored.

The *variable ordering* has a large influence on the size of a BDD. We employ an interleaved variable ordering for the transition relation. Moreover, propositions that have been instantiated with the same domain objects should be encoded close together, while preference variables are better to be queried at the top of the BDD.

4 Experiments

Results on the approach are collected and published in the context of the 5th International Planning Competition. The following ta-

ble compares the outcome of the symbolic exploration for the domain *TPP/SimplePreferences* with our own explicit-state heuristic search planner on the competition machine, having a time-out (t.o.) at 1.800s, and a memory-out (m.o.) at 1 GB. The explicit-state planner runs out of time even in smaller problems, while the symbolic planner terminates if it has validated the optimal solution (label *). The symbolic planner runs out of memory in larger instances. In this case the solutions are optimal only wrt. the search depth reached.

Problem	Symbolic Search			Explicit Search		
	Time	Cost	Steps	Time	Cost	Steps
p01	1.34s	16*	17	t.o.	16	21
p02	1.68s	24*	14	t.o.	14	22
p03	2.45s	29*	20	t.o.	29	22
p04	6.06s	35*	20	t.o.	35	24
p05	337s	89	27	t.o.	223	24
p06	242s	110	21	t.o.	275	19
p07	246s	126	17	t.o.	322	19
p08	295s	141	17	t.o.	369	17

5 Conclusion

We have devised an optimal propositional PDDL3 [7] planning algorithm based on BDDs. As the approach for state trajectory constraints relies on a translation to LTL, it has the potential to deal with much larger temporal constraint language expressiveness than currently under consideration. As an alternative, Model checkers like SMV directly encode LTL formula into the transition relation without using an intermediate automaton [11]. We will likely extend the approach to domains with linear expressions also in the actions. As a prerequisite to apply [1], numerical state variables have to fit into finite domains. Many metric planning problems belong to this group. For more general planning problems we will consider using exploration for state sets represented in form of automata instead of BDDs [4].

A Cooperative Distributed Problem Solving Technique for Large Markov Decision Processes

Abdel-Illah Mouaddib and Simon Le Gloannec¹

Abstract. In this paper, we consider the problem of solving a large MDP in a distributed way among several processors. To do that, we propose an approach which decomposes the large MDP into smaller ones each of which is solved on a unique processor. The obtained joint local policies derived from the small MDPs (subMDPs) behave in the same way of the policy of the initial MDP.

1 Introduction

The MDP provides a formal framework for modeling a large variety of stochastic planning and decision problems. The limitations of this framework are also well-known, where the most awkward for their application to realistic problems is the very large number of states. Many research lines have been developed using different (policy, space or action) decomposition techniques of MDPs [4, 3] to overcome this limitation. In this paper, we focus on a *parallel decomposition* where the construction, solving and execution of subMDPs are performed in a distributed way. Parallel decomposition planners in the literature consider simple interactions or an hierarchy structure. Our approach is a Parallel decomposition where subMDPs are connected as in a complete graph.

The concept of decomposition we consider is a problem formalized as a large MDP $\langle S, A, P, R, T \rangle$ that is decomposed into subproblems that can be further described by a subMDP of the initial MDP denoted by $M_i = \langle S_i, A_i, P_i, R_i, T \rangle$, where S_i is the state subspace, A_i is the action subspace, P_i is the probability transition in M_i , R_i is the reward function, and T the horizon. In this paper, we are interested in defining a mechanism for constructing subMDPs $M_i = \langle S_i, A_i, P_i, R_i \rangle$ from the global MDP $\langle S, A, P, R \rangle$ and deriving a global policy from local policies of subMDPs.

2 Decomposition of an MDP

The large MDP M is decomposed into a set of subMDPs (M_i) where each one is generated by a subset of actions A_i of the set A . All states generated by actions $A_{j \neq i}$ are cut and replaced by an abstract state that we name artificial state sa . We introduce, consequently, a null action aa that transitions to this abstract state. Also, states reachable at time t from the abstract state at time $t - 1$ (sa^{t-1}) are all states reached by actions of A_i from all states reached at time $t - 1$ by actions of the subsets $A_{j \neq i}$. These states that are represented abstractly with one state sa^{t-1} in the subMDP, should be communicated.

2.1 Decomposition of the action space A

The action space A is organized into a set of available actions at each time from 0 to T . A is decomposed into regions A_i s.t. : $A_i = \bigcup_{t=0}^{t=T} A_i^t$ and $A_i \cap A_{j \neq i} = \emptyset$ where A_i^t contains the available actions at time t of the region A_i (we consider any partition of A). Also, we add to each region the null action aa : $A_i = A_i \bigcup \{aa\}$

¹ GREYC-CNRS/Université de Caen, {mouaddib,sleglo} @info.unicaen.fr

where aa is considered to be available at any time. In the following, we describe, how from each region A_i , we construct a subMDP M_i .

2.2 State region S_i generation

The state region S_i for each subMDP M_i has an initial state s_i^0 . We consider that this initial state is the one of the original MDP s_0 . At step 0, all subMDPs M_i are initially at state s_0 : $\forall i, s_i^0 = s_0$. The generation of the region S_i consists in applying successively the actions of A_i^t followed by communication step from $t = 0$ to $t = T$.

S_i generation of M_i : return S_i

1. $reachable_i(0) = S_i = \{s_0\}$
 2. **for** $t = 1$ **to** T **do**
 3. $reachable_i(t) = \emptyset$
 4. **send** $reachable_i(t - 1)$
 5. **receive** $reachable_j \neq i(t - 1)$
 6. **for all** $s_i^{t-1} \in reachable_i(t - 1) \bigcup_{j \neq i} reachable_j(t - 1)$ **do**
 7. **for all** $a \in A_i^t$ **do**
 8. $reachable_i(t) = reachable_i(t) \bigcup \{transit(s_i^{t-1}, a)\}$
 9. $S_i = S_i \bigcup reachable_i(t)$
-

transit(s,a) generates states reachable from s by applying a . Let us note that $transit(s,aa) = \{sa\}$ the abstract state. Also, $transit(sa,a)$ generates states reachable from all states of M_j by applying action a . All these states should be communicated to the subMDP M_i . The cost of communication is that at each time t , subMDPs receive from the other a message containing the states generated at time $t - 1$. Therefore, the cost of generation is : $Cost_Gen = \sum_{i=1}^{i=n} \sum_{t=0}^{t=T} (n-1).|reachable_i(t)|$

3 Solving in Parallel subMDPs

The Bellman equation restricted to a subMDP M_i is then as follows:

$$V_i(s) = R_i(s) + \max_{a \in A_i} \sum_{s' \in S_i} P_i(s, a, s') V_i(s') \quad (1)$$

$$V_i(s_T) = R_i(s_T) \quad (2)$$

A policy π_i is a mapping from S_i to A_i assigning an action to each possible state in the subspace S_i . Solving this subMDP consists in deriving an optimal policy π_i^* s.t.:

$$\pi_i^* = argmax_{a \in A_i} \left(\sum_{s' \in S_i} P_i(s, a, s') V_i^*(s') \right) \quad (3)$$

We rewrite differently equation 1 in order to show more clearly the value of action aa : $V_i(s) = R_i(s) + \max_{a \in A_i - \{aa\}} \sum_{s' \in S_i} P_i(s, a, s') V_i(s')$ (4)

In Equation 4, we optimize over two terms: $P_i(s, aa, sa) V_i(sa) = V_i(sa)$ (aa is deterministic) and, $\max_{a \in A_i - \{aa\}} \sum_{s' \in S_i} P_i(s, a, s') V_i(s')$. These values are respectively of states reached by actions $A_{j \neq i}$ and the states reached by local actions $A_i - \{aa\}$ of a subMDP M_i . Stated differently, which first term is the value of state sa^t reached by action aa is obtained by communication while the values of states reached by local actions are computed locally.

3.1 Transitions and Value and Reward functions

- **Transition Probability:** The probability $P_i : S_i \times A_i \times S_i \rightarrow [0, 1]$. The probability P of the original MDP is given by $P : S \times A \times S \rightarrow [0, 1]$. Since $S_i \subset S$ and $A_i \subset A$, the transition probability $P_i(s, a, s')$ is s.t.: $P_i(s, a, s') = P(s, a, s')$, $P_i(s, \text{aa}, sa) = 1$ because there is no uncertainty on the fact that this subMDP does not execute any local action and $P_i(sa^t, a, s')$ is not needed because the value of the abstract state sa^t is communicated from $M_{j \neq i}$.
- **Values V_i and Rewards R_i :** Since $S_i \subset S$ then $R_i(s) = R(s)$. The reward function is not defined on abstract state sa^t because the value of these states are computed from equation 5.

Let us recall that the action **aa** is executed by a subMDP M_i when it expects that one of subMDPs $M_{j \neq i}$ can do better. Consequently, the value $V_i(sa)$ of state sa (reachable by action **aa** of M_i) represents the highest value that we can reward from the subMDPs $M_{j \neq i}$. Let the decision process at step t and s_j^t be the state at step t for any subMDP $M_{j \neq i}$ while subMDP M_i is in a reachable state s_i^t . The value $V_i(sa^t)$ at step t is the maximum of the values of states s_j^t reachable by an action $a \in A_j$. More formally :

$$\forall t, M_i \text{ and } M_{j \neq i} : V_i(sa^t) = \max_{j \neq i} V_j(s_j^t) \quad (5)$$

In this equation let s_j^t be the state of M_j corresponding to the state sa^t . The problem to solve is to select for each sa^t its corresponding states s_j received from subMDPs M_j . Then, to solve this equation, for each state sa_i^t , each subMDP M_i should receive from the other subMDPs $M_{j \neq i}$ all the values of their current state s_j^t . The subMDP M_i selects for each of its states sa_i^t the corresponding states s_j^t to solve equation (5). The interaction of subMDPs and value selection algorithms are given in the next sections.

3.2 Selecting appropriate values of a state sa_i^t

The objective of this section is the selection from the set of received values, the appropriate ones to compute the value of a given sa_i^t . At a step t , all subMDPs send values of the states s_j^t reached by one of its local actions ($\neq \text{aa}$). Not all states s_j^t are needed to compute the value of sa_i^t , but only the ones which are compatible with this state. The notion of *compatibility*, is defined using the notion of *sequence* of actions to reach a state and its duals.

3.3 Distributed Computation of values

The value computation algorithm starts by communicating the values of its terminal states for which $V_i(s^T) = R_i(s^T)$, while the value of states $V_i(sa^T)$ is computed using equation (5) where each $V_{j \neq i}(s_j^T)$ is sent from M_j to subMDPs $M_{k \neq j}$ including the subMDP M_i . In this way, all values at decision step T are known and allow subMDP M_i to compute the values of states at the previous decision step $T-1$. This processing combining the values communicated from the other subMDPs needed for equation (5) that in the same way is used to solve equation (4) is used backward from terminal states to the initial state for each subMDP. The value computation process uses a function **COM** which allows subMDPs to exchange their respective available information to compute all their values $V_i(sa_i^t)$.

3.4 Coordination of local policies

The local policies could be in conflict because only one action should be executed at a time as in the original MDP. To avoid the conflicts, the local policies should be able to select a local action when none of the other subMDPs can do better. The null action **aa** we added in each region A_i allows each local policy to do nothing (let the others do). Stated differently, at step t when the subMDP M_i decides to execute **aa**, one and only one of $M_{j \neq i}$ executes one of its local actions $a_j \neq \text{aa}$. The policy takes this decision when its value is greater than all the values rewarded by the local actions. To do that, the subMDP M_i needs to compute the value that we describe in the next section.

In the rest of the paper, we note sa_i^t by state reached by action **aa**, at step t , in subMDP M_i . Let us note that at step t , many states sa_i^t are generated which are distinguished by their parent state s^{t-1} .

3. foreach  $sa_i^t$  do
4.   select from received values  $V_j(s_j^t)$ , values of compatible states  $s_j$ . Let these states be  $s_j^{sa}$ .
5. compute  $V_i(sa_i^t) = \max_{j \neq i} V_j(s_j^{sa})$  (equation 5)

```

4 Execution of subMDPs

In this section, we describe the execution of each subMDP M_i that follows its local optimal policy π_i^* . Let us recall that initially all the subMDPs are at the same state s_0 . At step t , each subMDP M_i is at a state s_i^t or sa_i^t . The decision made at this step is to select one of the actions $a \in A_i$ or **aa**. When the policy $\pi_i(s_i^t) \neq \text{aa}$, this means that all values received from the other subMDPs $M_{j \neq i}, V_j(s_j^t) < V_i(s_i^t)$. **Theorem 1** *The joint policy of subMDP is equivalent to the policy of the original MDP.*

Proof: contact the authors \square .

5 Costs of communication and computation

The decentralized way to perform MVIA uses a large amount of information exchanged via communication as shown in lines 3 and 7 of the MVIA. The cost of this communication is measured by the number of messages and the size of their contents. The cost of communication is of an order of magnitude of $O(n^2)$. This complexity can be reduced by using some specific architectures (router machine based on uni-cast or multi-cast technique) to linear complexity $O(n)$.

6 Discussion and Future work

Parallelizing the resolution of MDP is a hard problem that should consider three main issues : (1) completing the information lost during the decomposition, (2) solving in parallel decentralized MDPs and (3) monitoring the execution of local policies. These issues have been addressed by a new approach which allows us to construct from local policies a global optimal behavior. This approach can be seen as a distributed planning contribution of DEC-MDPs [1, 2] since most of algorithms are centralized planning approaches. Future work will concentrate on deep analysis of the type of MDPs and actions to better decompose the MDP or assuming some topologies of the network to make the parallelization more efficient.

Integrating Off-line and On-line Schedulers

Riccardo Rasconi and Nicola Policella and Amedeo Cesta¹

Abstract. This work pursues an empirical study on the mutual interactions among a set of off-line and on-line constraint-based scheduling approaches. We devise a set of closed loop execution management algorithms, and compare their behavior within an experimental framework which allows to directly assess the consequences of each chosen strategy combination against the injection of a number of disturbing events, through simulated schedule executions.

1 SCHEDULE SYNTHESIS vs. EXECUTION

This work introduces an experimental platform which allows to compare different approaches to schedule synthesis and execution in a fair and controlled way. In this schema a schedule is initially produced off-line and thereafter delivered to an on-line module which takes care of assessing its dynamic characteristics by stressing it in a variety of ways, e.g. by simulating its execution under different environmental conditions.

Our aim is to reveal crucial “execution” aspects by plugging in different versions of either off-line solvers and/or on-line reschedulers. In particular the experimental framework is organized according to the following general conditions: (a) the solvers are chosen so as to produce initial solutions characterized by different levels of temporal flexibility; (b) the designated set of rescheduling algorithms generally follow a constraint-based approach; (c) the exogenous events set to disturb the execution of the schedules are exclusively of temporal nature (e.g., delays in the activities start times, lengthening in the activities durations, etc.).

In contrast to most off-line schedulers, which deliver fixed-time solutions, our approach is based on the general concept of “temporal flexibility” [4]. A temporally flexible solution can be described as a network of activities whose start times (and end times) are associated with a set of feasible values (feasibility intervals). Underlying the activity network there exists a Temporal Constraint Network (TCN [5]), composed of all the start and end points of each activity (time points), bound to one another through specific values which limit their mutual distances (activity-on-the-arc representation). The search approaches used in our schema focus on decision variables which represent conflicts in the use of the available resources; the solving process proceeds by ordering pairs of activities until all conflicts in the current problem representation are removed. This approach is usually referred to as Precedence Constraint Posting (PCP [4]), because it revolves around imposing precedence constraints (the *solution constraints*) on the TCN in order to solve the resource conflicts, rather than fixing rigid values to the start times.

In this analysis, schedules with different degrees of flexibility are initially generated. A certain level of temporal flexibility is guaranteed by a generic **Flexible Schedule (FS)**: a flexible schedule is a network of activities such that a feasible solution for the problem is obtained by allocating each activity at the temporal lower bound allowed by the network (in our experiments, flexible schedules are produced using the ISES procedure [3]).

In order to overcome the limitation imposed by flexible schedules, i.e. having only one consistent solution, a generalization of the TCN produced by a PCP phase is proposed in works such as [2, 7], in which methods for defining a set of both time and resource feasible solutions are presented. This new representation is called **Partial Order Schedule (POS)**: a Partial Order Schedule (*POS*) is an activity network, such that any possible temporal solution is also a resource-consistent assignment. A *POS* is a special case of a flexible solution and it can be obtained by replacing the solution constraints with a new set of constraints that impose a stronger condition on the TCN.

Regarding the on-line module, as soon as an event is acknowledged, a re-scheduling algorithm is invoked in order to produce an “updated solution” that will be used to continue the execution. In our schema, we model a local and global approach to rescheduling by enabling different constraint removal strategies on the current solution.² More specifically, we use a (1) *No-Retraction strategy (NR)* where all the constraints imposed are preserved, and the subsequent solution is computed by adding further constraints; and a (2) *Retraction strategy (R)* where, all the previously imposed solution constraints are removed and the subsequent solution is computed by adding new constraints to this “clean” representation.

Finally, regarding the exogenous events used to disturb the schedule execution, we limit ourselves to the generation of temporal events, such as delays of the activities start times (the activity a_i might undergo a delay of Δ_{st} time units, at $t = t_{\text{aware}}$) and/or modifications of activity processing times (the activity a_i ’s processing time p_i might be extended by Δ_p time units, at $t = t_{\text{aware}}$).

2 EXPERIMENTAL EVALUATION

The scope of this paper is to evaluate the behavior of schedules characterized by different temporal flexibility (**FS**, **POS**), as they are disturbed with a number of exogenous events, using different rescheduling strategies. The results of this analysis, never performed before, are presented in Table 1, and will be described in this section. The evaluation proposed below is based on the Resource-Constrained Project Scheduling Problem with minimum and maximum time lags, or RCPSP/max [1], a particular project scheduling problem which presents constraints that define the minimum and maximum distance between the execution of two activities.³

Eight different batteries are considered, where each of these is obtained coupling two scheduling problem benchmarks, *j30* and *j100* [6], with four execution simulations. The former consist of two sets of respectively 270 and 540 scheduling problem instances of different size, namely 30×5 and 100×5 (number of activities \times number of resources). On the other side, each execution simulation is composed of a set of properly modeled disturbing events: each scheduling problem is executed with four instances of world simulations of different size (1, 2, 3, and 5 events each) where each event represents either

¹ ISTC-CNR, Institute for Cognitive Science and Technology of the Italian National Research Council, email: name.surname@istc.cnr.it

² Exception is made for the constraints which model the dynamic aspects of the progressing execution. These constraints are, of course, always preserved.

³ RCPSP/max is a NP-hard problem. This is due to the presence of maximum time-lags, which imply the satisfaction of deadline constraints.

Table 1. Summarizing data for each execution strategy (computed on the intersection set of all successfully executed problems)

a delay on the start time, or a delay on the end time of the activities (these two different kinds of event are produced with the same probability).

The execution strategy combinations analyzed in this work are the FS-R, POS-R, FS-NR, and POS-NR, and are shown in Table 1. To make the comparison more complete, we add a further execution mode based on the use of fixed time solutions, where each activity is assigned a single start time instead of a set of alternatives.

For each execution policy, the table shows the average makespan at the end of every execution (mk), the average difference between the makespan at the beginning and at the end of every execution (Δmk), the number of performed reschedulings (*reschedulings*) related to the number of injected disturbances, the average CPU time necessary to compute the initial schedule (*CPU off-line*), and finally, the average CPU time which is necessary to perform all the reschedulings during the execution (all CPU times are expressed in milliseconds). For a fair comparison of the different policies, all the averages presented in this table are computed on the basis of the problem instances commonly executed with all the execution strategies.

A relevant result of this analysis is the extremely low rate of necessary reschedulings exhibited by the POS-R/POS-NR policies: this circumstance confirms the theoretical expectations which motivated the introduction of the \mathcal{POS} s. As shown, the need for schedule revision in case of \mathcal{POS} utilization decreases by more than 75% in case of the j30 set, and by at least 50% in case of the j100 set with 5 disturbances. It is worth noting as this result is confirmed by the better makespan and CPU on-line values in the case of \mathcal{POS} s. We note also the $\approx 100\%$ *reschedulings* figure relative to the case of *fixed time* schedules where repairs are practically always needed. This case reveals the highest makespan elongation (see mk and Δmk) and *CPU on-line* values: in fact, the frequent rescheduling actions inevitably tend to spoil makespan quality.

Another interesting aspect is related to the comparison of the *CPU on-line* values between the *Retraction* and *No-Retraction* strategies: NR strategies reveal lower CPU-load rates with respect to the R strategies, *despite the comparable amount of performed reschedulings*. In fact, NR execution modes retain all the temporal constraints of the previous solution: hence, the rescheduler is bound to work on a smaller search space, finding the next solution almost immediately. Additionally, the tremendous on-line CPU load in the case of fixed time solutions, as well as how the reactivity of NR technique, combined with the low revision requirements featured by the \mathcal{POS} , allows the fastest dynamic reactions of the whole set (see the *CPU on-line* values for POS-NR).

We conclude mentioning that in further analysis we have also discovered some limitations in using \mathcal{POS} s with respect to the ability

of completing the schedule execution. We refer the reader to [8] for a more detailed presentation of these issues.

3 CONCLUSIONS

This paper discusses alternative approaches to the execution, monitoring and repair of scheduling solutions. We obtained different insights on the combination of two aspects: (a) the use of temporal flexible solutions to increase proactive robustness and (b) the use of complementary re-scheduling policies to react to unexpected events. In particular we analyze two alternatives to the classical fixed time schedule – flexible schedules, containing a single point solution, and partial order schedules or \mathcal{POS} s. Moreover, we distinguish between the incremental modification of the initial schedule vs. the retraction of previously made decisions followed by a new resolution. The empirical results support the usefulness of this analysis and represent a direct confirmation of theoretical expectations. For the first time, the positive effects of temporal flexibility in the definition of temporal solutions are emphasized. This represents a clear starting point for further investigations and opens the ways to new perspectives.

Environment-Driven Skeletal Plan Execution for the Medical Domain

Peter Votruba¹, Andreas Seyfang¹, Michael Paesold¹, Silvia Miksch^{1,2}

Abstract. An important application of both data abstraction and plan execution is the execution of clinical guidelines and protocols (CGP), both to validate them against a large set of test cases and to provide decision support at the point of care. CGPs can be represented and executed as a hierarchy of skeletal plans. To bridge the gap between low-level data and high-level concepts in the CGP, intelligent temporal data abstraction must be integrated with plan execution.

In this paper we describe a solution to this challenge which was implemented as part of the European project Protocure II to improve the quality of CGPs. They are translated to the high-level plan representation language Asbru which again is compiled into a network of abstraction modules by the system. Then this network performs the content of the plans triggered by the arriving patient data.

By this, we seamlessly integrate the synchronisation of guideline execution with observed patient state, complex temporal abstractions and execution of complex plans without requiring the user to handle the low-level details. Instead, user-friendly tools are used to create and maintain the guideline.

1 Introduction

In the field of medicine, the application of clinical guidelines and protocols helps to improve the quality of care by ensuring the optimal choice of treatment. A precondition for the successful application of clinical guidelines and protocols is the automatic abstraction of context-dependent time-annotated raw-data (e.g., percent of oxygen in blood at a certain second) to high-level medical concepts (e.g., sufficient oxygen saturation during an extended period of observation). This is performed by temporal data abstraction.

Within the domain of medicine, intensive care poses additional challenges to plan execution. The nature of the data raise the need for elaborate pre-processing of the data, including complex knowledge-based plausibility checks and correction heuristics which involve multiple channels and time windows and the synchronisation of low-frequency and high-frequency inputs. This processing together with the sometimes complex propagation of plan states needs to be performed in a timely manner to meet the real-time requirements of online patient monitoring.

To meet these requirements, we integrate time-oriented, skeletal planning using the Asbru representation with real-time monitoring and temporal data-abstraction.

There are many guideline modelling approaches today [4, 6, 1], but only few integrate strong data abstraction resources. This may

be caused by the fact that in most settings, data is entered manually which allows to delegate the data abstraction task to the user by demanding qualitative high-level input instead of the original data. However, the integration of guideline execution into the clinical data flow becomes more and more important in order to apply decision support systems in clinical daily practice [2].

2 Plan Representation in Asbru

Asbru is a time-oriented plan representation language that represents clinical guidelines as skeletal plans [5]. Asbru's distinguishing features are that intentions, conditions, effects and world states have a temporal dimension and are continuous (durative). Because of the advanced temporal data abstraction capabilities, diagnosis and treatment can be tightly integrated allowing each one to support the other one.

All conditions for the transition from one plan state to another are expressed in terms of temporal patterns. A temporal pattern consists of one or more parameter propositions or plan-state descriptions. Each parameter proposition contains a value description, a context, and a time annotation. The time annotation used allows a representation of uncertainty in starting time, ending time, and duration of an interval. Start and end are defined as shifts from a reference point. Reference points can be defined as sets of cyclical time points or references to parameter changes, allowing repeated temporal patterns.

3 The Asbru Interpreter

Conceptually, the Asbru Interpreter consists of three basic units: data abstraction, monitoring, and plan execution. In the data abstraction unit, various temporal or atemporal abstractions are applied to the patient data to gain information at higher conceptual levels. The provided quantitative or qualitative data is monitored to detect temporal patterns in the abstracted data. This information is used to control the selection and execution of plans. This data flow is not unidirectional, instead, the execution unit can interact with both monitoring and abstraction unit to adjust the monitored patterns and to adapt the abstraction process to the context given by the current plan states.

The interpreter has two different modes of operation: Batch mode and interactive mode. In batch mode, a large set of records is read to validate a guideline against patient data or to create complex abstractions of the data for later analysis. In interactive mode, data can be read from monitoring devices in addition to the user input.

Figure 1 shows the parts of the interpreter on the implementation level. The main parts are the Asbru Compiler and the Execution Manager. The three conceptual components mentioned above – data abstraction, monitoring, and plan execution – are seamlessly integrated in the module graph.

¹ Institute of Software Technology, Vienna University of Technology, Austria

² Department of Information & Knowledge Engineering, Danube-University Krems, Austria

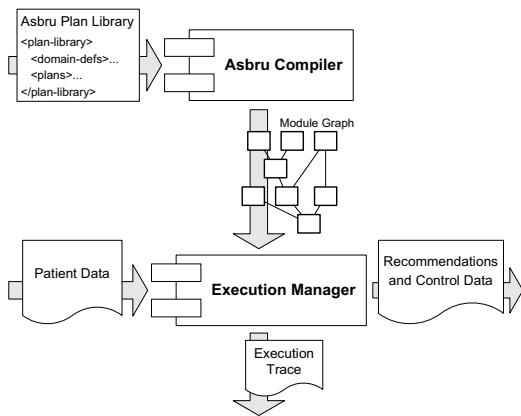

Figure 1. System architecture and data flow in the Asbru Interpreter. The Asbru plan library is compiled into a directed graph of modules by the Asbru Compiler. The Execution Manager uses this module network to process patient data and execute the plans representing the guideline.

At program start-up, the Asbru plan library XML file is compiled into a directed graph of modules.

For each time step, the Execution Manager enacts each of the modules in the network to process patient data, monitor temporal patterns, and execute the plans in the guideline. These modules are largely compatible with each other, which allows information extracted by any module to flow back into the abstraction or monitoring process. To handle complex networks with many inputs in high-frequency applications, the Execution Manager ensures that each module is enacted exactly when needed, allowing for small time steps by some modules without the overhead created by other modules which would not provide new information at that moment.

Modules can set alarms, to be triggered when a certain span of time is elapsed. Here we distinguish between *pre-alarms* and *post-alarms* depending on whether the alarm is triggered before or after processing the data for this time step. This distinction allows the implementation of both complex and convex temporal intervals. Alarms are set by various monitoring and value aggregation modules.

The available modules can be divided into the following categories.

Raw data modules. These modules interface the input channels and map the raw-data parameter definitions in Asbru.

Value abstraction modules. This group comprises the logical and arithmetic combination of inputs, and the mapping of quantitative values to qualitative categories.

Value aggregation modules. In order to map high-frequency, error-prone inputs to high-level concepts, it is mandatory to aggregate series of measurements and to derive the abstractions from them, and not from single measurements.

Monitoring modules. These modules handle temporal patterns, such as parameter propositions, which control the state changes of Asbru plans.

Temporal abstraction modules. The patterns detected by monitoring modules and aggregates of the measurements often need one or more steps of temporal abstraction to detect complex patterns in the input data such as "five episodes of apnea followed by hyperoxemia during the previous hour".

Plan modules. Modules in this category represent Asbru plans or single plan steps. The network of parent and child plans is fully integrated with the other modules to form the module graph.

4 Evaluation and Future Work

An extensive real-world guideline [3] was modelled in Asbru and test runs of the resulting model in the interpreter were successful. Running the interpreter on patient cases will allow the comparison between the expected outcome of applying the guideline and the actual outcome according to the model in Asbru.

In practical tests with high-frequency data recorded at an intensive care unit, the interpreter processed input from 10 channels and moderately complex abstractions thereof at a rate of more than 1 kHz on a standard PC. Most clinical data is recorded at 1 Hz, or 200 Hz. We therefore conclude that the computational performance is sufficient for real-time applications in clinical monitoring.

Future work will go into the construction of dedicated modules to interface equipment at intensive care units, where it will be employed in clinical studies. In addition, a graphical user interface to allow the interactive use of the interpreter by non-computer experts is under development.

5 Conclusion

Plan execution in real-world high-frequency domains such as intensive care units demand for tight integration of temporal data abstraction and plan execution to achieve the required intelligent reaction to unpredictable changes in the environment, i.e., the patient state.

While the knowledge in such domains is abstract, partly vague or incomplete, and often complex, the data arrives at a high rate and in a format that is far from the level in which the domain knowledge is specified. Translating the domain knowledge to such low levels by a knowledge engineer leads to well known short-comings regarding maintenance and assuring the correctness of the model.

We therefore designed an interpreter, which takes a high-level specification of skeletal plans and temporal data abstraction and compiles them into a network of abstraction modules. Using elaborate management of data flow, these modules process the data at a high rate, even in complex configurations.

Tests have demonstrated that the interpreter can handle a complete guideline, large sets of patient records, and high-frequency measurements. Applications to a large set of data are currently in progress.

Time constrained VRP: an agent environment-perception model

Mahdi Zargayouna¹

Abstract. In this paper, we present a multiagent model in which agents have a perception upon their shared environment, a measure is associated to the agents' perception field. We apply the model on the Vehicle Routing Problem with Time Windows (VRPTW). The overall process adopts the general schema of parallel insertion methods and it uses the contracting of perception's field of the vehicle agents as a new distance between them. This new measure expresses the feasibility universe of the vehicles and is used as a criterion of choice between candidates vehicles for the insertion of a customer in their plan. Our approach provides a new method to tackle the Time constrained VRP in which the solving process is focused on the future and constitutes an alternative for handling the dynamic version of the problem.

1 Introduction

Vehicle routing problems (VRP) have been an intensive research area in the last decades because of their large applicability in real life problems. Several constrained variants were proposed in order to meet specific operational applications, they concern time restrictions, requests configuration etc. One of the most widely studied problem is the time (and capacity) constrained version: the Vehicle Routing Problems with Time Windows (VRPTW henceforth). VRPTW and their variants (PDPTW, DARPTW etc.) are hard combinatorial optimization problems. Exact approaches for the static VRPTW are only of theoretical interest and artificial intelligence heuristics succeeded in finding good solutions, within reasonable computational times. In the dynamic problem, the whole customers set is not available before the start of execution.

In this paper, in order to tackle the dynamic VRPTW, we consider that zero demands are known *a priori*. To this purpose, we propose to model a multiagent system (MAS henceforth) composed of *vehicle* agents, a queue of *customer* agents and events representing customers' requests occurring *ad hoc*. They evolve in the same environment in which they are described by their observable descriptors. *Vehicle* agents' perception field is modeled as a subpart of the environment observation domain and is quantified. *Customer* agents select the vehicle into which they want to belong following a criterion: the minimal decrease of the *vehicle* agent's perception field quantification. This criterion helps us in dealing with uncertainty concerning future (unknown) customers' demands. The remainder of the paper is then organized as follows. In the next section, we first present a generic model of the environment and of the agents' perception, then its application to the VRPTW problem. In section 3, we conclude and give some perspectives to our work.

¹ Inrets institute and Paris-Dauphine University, France, email: zargayou@inrets.fr

2 Our proposal

2.1 Multi-Agent environment and Agents' perception

Our environment model could be seen as an extension of [1, 6]. Our definition is based on the principle of observability i.e. the entities' external description. The formulation is inspired from the Symbolic Data Analysis paradigm [2].

Definition 1 (Environment) $ENV = \langle A, E, Y, M \rangle$ with:

- $A = \{a_1, \dots, a_m\}$ a set of agents,
- $E = \{e_1, \dots, e_n\}$ a set of events,
- $Y = \{y_1, \dots, y_p\}$ a set of variables (functions)

$$Y : A \cup E \rightarrow \Omega$$

$$\Omega = \prod_{i=1}^p \Omega_i, \text{ with } \Omega_i \text{ the description domain of the variable } y_i,$$

$$\bullet M : \prod_{i \in I} \Omega_i \rightarrow \mathcal{P}(A), I \subseteq \{1..p\}$$

In addition, to every agent a_k , we associate:

$$Restr_k : \prod_{i \in I_k} \Omega_i \rightarrow \{\text{true}, \text{false}\}, I_k \subseteq \{1..p\}$$

A quantification: $\| a_k \| \in \mathbb{R}^+$

Every agent and every event are accessible via their observable descriptions (set of variables). To every agent a_k , we associate a conjunction of perception restrictions (assertions, we note $Restr_k$) on the values of the variables it wants to perceive (I_k is defined by a_k). If $Restr_k$ is empty then a_k can perceive everything. To every $Restr_k$ of an agent a_k , we associate a quantity in $\mathbb{R}^+ (\| - \|)$ which reflects the capacity of perception of agent a_k , based on its restrictions $Restr_k$. For instance, if $Y = \langle \text{age}, \text{sex} \rangle$, $\Omega = [0, 100] \times \{\text{"male"}, \text{"female"}\}$, and $Restr_1 = \langle \text{sex} = \text{"male"} \wedge \text{age} \geq 50 \rangle \Rightarrow \| a_1 \| = 1 \times 50 = 50$.

The environment is responsible of the aggregation of the different $Restr$ of the agents -via the function M - in order to know, when an agent or an event reveals to the system (partially defined by $\bigcup_{i \in I} y_i$ with $I \subseteq \{1..p\}$), which agent actually perceives it.

Analogically to the Symbolic Data Analysis paradigm, every function $Restr_k$ is a symbolic object which extension is composed of $Ext_k = \{\omega / Restr_k(\omega) = \text{true}\}$.

Such an abstraction of the environment can model any MAS where the environment is a first-class abstraction [5] i.e. the environment is an explicitly designed entity. Note that to our knowledge, in the domain of the modeling of environment for multiagent systems, there is no propositions in the literature that quantify the agents' perception.

2.2 Application: the VRPTW problem

The VRPTW problem is a multi-vehicle Traveling Salesman Problem with limited capacity and with time intervals associated to the nodes to be visited. We consider an Euclidean VRPTW for presentation clarity (distances and time-travel computed following the Euclidean metric). In our system, we have two types of agents: *customer* agents and *vehicle* agents. *customer* agents are in a queue, they sequentially reveal to the system and each one is considered independently from its successors. Every *customer* agent is described by (x, y, e, l, s, q) , with (x, y) its cartesian coordinates, $[e, l]$ its time window, s its service time, and q its requested quantity. Each *vehicle* agent is described by cap its capacity and is initially located at a depot. The overall process is greedy-like and is based on a CNP (*Contract Net Protocol* [3]), where every *vehicle* agent that is able to visit the considered customer (w.r.t the customers already inserted in its plan) proposes an offer, and the best offer (following a criterion that we defined, see below) is retained by the *customer* agent. In order to be perceived by the *vehicle* agents, a *customer* agent, when it is its turn to reveal to the system, creates events representing it by discretizing its time window $[e, l]$ and puts them in the environment, every event is then described by (x, y, s, t, q) . The offer computed by every *vehicle* agent is equal to its contracting of perception i.e. the decrease of its perception quantification as presented in the model. The initial restrictions, say *Restro* of a *vehicle* agent, say v_0 , following the Euclidean metric and the capacity constraints, are equal to:

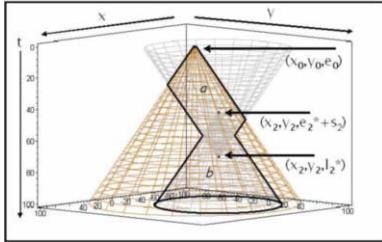

Figure 1. Space-time perception

$$Restro_0 = ((x - x_0)^2 + (y - y_0)^2)^{1/2} \leq (t - t_0) \wedge (q \leq cap_0)$$

(x_0, y_0, t_0) are the cartesian coordinates of the depot and the scheduling starting time (constants) and cap_0 the initial capacity of the vehicle v_0 . From the point of view of an agent, following this inequality, the environment is a hypercube of four dimensions (two for the cartesian coordinates x, y , one for the time t and one for the capacity q). Initially, $\|v_0\|$ is equal to the volume of the cone of vertex (x_0, y_0, t_0) (cf. Figure 1, the big cone) multiplied by cap_0 . Now, let us consider a *customer* agent c_2 described by $(x_2, y_2, e_2, l_2, s_2, q_2)$. Suppose that v_0 perceived a subset of the events describing it. v_0 computes the new time-window values e_2^* , l_2^* ², and computes its new *Restro* and $\|v_0\|$. The new *Restro* is equal to $[a] \vee [b]$ with:

$$[(x - x_2)^2 + (y - y_2)^2]^{1/2} \leq (l_2^* - (t + s)) \quad [a]$$

$$[(x - x_2)^2 + (y - y_2)^2]^{1/2} \leq (t - (e_2^* + s_2)) \quad [b]$$

[a] is the condition to be satisfied by any customer if it had to be inserted before c_2 and [b] is the condition it has to satisfy if it had to be inserted after c_2 . The new quantification $\|v_0\|$ is equal to the

² how to recompute e_2^* and l_2^* is out of the scope of this paper

volume of the intersection of the old cone with the union of the two new cones described by [a] and [b] (cf. Figure 1), multiplied by the new cap_0 ($= cap_0 - q_2$). v_0 is a candidate for the insertion of c_2 , the offer it will propose is $\Delta_{\parallel - \parallel}$, the difference between its old and its new perception quantification, which is equal to $\|v_0\|_{new} - \|v_0\|_{old}$. c_2 selects the vehicle with the minimum loss of perception $\min \Delta_{\parallel - \parallel}$. This criterion expresses the decrease of the probability for a vehicle to be a candidate for future customers' demands.

We ran our system on the Solomon's benchmark [4]. Although our system could not actually be compared to any state-of-the-art works, because our proposal is the only one that could work with zero known demands, we compared it with the best known static systems focusing on the verification of two results: the computational times' variation and the explosion of the number of vehicles used. The results showed that the computational times increase slowly with respect to the number of considered customers, which makes our proposal a good candidate to operate in a dynamic configuration. The gap in the number of vehicles used by our system w.r.t those used by the best algorithms is of 50% when considering 100 customers and 16% when considering 200 customers, thus the fleet of vehicles remains stable even assuming this handicapping scenario.

3 Conclusion and perspectives

In the state-of-the-art approaches, all the works try to handle the dynamic requests in the VRPTW by, firstly, considering a subpart of requests known in advance. Secondly, some of them try to reconsider previous requests assignment in order to increase the quality of the solution, which is time consuming. We try to follow neither the first nor the second approach: no customers are known in advance (the newly incoming ones simply enqueue themselves), and every assignment is definitive. We present a generic multi-agent model based on the observability principle, we quantify agents' perception and we use the loss of perception as a new distance between partial *vehicle* agents' plans in order to lessen the myopic behavior of the traditional metrics. This model provides a new method to tackle the dynamic VRPTW in which the solving process is focused on the future. Future works will consider variants of the VRPTW such that the Pickup and Delivery Problem with Time Windows and the Dial-A-Ride problem, the latter problem fits very well with the multiagent paradigm since customers also try to maximize their own utility.

On Packing 2D Irregular Shapes

Alexandros Bouganis and Murray Shanahan¹

Abstract. Designing and implementing an intelligent system that tackles the problem of placing two-dimensional shapes on a surface, such that no shapes overlap and the uncovered surface area is minimized, is highly important in industrial applications. However, it is also interesting from the scientific perspective, in terms of artificial intelligence, since autonomous systems developed up to now have found it difficult to compete with humans in this task. This paper presents a new algorithm which addresses the on-line packing of two-dimensional irregular shapes, and achieves high quality solutions in short computational times. The key point of this algorithm is the utilization of techniques drawn from computer vision and artificial intelligence.

1 Introduction

The two-dimensional *packing problem* can be defined as the problem of placing a number of two-dimensional shapes on a surface, such that no shapes overlap and the uncovered area of the surface is minimized. This problem arises in a variety of industrial applications within shipbuilding, textile, wood, plastic, sheet metal and leather manufacturing. However, this problem is not only interesting for industrial reasons, but also from an artificial intelligence perspective, since algorithms that have been developed up to now have found it difficult to compete with humans [7].

Two variations of the problem are *on-line* and *off-line* packing. In off-line packing, the shapes of *all* the parts to be placed are given *a priori* to the packing algorithm. In this way, the packing algorithm enjoys the flexibility of placing the parts in a sequence that it considers best. Contrary to off-line packing, in the on-line instance of the problem, the sequence of the parts to be placed is *randomly* generated and the packing algorithm acquires *only* the part that it has to place at each time, and does not have *a priori* knowledge of the parts that has to place in the future. Obviously, in on-line packing it is much harder to achieve high quality solutions than it is in the off-line case. The present paper introduces an intelligent system that tackles the on-line packing problem effectively and in an efficient way. Techniques drawn from computer vision and artificial intelligence aim to endow the system with the flexibility that humans seem to have when undertaking such a difficult task.

2 Description of the system

The present system evaluates the resulting solutions employing a performance measure that is widely used in the literature, known as the *packing density* (PD). This measure is defined as the ratio of the total

area of all the packed shapes to the area of their enclosing rectangle (1). The maximum value is 1 which implies that there is no waste of resource material.

$$\text{Packing Density} = \frac{\text{Area of Nested Parts}}{\text{Area of Enclosing Rectangle}} \quad (1)$$

The core algorithm of this system has some similarities with our algorithm in [2], where the case of the off-line packing problem was examined. In the present paper, modifications of this algorithm have been made, so that it can be applied effectively to on-line packing. A detailed description of the new system follows.

First of all, the sheet and the part that has to be placed each time are given as inputs to the system in the form of bitmap images. The placement of the parts follows a single-pass placement strategy. Two approaches of placing a part are considered before the system actually places it. These approaches are: *the Object-Based Approach* and *the Scene-Driven Approach*. Each of them suggests a potential placement of the part under consideration. The system carries out that placement of the part that gives the best packing density. In case both potential placements achieve the same packing density, the system favors the placement that fixes the part most bottom in the sheet.

2.1 The Object-Based Approach

The first approach examines four possible placements of the part. This is due to the four orientations that the part could take so that one side of its MER (Minimum Enclosing Rectangle) is aligned with a side of the sheet. Considering each one of these orientations, the system determines the most bottom-left position that the part can take without overlapping with the already nested parts and measures the packing density (1). For accomplishing the aforementioned procedure, the system utilizes operations of mathematical morphology [5]. As the layout and the part have both been stored in the system as images, let's denote the layout as the image set A and the part as the structuring element B . The operation of *erosion* is applied to the image set A by the structuring element B , denoted by $A \ominus B$ (2):

$$A \ominus B = \{x \in \mathbb{Z}^2 | B_x \subseteq A\} \quad (2)$$

where B_x denotes the translation of B so that its origin is located at x . By this operation, the set of all elements x of \mathbb{Z}^2 , such that B translated to x is contained in A , are identified [5]. The result of this operation is another image where all the feasible locations for the oriented part have been identified. The system keeps the most bottom-left placement and calculates the packing density. The Object-Based Approach has similarities with the method proposed by Whelan et al. [8].

¹ Department of Computing, Imperial College London, London SW7 2AZ, U.K., email: {alexandros.bouganis, m.shanahan}@imperial.ac.uk

2.2 The Scene-Driven Approach

The second approach searches for an unoccupied, by the already nested parts, region in the sheet, the shape of which matches well with the shape of the underlying part. This is carried out by temporarily approximating the shapes of the void regions in the layout and the parts by polygons [4], and employing the method of Arkin et al. [1] for measuring their resemblance. Let's consider two polygons A and B , as the approximated contours of a part and a void region respectively. Their resemblance can be measured by taking the minimal distance (according to the L_2 metric) between their turning functions $\Theta_A(s)$ and $\Theta_B(s)$ [1]. Thus, the similarity measure M of these two shapes is given by:

$$M = \min_{\theta_0 \in \mathbb{R}, t \in [0,1]} \left(\int_0^1 (\Theta_A(s+t) - \Theta_B(s) + \theta_0)^2 ds \right)^{\frac{1}{2}} \quad (3)$$

As proved in [1], the angle θ_0 that minimizes the distance between A, B is given by:

$$\theta_0 = \int_0^1 (\Theta_B(s) - \Theta_A(s)) ds \quad (4)$$

When the shape of a void region VR_i matches well with that of a part (i.e. M meets a predefined threshold), the system rotates the underlying part by the correspondent angle θ_0 and determines its potential location in the layout. Similarly to the Object-Based Approach, the potential location of the part is being found using the erosion operation. The void region VR_i and the oriented part comprise the image set and the structuring element respectively. Finally, the system measures the packing density (1) of this potential placement.

3 Performance Evaluation

The performance of any packing algorithm depends significantly on the parts' geometry, especially in the case of irregular packing. Thus, our packing method can only be evaluated properly when it is compared against other methods using benchmark problems from the literature. The proposed method is evaluated using nine benchmark problems, available from the EURO Special Interest Group on Cutting and Packing (ESICUP) website² and produced by Hopper [6]. The experiments conducted in this paper have been performed on a PC with a 3GHz Intel Pentium 4 processor and 1 GB RAM.

Aiming to test our method appropriately in on-line packing, a random generator is used and, for each benchmark problem, 20 experiments with random part orderings are examined. The results are illustrated in Table 1, which demonstrates, for each benchmark problem, the average value of packing density, the best packing density achieved among the 20 experiments, and the average execution time per experiment. As it can be seen, the system achieves solutions of high quality, requiring some milliseconds per placement of a part, fact that renders it well suited to on-line industrial applications.

To the authors' knowledge, no other on-line packing method of the literature has been applied to benchmark problems. However, we can consider as measure of comparison the performances of *off-line* methods that have been applied to the same benchmark problems (see [3], [6]). Although it is much harder for an autonomous system to achieve high quality solutions in on-line packing than it is in off-line, our algorithm proved to obtain solutions of comparable quality to the aforementioned off-line methods, in extremely shorter

times. Moreover, the structure of these methods does not allow them to be applied to on-line packing. It must be mentioned that our algorithm, in contrast to ([3], [6]), achieves these solutions without considering orientation constraints for the parts. Although their methods may find even better solutions without these constraints, their computational time would become prohibitive due to the large search space.

Table 1. Performance of our method on Hopper's benchmark problems. By Average PD and Best PD, we denote the Average Packing Density and the Best Packing Density achieved from our method among the 20 experiments for each benchmark problem, respectively. Moreover, the average time required per experiment, for each benchmark problem, is provided.

Benchmark problem	Number of parts	Average PD (Average time per experiment)	Best PD
poly1a	15	60.6% (4 sec)	71.1%
poly2a	30	64.3% (12 sec)	69.2%
poly3a	45	66.4% (23 sec)	68.7%
poly4a	60	67% (36 sec)	69.8%
poly5a	75	68.3% (51 sec)	70.4%
poly2b	30	65.5% (12 sec)	72.1%
poly3b	45	68.4% (23 sec)	71.9%
poly4b	60	68.2% (36 sec)	71.5%
poly5b	75	69.2% (56 sec)	73.4%

4 Conclusions

In this paper, an intelligent system for on-line packing of two-dimensional irregular shapes is presented. Computer vision and artificial intelligence techniques are utilized for endowing the system with the flexibility that an autonomous system needs to have while tackling such a difficult task. The proposed method is assessed on nine established benchmark problems and achieves high quality solutions in significantly short times.

Aliasing maps for robot global localization

Emanuele Frontoni and Primo Zingaretti¹

Abstract. In this paper we present a mobile robot localization system that integrates Monte-Carlo localization with an active action-selection approach based on an aliasing map. The main novelty of the approach is in the off-line evaluation of the perceptual aliasing of the environment and in the use of this knowledge to perform localization processes faster and better. Preliminary results show improved performances compared with the classic Monte-Carlo localization approach.

1. INTRODUCTION

Localization is one of the most basic abilities for a mobile robot. To localize, i.e., to be able to determine its own position in the environment, the robot needs some kind of representation of the environment.

Explicit (or geometric) representations are based either on maps of free spaces in the environment (using, for instance grid maps or polygonal-based representations) or on maps with locations of distinct observable objects (i.e., landmarks). Both methods rely on the assumption that geometric information (shape and position of obstacles, landmarks, etc.) can be extracted from robot's sensor readings. However, the transformation of sensor readings into geometric information is, in general, complex and prone to errors, increasing the difficulty of the localization problem [4].

In general, the localization model is implemented as a background process (i.e. localization is performed while the robot is involved in another task). However, when the robot is uncertain about its position it makes little sense to continue with the navigation task and it is more advisable to reduce the uncertainty in the robot position first, then continue with the navigation. Therefore, sometimes robot's actions have to be determined by localization criteria and not by navigation related ones. The question in such cases is how to determine the appropriateness of actions as far as localization is concerned.

In the context of mobile robot localization, actively controlling a robot is particularly beneficial when the environment possesses relatively few features that enable a robot to unambiguously determine its location. This is the case in many office environments. For example, corridors and offices often look alike for a mobile robot, which is often unable or very inefficient in determining robot's position, resulting in random motion or perpetual wall following.

Other approaches were presented to solve this kind of problem dealing in particular with the concept of entropy minimization [1, 3, 5].

We propose a mobile robot localization system that integrates Monte-Carlo localization with an active action-selection approach based on an aliasing map. The concept of aliasing maps is introduced in the next section, while results and discussion are reported in the final section.

2. ALIASING MAPS

The main idea of the proposed approach is to evaluate off-line the perceptual aliasing (i.e., different places that perceptually appear the same) of the environment and to use this knowledge to perform localization processes faster. In particular, we exploit this knowledge to bring the robot to a less aliased position in the environment, thus disambiguating robot belief and allowing a faster and more accurate localization.

The approach here proposed for off-line perceptual aliasing evaluation over a known map is general to every kind and number of range sensors (e.g., laser or sonar).

An aliasing map is defined by the function $\text{Aliasing}(x, y)$ that is a measure of the similarity of a certain point with other points of the map. In our approach we do not consider rotations to obtain a rotational invariant map: indeed measures used for aliasing evaluation covers 360 degrees around the robot.

The map is divided in areas reachable or not from the robot. A mesh is defined over the map of the environment and for each node of the mesh in the reachable areas a simulated sensor reading is performed. Sensor readings are range measurements without any particular need about noise modeling. For this reason a sensor measurement is divided into different steps. A sensor reading is performed for every node and its aliasing is measured as the number of sensor readings in different nodes that are in the same range step of the current reading. This approach is repeated for every sensor available in the robot, resulting in n_{Sensors} similarity values for every mesh node ($MeshNodes$ is the total number of mesh nodes). Results are stored in the matrix AliasingMatrix whose number of rows and columns is equal to the number of mesh nodes and different range sensors, respectively.

To obtain the map that represents the perceptual aliasing of every node of the mesh, the above similarities are fused together evaluating the following expression:

$$\prod_{j=1}^{n_{\text{Sensors}}} \frac{\text{AliasingMatrix}(k, j)}{\sum_{i=1}^{MeshNodes} \text{AliasingMatrix}(i, j)}, k = 1, \dots, MeshNodes$$

¹ Dipartimento di Ingegneria Informatica, Gestionale e dell'Automazione (DIIGA) - Università Politecnica delle Marche Ancona, Italy. E-mail: {frontoni, zinga}@diiga.univpm.it

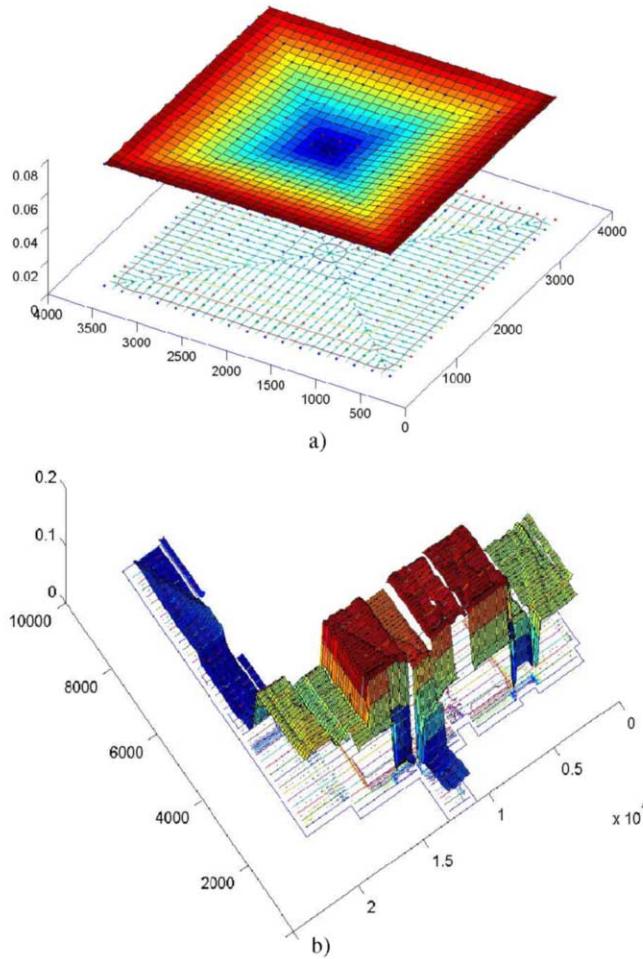

Fig. 1. a) The aliasing map of a squared environment where every point has a constant aliasing and the minimum of perceptual aliasing is in the square's center. b) A real aliasing map of an indoor environment of our department.

The mesh cells are then interpolated using a bi-cubic interpolation algorithm to obtain a fine grid aliasing map.

The map will be used in the algorithm to evaluate the direction that brings every particle to a minimum aliasing position in the environment (Fig.1).

The weighted sum of these optimal particle directions will be the optimal robot movement.

We assume that robot knows its initial orientation with a certain error. The direction of the best robot's action is given by the sum of all the minimum aliasing directions of each particle that allow to bring robot and particles to a minimum aliasing region of the environment.

The computational cost of the action selection is very low. Indeed only a differential evaluation for each particle is performed and this computation can be performed off-line and stored in a look up table.

3. RESULTS

Results have been obtained using a robot simulator in a high aliased environment. The used framework is a mixed Matlab – C++ mobile robotics platform that well suites to research and educational purposes. Further details about the framework can be found in [2].

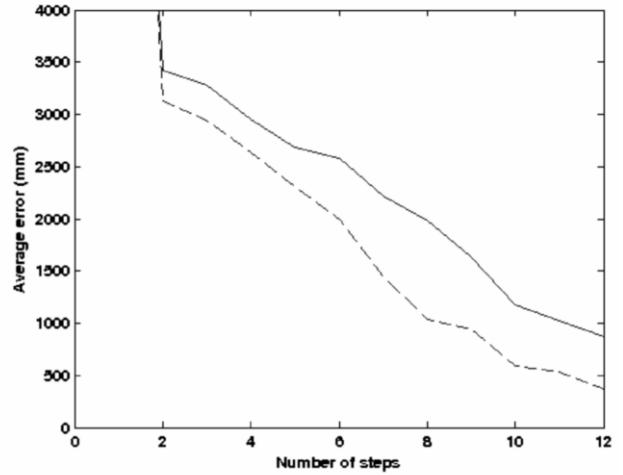

Fig. 2. Results of tests to compare classical particle filtering (continuous lines) approach and the proposed algorithm (dashed lines).

Fig.2 shows the better results obtained using the proposed approach. Results are obtained using 200 particles with a localization process that ends after 12 robot's steps. Due to the randomness of the MCL algorithm, results are the mean value of 10 localization processes starting from the same position.

4. CONCLUSIONS

The paper advocates a new, active approach to mobile robot localization. In active localization the robot controls its various effectors to most efficiently localize itself. In essence, actions are generated by maximizing the expected decrease of uncertainty, measured by perceptual aliasing.

The key result of the experimental comparison is that the efficiency of localization is increased when actions are selected minimizing global aliasing. In some cases, the action selection component enabled a robot to localize itself where the passive counterpart failed.

The main drawback of this approach is on its application to dynamic environments. Actually the off-line map aliasing evaluation does not guarantee a reconfiguration of algorithm parameters when dynamics events happen (i.e., people moving around the robot).

On Interfacing with an Ubiquitous Robotic System

Donatella Guarino¹ and Alessandro Saffiotti²

Abstract. The emerging field of ubiquitous robotics presents new challenges for human-robot interface. In this note, we introduce the concept of a *common interface point* using an *expression-based semantics* as a way to address some of these challenges. We illustrate this concept in the framework of the PEIS-Ecology approach to ubiquitous robotics.

1 Introduction

There is a marked tendency toward the embedding of many ubiquitous, intelligent, networked robotic devices in our homes and offices. This tendency is witnessed by the growing interest in the fields of ambient intelligence and smart homes, as well as by the new emerging field of ubiquitous robotics [1, 3]. The development of these ubiquitous systems is often motivated by the desire to improve the quality of life of citizens in general, and of elderly people in particular. In this context, it is essential that this development is accompanied by the development of suitable *interfaces* that ensure the usability and acceptability of these systems.

The problem of interfacing with an ubiquitous system is different from, and more complex than, the conventional human-computer and human-robot interface problems. First, although the system consists of a collection of many inter-connected devices, the user should perceive it as one system, and interact with all the devices in it through *one and the same* interface. Second, the interaction between the user and (the different devices in) the system should be based on a *uniform model*, hiding the heterogeneity of the devices. Note that this interaction should be *two-way*, that is, the user should be able both to control the system and to get information from it.

In this note, we study how an ubiquitous robotic system can provide a human user with information which is unobtrusive, intuitive and relevant. We introduce two concepts that address the two challenges above: the concept of *common interface point*, which collects and summarizes the relevant information about the status of the system; and the concept of *expression-based semantics*, which provides a uniform semantics to talk about status information, and an intuitive way to convey this information to the user. In order to illustrate these concepts, we consider a specific concrete approach to ubiquitous robotics: the PEIS-Ecology approach.

2 The PEIS-Ecology Approach

The concept of PEIS-Ecology [3] puts together insights from the fields of autonomous robotics and ambient intelligence to generate a radically new approach to building assistive, personal, and service

robots. The main constituent of a PEIS-Ecology is a *physically embedded intelligent system*, or PEIS. This is any computerized system interacting with the environment through sensors and/or actuators and including some degree of “intelligence”. A PEIS can be as simple as a smart toaster and as complex as a humanoid robot. Notice that PEIS are *physically embedded systems*, not just software agents.

Individual PEIS in a PEIS-Ecology can cooperate by *linking functional components*: each PEIS can use functionalities from other PEIS in the ecology in order to compensate or to complement its own. The power of the PEIS-Ecology does not come from the individual power of its constituent PEIS, but it emerges from their ability to interact and cooperate. In a sense, the PEIS-Ecology approach redefines the very notion of a *robot* to encompass the entire environment.

Consider the example in figure 1. By itself, the simple autonomous cleaner can only use basic reactive cleaning strategies. If the home is equipped with an overhead tracking system, though, the robot can use it to know its own position in the house and hence use smarter cleaning strategies. Suppose then that the cleaner encounters a plant, and that the plant is equipped with a micro-PEIS (e.g., a mote) able to communicate its properties (size, wheel-support, humidity, temperature, etc) to the robot. Then, the robot can decide if it can push the plant away and clean under it.

3 The Common Interface Point

In a PEIS-Ecology, the single robot servant assumed in most literature on human-robot interface is replaced by a network of devices distributed all around the environment. Correspondingly, the notion of a single-robot interface should be replaced by a multitude of PEIS-specific interfaces, which are distributed all over the environment.

However, asking the user to interact with a large number of devices using a correspondingly large number of specialized and possibly different interfaces is clearly a bad idea. We therefore envision one single main *interface point* that integrates all the information from the different PEIS in the ecology, and dispatches all the com-

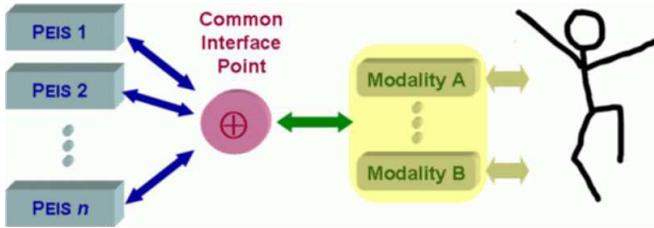

Figure 2. The common interface point for a PEIS-Ecology.

mands to them. This interface point may communicate with the user by a number of different modalities (e.g., speech, gestures, expressions), including remote ones (e.g., a mobile phone). The interface point, however, should be perceived as a single interface toward the whole ecology, as well as toward each individual PEIS. This concept is illustrated in figure 2.

In our work, we explore the realization of the common interface point in the system-user direction to convey status information. For the above schema to work, four problems must be solved: (1) how to encode status information from each PEIS, endowed with a *common semantics*; (2) how to *combine* status information coming from different PEIS, so as to reflect the status of the entire PEIS-Ecology (or parts of it); (3) how to *present* the status information to the user; and (4) how to *generate* this status information inside each PEIS. In the next section, we outline our solution to the first three problems; the fourth one is part of our current research.

4 Expression-Based Semantics

In many cases, a PEIS has an internal status from which we can distinguish “normal” and “abnormal” conditions. Different PEIS, however, have different ways to represent their status, and different measures to be used to detect a normal or abnormal condition. For instance, in the above scenario, the plant may need watering, or the cleaning robot may be running out of batteries: the relevant measures are the ground humidity or the battery voltage, respectively.

In order to provide a uniform way to treat these conditions we consider an abstract notion of “satisfaction”. Each PEIS represents its internal satisfaction status in a succinct way as an *expression*, ranging from “sad” to “happy”, and encoded by a real number in the $[0, 1]$ interval. These numbers are combined into a joint measure of the degree of satisfaction of the whole PEIS-Ecology, through some combination operator \oplus . Intermediate combination steps may be performed if the PEIS-Ecology is partitioned into sub-ecologies.

The satisfaction status is shown to the user in the form of a human understandable expression, which gives an immediate impression about the overall status of the PEIS-Ecology. Figure 3 shows some realizations of these expressions in our test implementation.

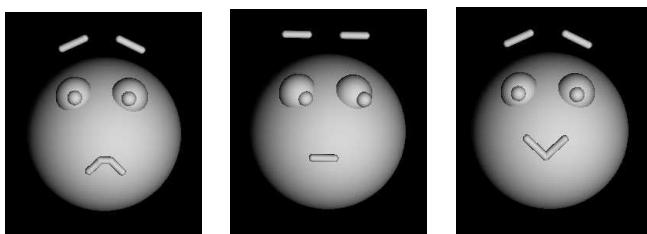

Figure 3. Visualization of the satisfaction status for three different values: 0.2 (very sad, left); 0.6 (rather worried, middle); 1.0 (quite happy, right).

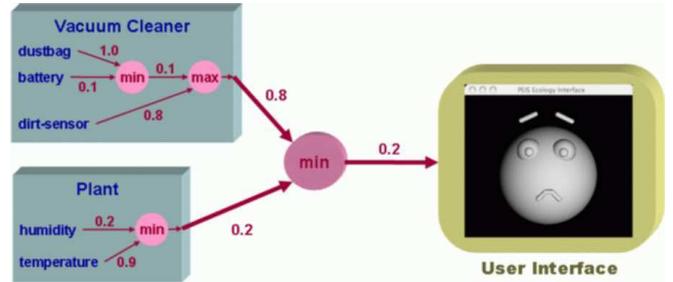

Figure 4. The overall satisfaction status of a simple PEIS-Ecology is computed, and it is conveyed to the user by a corresponding expression.

In general, the satisfaction state of each individual PEIS may depend on the combination of a number of different factors. For example, the state of the autonomous vacuum cleaner will be “happy” if the batteries are not empty and its dust-bag is not full. However, if the room is already clean, its state will be “happy” even if the batteries are empty, since no more cleaning is needed. This example shows that the behavior of the \oplus operator may need to be fairly complex, and that we may need different operators inside each PEIS, and between different subsets of PEIS.

To allow this, we combine satisfaction states using the mechanisms of fuzzy logic. Fuzzy logic has been given semantics in terms of desirability values [2]. These semantics are compatible with the expression semantics adopted here, by stipulating that the degree of satisfaction of a PEIS in a given state corresponds to the degree by which that state is *desirable* for that PEIS. Fuzzy logic provides mechanisms to write and evaluate logical combinations of $[0, 1]$ desirability values. For example, the following formula in (propositional) fuzzy logic could express the combined desirability for the vacuum cleaner example above:

$$\text{cleaner-happy} \Leftrightarrow \text{clean-floor} \vee (\text{full-battery} \wedge \text{empty-dustbag}) .$$

The degree of happiness of the cleaner PEIS, then, is obtained by computing the truth value of the above formula using the rules of fuzzy logic. Figure 4 shows an example of computation of the overall state of a simple two-PEIS ecology. In this example, the vacuum-cleaner is fine but the plant needs attention.

5 Next Steps

The study of expression-based semantics for ubiquitous systems has just started, and very many issues remain to be investigated. Among these: How can each PEIS generate its satisfaction value? How can we weight these values to take into account the user’s needs and preferences? How can we extend the expression-based semantics to other types of states, like danger or surprise? How can we convey “expressions” using other modalities, like sound or color? How can we help the user to pinpoint the cause of a “sad” status?

Leaf classification using navigation-based skeletons

Georgios Sakellariou and Murray Shanahan¹

Abstract. In this paper, we present a leaf classification method based on skeletons produced by a navigation-inspired technique. The classification system comprises three separate stages. First, a *navigation-based* skeletonisation algorithm is used to gather low level structural and morphological information about the shape. Subsequently, the data is converted into a series of attributed graphs. Graphs of the same type are then compared using an approximate graph matcher, which identifies a degree of similarity between them. Each degree of similarity corresponds to a *dimension* in a *conceptual space*, as defined by Gärdenfors. We test the performance of our technique on a set of leaves belonging to three different species.

1 Introduction

While vision-based classification systems offer solutions to various problems in areas ranging from mobile robotics to medicine, less application-dependent methods of classification have not been as abundant. Our proposed system aims to overcome this issue, by following a modular object description and classification procedure. We apply our technique to the challenging problem of leaf classification, without using any expert knowledge with regard to the leaf types to be classified. The technique consists of the following stages. First, *navigation-based skeletonisation* [7] is performed on the object. The skeletons are then converted into *attributed graphs*. Finally, the graphs are compared by means of an *approximate graph matcher* [9]. The similarities between pairs of graphs act as *dimensions* in a *conceptual space* [3]. Distances between points (*knoxels*) in this conceptual space will be a measure of similarity between them. We claim that this approach enables the decoupling of the performance of the system from the application. In part, it owes its adaptability to the underlying skeletonisation method. Unlike other object description techniques [4], the exploratory nature of our navigation-based skeletonisation algorithm allows it to identify points of structural importance as well as morphological attributes on the fly, which facilitates later high-level processing. In addition, the method is more generic than others, in the sense that it can be adjusted to create graph representations containing a variety of different sorts of morphological information. The development of the algorithm took place with the aim of using the data it yields for *geometric representation*. This is achieved by means of attributed graphs, and the definition of a similarity metric to compare them. This method features two major advantages. First, the skeletonisation process is not continuous. It consists of hops from one skeletal point to another, which makes it easy to identify landmarks such as junctions. The data produced is therefore more easily processed by a high-level graph matching algorithm, such as those proposed in [9][12][6]. Second, unlike other systems [5], this technique allows for the collection of any kind of

morphological information about the shape in one pass. Finally, all topological and morphological attributes are extracted with no post-processing on the skeletons.

2 Conceptual Spaces for shape comparison

A *conceptual space* is a *metric* space in which entities are characterised by a number of quality dimensions [3]. In this respect, the goal of our classification system is to not just consider a single shape descriptor, but several of them. The comparison of each of those descriptors will correspond to a different *dimension* in our conceptual space. Conceptual spaces have already been employed in vision applications [2]. To each conceptual space corresponds a *similarity metric*. In this way, a degree of similarity can be determined when comparing *knoxels* (points in the conceptual space). In our system, we make use of three dimensions, all of which are measures of similarity between attributed graphs. The low-level information from a navigation-based skeletonisation algorithm is converted into attributed graph form. The skeletonisation algorithm that was used for this work draws on techniques originating in mobile robot navigation. The most attractive element of such an approach is modularity. Clearly, skeletonisation alone is not sufficient to successfully describe, and hence distinguish between, a multitude of shapes. This problem stems from the fact that the skeleton of an object merely encodes structure. However, objects of similar shape can produce very different skeletons. Conversely, objects whose shape differs substantially can produce very similar skeletons. One solution to the aforementioned problem, which is inherent to skeletonisation, is to enrich the produced skeleton with additional *morphological information*, thereby creating an attributed skeleton [1]. *Shock graphs* go one step further and use grammars of shape for description and shape matching purposes [10][11]. Attributed skeletons have been successfully used in a wide range of applications, including river segment classification [8].

3 Graph representation and matching

NavGraphs are attributed graph representations of navigation-based skeletons. Each node and each edge hold additional attributes for the purpose of describing shapes in a more distinctive way. Attributed graphs were our representation of choice due to their capacity to contain both topological and morphological information. In order to make the transition from skeletons to attributed skeletons, additional attributes must first be associated with every skeletal point. To achieve this, two separate steps have to be made. First, attributes that are appropriate to the application have to be chosen. Second, this information has to be represented in a suitable way for further processing and comparison purposes. As described in section 2, we make use of the outcome of graph matchings as dimensions of our

¹ Imperial College London, United Kingdom email: {georgios.sakellariou, m.shanahan}@imperial.ac.uk

conceptual space. The *Approximate Graph Matcher* [9] immediately seemed an appropriate choice. The original motivation for the development of the algorithm has been various biology-related applications. Two features of the algorithm render it most suitable for classification in the context of conceptual spaces. First, the matcher allows for attributed graphs to be compared. Second, the nature of its input facilitates comparisons and identifications of matches between many different graphs in one go. The graphs that need to be classified are encoded in a text file. The program then compares every graph to every other graph in the file, which effectively acts much like a database. Hence, even when comparing a large number of graphs, the process of classification is uncomplicated.

4 The leaf classification system

In order to evaluate the performance of our proposed approach, a series of comparisons was carried out. The system was tested on a set of leaves belonging to three different species. The leaf images were obtained from the database contained in the free version of the *Leaves Recognition* software by LightSpeed Communications. For the purposes of our experiments, we used ten samples per species. Each comparison involved three graph matchings, corresponding to the three dimensions. The similarity between two knoxels is defined as being inversely proportional to the vector distance of their corresponding points in the three-dimensional conceptual space. The experimental procedure consisted of a series of comparisons of leaves belonging to the same species, followed by a series of inter-species comparisons. Intra-species comparisons consisted of one specimen of a species being compared with all the other available specimens of the same species. Inter-species comparisons involved comparing a selected specimen of a species with all the specimens belonging to different species. The results show that there is a clear distinction between inter-species and intra-species comparisons. All three types of graph representations belonging to leaves of the same species have been determined to be more similar than those belonging to different species. In turn, the average dissimilarity between knoxels of inter-species and intra-species comparisons was significantly large. This facilitates the classification process.

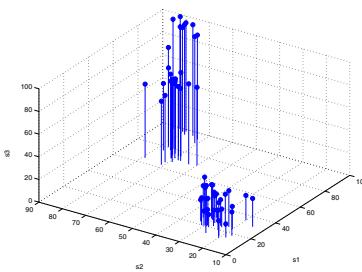

Figure 1. Large separation between intra-species and inter-species comparisons

The results can be viewed in terms of a three dimensional plot (Figure 1). The axes $s1$, $s2$ and $s3$ correspond to similarity using radius, rate of change of radius and angle respectively. We subsequently performed *Principal Components Analysis* on our set of data. The motivation for this was the fact that by determining the number of principal components needed to sufficiently describe the data, this analysis is an adequate method of proving the success of the system. We claim in this paper, that inter-species knoxels are clearly

distinguishable from intra-species knoxels, hence a reduction to one dimension would be a proof of this claim. Looking at the variance of the first principal component, one can draw conclusions concerning how much of the total information this component can describe. Indeed, almost all (97%) of the variance of all three principal components is contained in the first component. This proves that only one dimension is needed to include most information in the data set, implying that the polarisation between intra-species and inter-species knoxels is high.

5 Conclusions

In this paper we presented a leaf classification system based on a novel navigation-based skeletonisation algorithm. The extracted skeletons are transformed into multiple attributed graphs representations in a conceptual spaces inspired approach. This method proves advantageous in two major respects. First, by making attributed graph representation an integral part of the navigation-based skeleton, we eliminate the need for manipulation of the output of the skeletonisation algorithm. The extraction of descriptive attributes that are needed for matching and classification is done simultaneously with the skeletonisation process. Second, the fact that multiple graph representations of the same leaf are extracted, allows for a more generic and less application-dependent representation of the leaf.
